A transient WASH123D model was developed for the same domain and calibration time period as the transient SEAWAT model. As stated in Section F2.0, the Phase I study indicated that similar results are expected for the WASH123D and SEAWAT models given similar model inputs. To use this similarity to limit the number of transient WASH123D calibration runs, the draft calibrated transient SEAWAT input parameters were used to estimate the initial transient WASH123D input parameters. The input parameters include specific storage, porosity, dispersivity, and molecular diffusion coefficient; however the primary transient calibration parameter in SEAWAT was specific storage. Hydraulic conductivity values used in the WASH123D transient model were the same as the values used for the draft calibrated WASH123D steady state model.

Like the hydraulic conductivity values, the aquifer compressibility values are assigned in WASH123D using material zones. Because the zones created for the hydraulic conductivity and the zones created for the compressibility do not align, much smaller zones with common conductivities and compressibilities are necessary to adequately define the aquifer heterogeneity. Establishing the

material zones required several steps. First, the calibrated SEAWAT specific storage values were contoured by layer at sufficient contour intervals to define the storage variation. The contours were used to create zones of similar specific storage with one value for each zone. Using the polygons representing storage zones and the polygons representing the WASH123D calibrated hydraulic conductivity zones, an "intersect" analysis was performed in the Environmental Systems Research Institute's ArcMap 9.3 program. The result of this analysis was a set of refined polygon zones that defined a set of conductivity and storage values consistent with the original independent sets of polygons for these parameters. The storage values for each material zone were then converted to modified aquifer compressibility using Equation F3.1.2. A total of 1,974 material zones were assigned for the transient WASH123D model.

Because it is difficult to make incremental changes with so many zones and because automated parameter calibration programs cannot revise zone boundaries, no additional calibration by trial and error or automated methods was performed for the WASH123D transient model.

The WASH123D head results over the calibration period are shown in Figures F3-30 to F3-50. These figures are the same format as Figures F3-1 through F3-21 for the SEAWAT transient calibration with the addition of the WASH123D model results.

For the wells in the north, east and south parts of the model, the WASH123D heads are very similar to the SEAWAT heads in the UF, APPZ and LF1. Note that at many of these wells, apparent differences between the two models are only due to differences in the initial condition. Other than this starting head value, the two codes show the same aquifer response in these areas.

West of Lake Okeechobee, the head results differ between the two codes. Figure F3-38 shows 3 wells where this occurs in the UF. The starting heads for these 3 wells are approximately the same for SEAWAT and WASH123D. However, the WASH123D low point in May 2004 is not as low as the SEAWAT low point and the WASH123D recovery from May 2004 to October 2004 is lower and lagged compared to the SEAWAT solution. This same pattern is found at many other western UF and APPZ wells. Further, the observed data displays a larger recovery from May to October 2004 than the SEAWAT solution so the WASH123D solution does not provide a better match to observed data than the SEAWAT solution in these areas. Lowering the modified compressibility values west of Lake Okeechobee could yield an improvement in the recovery. Because the majority of the pumping in the model domain occurs west of Lake Okeechobee, it is likely that the differences between the two models are due to a combination of the differences in assignment of storage coefficient and pumping locations (see Appendix D).

Head differences are also notable at the BZ well, OSF-97, shown on Figure F3-50. The pattern of the head results in the SEAWAT and WASH123D solutions is similar with a slightly lagged and lower recovery in the WASH123D model. The biggest difference, though, is the magnitude of the heads. The SEAWAT heads and observed heads vary between 49 ft and 56 ft whereas the WASH123D heads vary between 16 ft and 20 ft. This difference results from the differences between the two models in TDS assignment (See Section 3.4.1 of the main report) and the impact of TDS on head. The open hole interval for OSF-97 extends up near the top of the BZ aquifer in both models. In the WASH123D model, the top interface of

the BZ aquifer has a nodal computational point where the TDS is set at the BZ aquifer TDS value of 26,400 mg/l. The TDS value used to calculate the OSF-97 head for comparison with the WASH123D model results is the BZ TDS value of 26,400 mg/l. In the SEAWAT model, there is no computational point at the top BZ aquifer interface. The initial condition is set at the center of the BZ aquifer cell at 26,400 mg/l and at the center of the LC confining unit cell at 3,700 mg/l. Thus, the TDS value used to determine the head in the calibration well in the SEAWAT model near the top of the BZ aquifer is an average of the high BZ TDS and the lower LC TDS. This significant difference in TDS value used to compute the calibration well head causes the difference in computed head between the two models.

4.0 Sensitivity Simulations from the Draft Calibration

4.1 WASH123D Timestep Sensitivity

To ensure that the selected timestep size does not affect the numerical accuracy, the WASH123D transient model was run using several timestep sizes. A smaller timestep size should provide a more accurate solution, however the model run time will be longer. The goal is to limit the error in the solution while limiting the execution time. The timestep sizes tested were 1 day, 5 days and 10 days.

Figure F4-1 shows plots of the computed heads for the 3 timestep sizes at 3 UF wells across the model domain. The differences in timestep size have little effect on the head solution across the majority of the model. Proximity to large pumping centers increases the head differences because as the pumps turn on and off, the finer timestep intervals can capture the changes more accurately. In Figure F4-1, it's clear that ROMP 39 SWNN is near a large pumping center because the head range over 15 months is more than 20 feet. At the beginning of July 2004, recovery of the head at ROMP 39 SWNN begins as pumping decreases or stops. On July 16, 2004, the maximum difference in head, 1 foot, between the 1 day and 5 day timestep solutions occurs because with the finer timestep, 15 computations were performed instead of only 3 computations with the coarser timestep. Because no change in pumping rates occur in the middle of the month, the difference in the solutions decreases toward the end of July 2004 as additional computations are performed in both models.

Near a few very large pumping centers, the head differences between the 1 day timestep and 5 day timestep solutions are as large as 10 to 13 feet at specific times when large changes in pumping occur. These differences occur at the nodes where pumping is assigned. As a result of the estimates in pumping locations and pumping rates (see Appendix D), it is impossible to accurately predict the heads at these locations using this regional model.

The 5 day timestep was chosen to compute the transient draft calibration for consistency with the 5 day timestep used for the SEAWAT transient draft calibration. Although the 1 day timestep provides a slightly more accurate solution, the difference in head across the majority of the model is within the calibration error. In addition, the model run time using the 1 day timestep size was unreasonably long at 1 week. The run time for the 5 day timestep solution was 48 hours which is comparable with the SEAWAT 5 day timestep run using the TVD advection scheme.

4.2 Specific Storage in SEAWAT vs. Compressibility in WASH123D

During draft calibration of the transient SEAWAT model, specific storage terms were varied within acceptable range until the model output matched the measured field values as closely as possible. The available data includes some measurements as low as 2 x 10^{-10} ft^{-1}. The minimum storage term in the draft calibrated model was 1 x 10^{-8} ft^{-1}. Since the WASH123D model draft calibration lagged slightly behind the SEAWAT model in the schedule, the SEAWAT draft calibration parameters were used as a starting point for the WASH123D parameters. Instead of specific storage, WASH123D requires the user to input the modified compressibility of the matrix, which it then uses to calculate the specific storage term required by the governing equation. The calculation is made according to equation F3.1.2.

To transfer the draft calibrated storage terms from SEAWAT to WASH123D, it was necessary to back calculate the modified aquifer compressibility that would result in the desired specific storage term. This resulted in a number of negative values for aquifer compressibility for some areas of the model. There is no physical explanation for a negative compressibility.

Because there are field measured values of specific storage that are lower than the threshold of positive aquifer compressibility, it is clear that this equation is an estimate and that there are other parameters involved in the storage response to driving forces in the aquifer. It is possible that a negative aquifer compressibility could be the best value for this parameter if the goal is to produce a model that accurately reproduces field conditions. However, these negative values would be difficult to defend.

To determine the effect of the negative compressibility values, the SEAWAT model was rerun for two additional sensitivity runs. In the first, the specific storage terms were truncated at 2.65 x 10^{-8} ft^{-1}, the minimum storage term reported in the Preliminary Hydrogeologic Framework. This resulted in only a slight change to a few storage values (13% of the LC values, 3% of the MC1 values, less than 2% for BZ, MC2, APPZ and IAS, and none of the UF values). For the second storage sensitivity run, the specific storage values were truncated at 3.05 x 10^{-7} ft^{-1}. This ensured no negative compressibility terms when the values were converted to the WASH123D model.

The effects of truncating the storage terms had minimal effects on the draft calibration. Those wells which did see changes to the model calculated heads were generally located in the south of the model or in the deeper layers. All noticeable changes occurred in the second of the two sensitivity runs (with storage truncated at 3.05x10^{-7} ft^{-1}). Figure F4-2 shows the effects for the three observation wells which showed the greatest effect. In each case, the truncation of the storage term (increasing it in some areas) resulted in a reduction in the range of heads over the 15 month calibration period. The low heads in June and the high heads in October 2004 occur later when the storage terms are increased significantly. The draft calibration might be said to be less precise when the storage terms are increased, but the difference is minor.

Notes:

This layer (4) underlies the Intermediate Aquifer (IA) in the regional model. Where the IA does not exist, (see Figure 4.28) the conductivities match those in layer 2 and 3.

Horizontal hydraulic conductivity was set to twice the vertical value (shown).

These conductivity values were organized in zones with constant values arranged to match the SEAWAT values as closely as possible. Some changes were then made during the WASH123D calibration.

Compare to Figure 4.29.

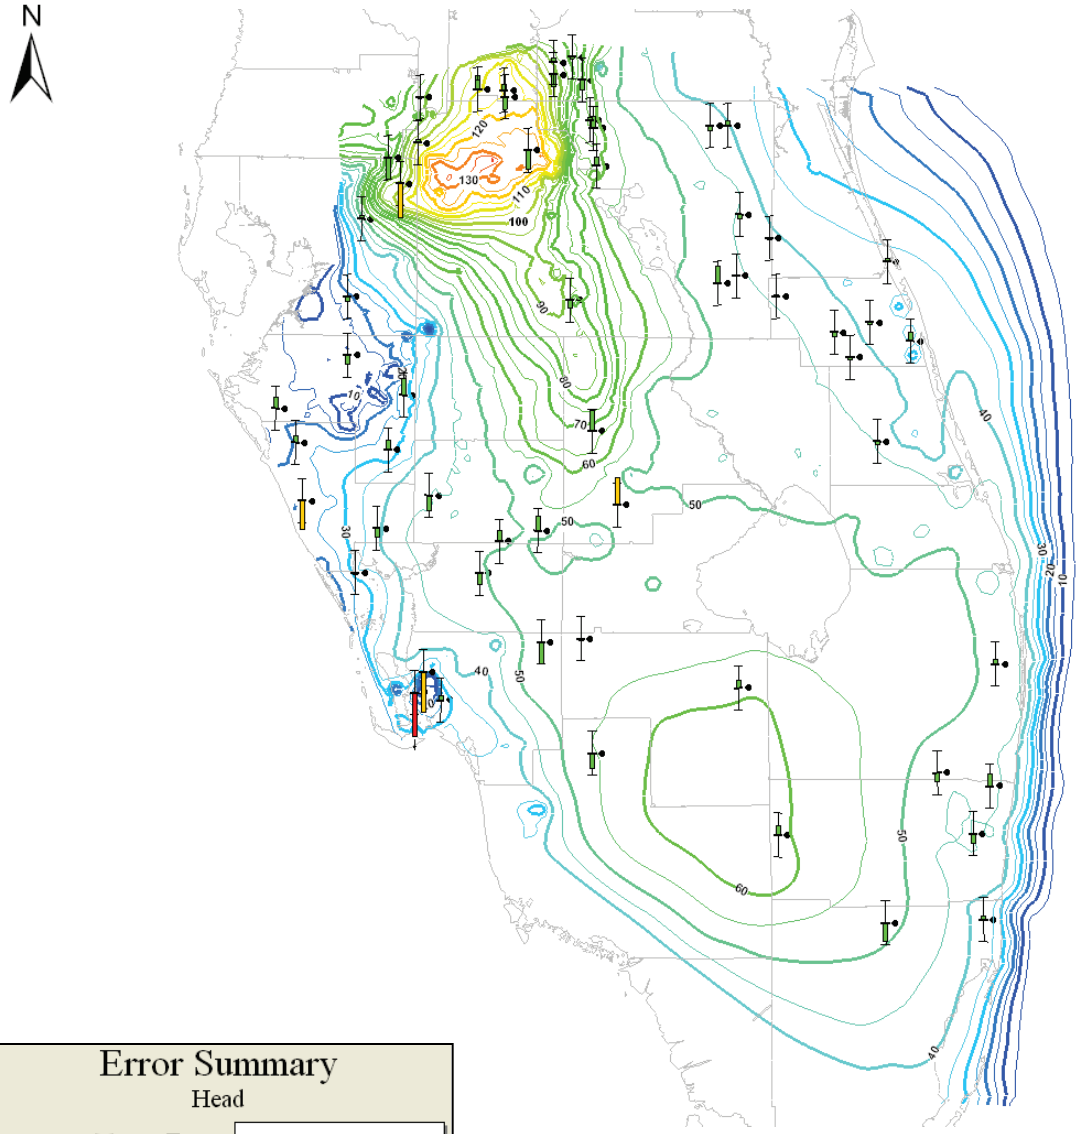
Regional Phase II ASR Vertical Hydraulic Conductivities Lower Confining Unit (WASH123D)

Final Groundwater Model Calibration Report

Figure F2-30

October 2010

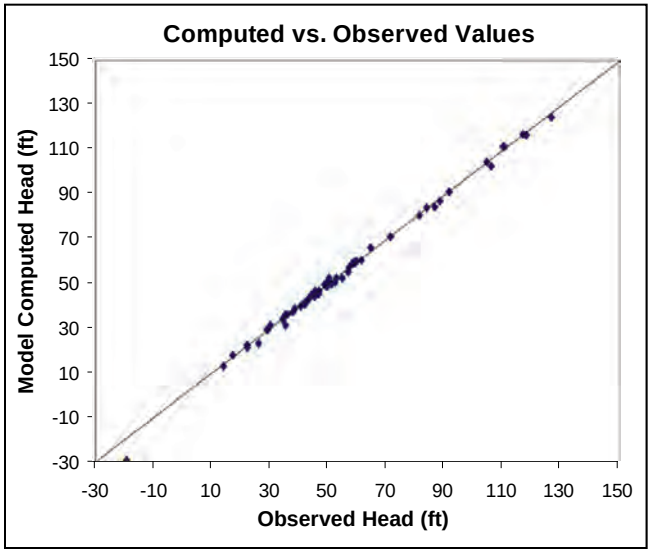


Notes:

Statistics (mean error, mean absolute error and root mean square error) are calculated based on equations presented in Section 4.1.

Calibration targets are green when the calculated value is within 2 feet of the measured head, yellow when within 4 feet and red when the model calculates a head more than 4 feet different from the measured value.

The direction of the colored bar on the calibration target indicates the sign on the residual: bars above the middle line indicate the model calculated higher heads than measured; bars below the middle line indicate negative residuals.



Error Summary

Head

Mean Error:	**-0.262**

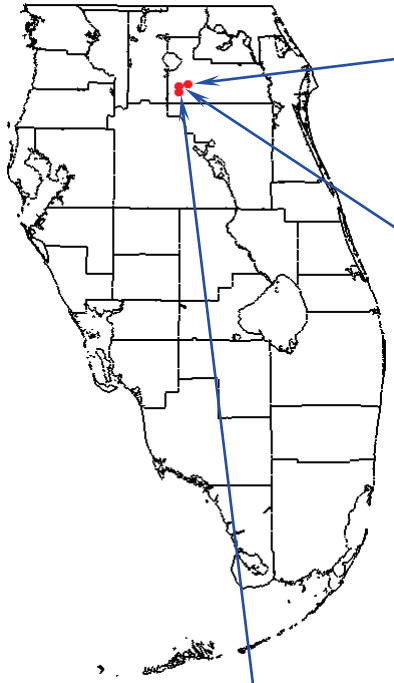
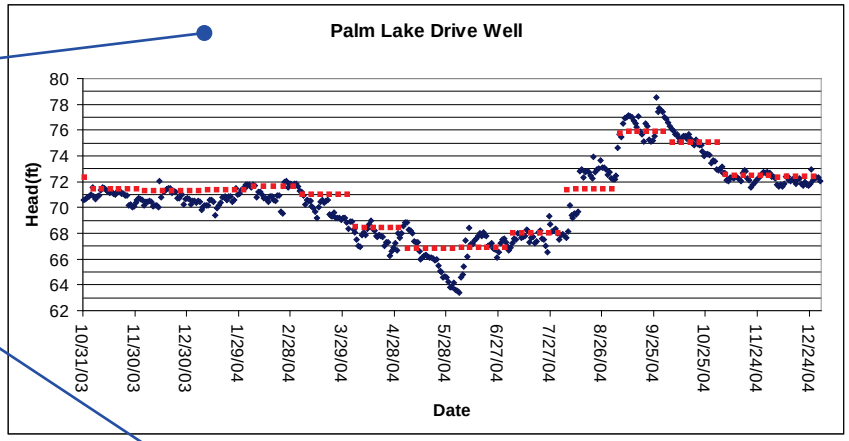
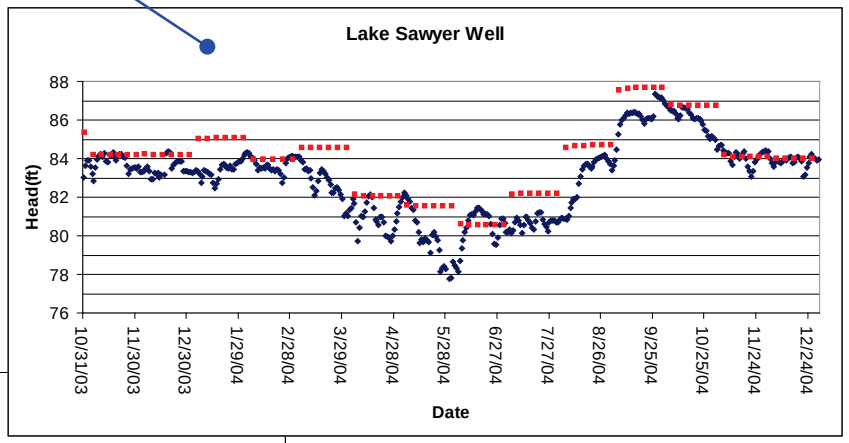
Boulder Zone – October 2003
Final Groundwater Model Calibration Report

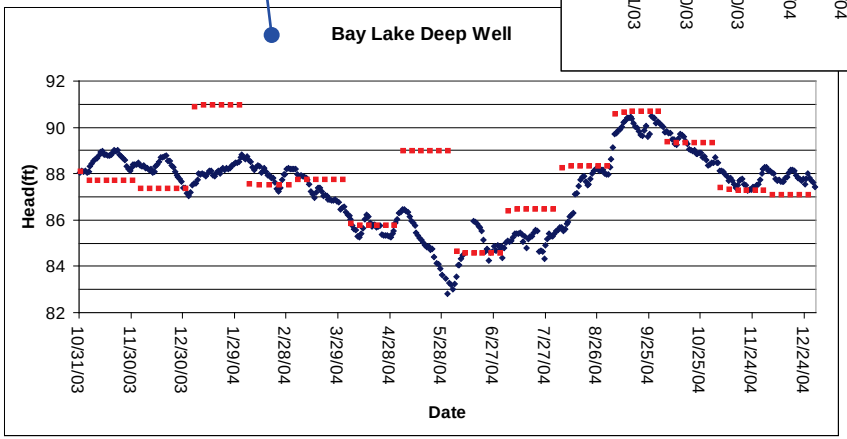
Figure F2-46

October 2010









Legend

- Measured Head
- Model Calculated Head

Notes:

Figures 4.57 through 4.77 show the comparison between measured head values and model-calculated head values at a number of observation wells for the calibration period. Although the scales vary on each plot, all plots have a horizontal grid line at each foot. This is to make it easy to determine the range of heads at a glance.

The model used month-long stress periods, so pumping and boundary conditions were input as step functions with constant values throughout each month and sudden changes at the end of each month. For this reason, the model cannot be expected to accurately predict day-to-day head variations in any of these wells. Calibration efforts were aimed at matching general trends and monthly averages.

Starting head conditions for this model were based on the October 2003 steady state calibrated model. Transient calibration efforts were focused on matching the head changes, not the actual heads, so it is not uncommon for residuals in the starting condition to be carried through the entire calibration period. This indicates that the model is correctly predicting responses to hydrogeologic forces even if the calculated head values vary somewhat from the measured values.

Notes:

Figures 4.57 through 4.77 show the comparison between measured head values and model-calculated head values at a number of observation wells for the calibration period. Although the scales vary on each plot, all plots have a horizontal grid line at each foot. This is to make it easy to determine the range of heads at a glance.

The model used month-long stress periods, so pumping and boundary conditions were input as step functions with constant values throughout each month and sudden changes at the end of each month. For this reason, the model cannot be expected to accurately predict day-to-day head variations in any of these wells. Calibration efforts were aimed at matching general trends and monthly averages.

Starting head conditions for this model were based on the October 2003 steady state calibrated model. Transient calibration efforts were focused on matching the head changes, not the actual heads, so it is not uncommon for residuals in the starting condition to be carried through the entire calibration period. This indicates that the model is correctly predicting responses to hydrogeologic forces even if the calculated head values vary somewhat from the measured values.

Notes:

Figures 4.102 through 4.122 show the comparison between measured head values, model-calculated head values from the SEAWAT model and model-calculated head values from the WASH123D model at a number of observation wells for the calibration period. Although the scales vary on each plot, all plots have a horizontal grid line at each foot. This is to make it easy to determine the range of heads at a glance.

The model used month-long stress periods, so pumping and boundary conditions were input as step functions with constant values throughout each month and sudden changes at the end of each month. For this reason, the model cannot be expected to accurately predict day-to-day head variations in any of these wells. Calibration efforts were aimed at matching general trends and monthly averages.

Starting head conditions for this model were computed in WASH123D based on October 2003 steady state conditions. Transient calibration efforts incorporated values of hydraulic conductivity and storage that were consistent with the SEAWAT model. As with the SEAWAT model, it is not uncommon for residuals in the starting condition to be carried through the entire calibration period. This indicates that the model is correctly predicting responses to hydrogeologic forces even if the calculated head values vary somewhat from the measured values.

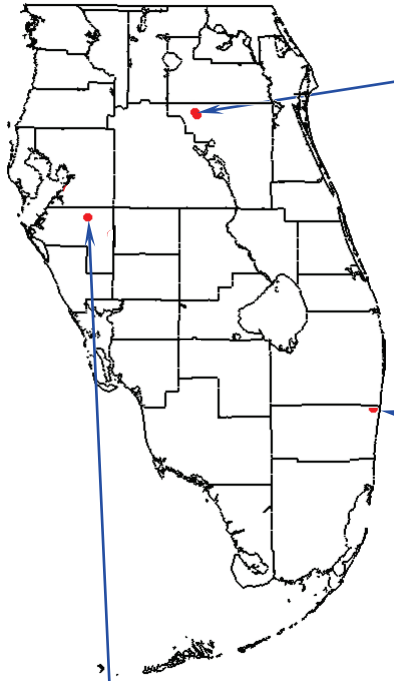
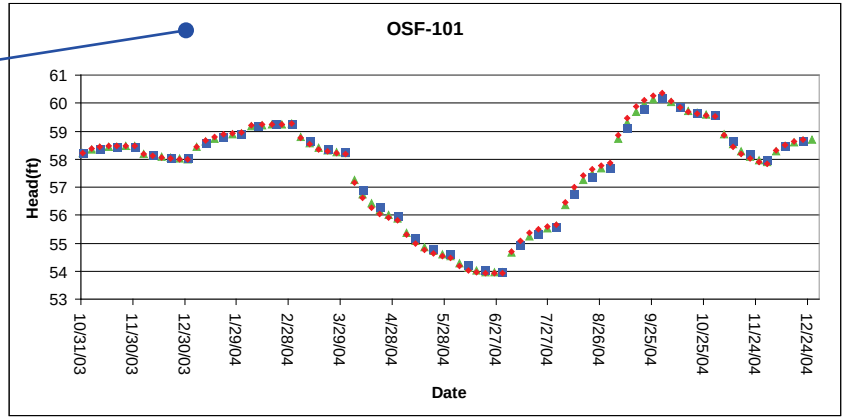
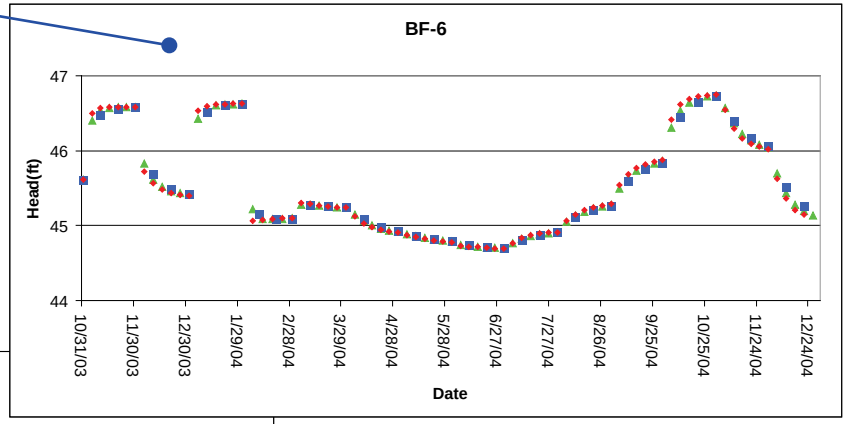
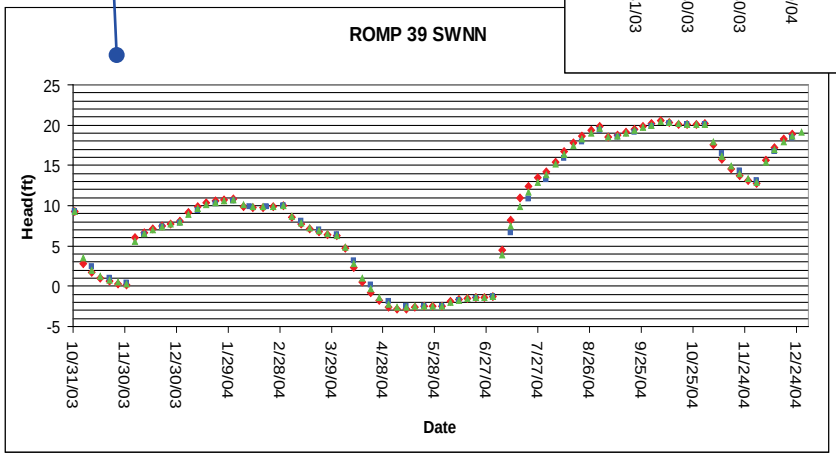
Figure F3-50

October 2010









Legend

- 1 Day Timestep
- 5 Day Timestep
- 10 Day Timestep

Notes:

The transient WASH123D draft calibration model run used a 5 day time step size.

Timestep sizes were varied to investigate the effects on the head solution. Head solutions for 3 UF wells across the model domain show that using a 1 day, 5 day or 10 day timestep produces head solutions with minor differences.

The largest difference of the wells shown is at ROMP 39 SWNN. In the middle of July 2004, the difference between the 1 day timestep head and the 5 day and 10 day timestep heads is 1.0 ft and 1.5 ft, respectively. ROMP 39 SWNN is near a large pumping center where the timing as pumps turn on and off is important.

While the 1 day timestep may more accurately compute heads in areas near pumping centers, the differences between the head solutions for the different timesteps is within the model error. A 5 day timestep size is appropriate for this regional application.

Effect of Timestep on WASH123D Solution at Selected Upper Floridan Aquifer Wells

Appendix G: IMC Comments to Draft Report With Responses

USACE Response to IMC Comments on "Draft Groundwater Model Calibration Report, Aquifer Storage and Recovery Regional Modeling Study"

The groundwater team at the Philadelphia District, USACE, is grateful to the IMC for their comments on the recently completed document, "Draft Groundwater Model Calibration Report, Aquifer Storage and Recovery Regional Modeling Study." Many of the comments were incorporated in their entirety to improve the report and model. Others of the comments indicate a lack of clarity in the presentation of the material in the report. In these cases, revisions and/or additions to the text and figures of the report were incorporated to better explain model construction, assumptions and/or conclusions. A few comments indicate a difference of opinion between USACE groundwater modelers/PDT and the IMC reviewers. This document contains individual responses to each comment and a description of the action taken, if any, to change the model and/or the report. The original text of the IMC comments are provided as black text, while the responses to comments are provided as red, italic text.

The SEAWAT model has been recalibrated based on IMC comments, as described in this document, and additional PDT comments. The WASH123D model has not been recalibrated but an appendix has been added to the final report to document the similarity in the results of the draft SEAWAT and WASH123D calibrations.

IMC MSR 324 – Task 4B: Review of "Draft Groundwater Model Calibration Report, Aquifer Storage and Recovery Regional Modeling Study"

Interagency Modeling Center (IMC)

Purpose

The purpose of this document is to provide comments based upon the review of documents submitted in support of the Aquifer Storage and Recovery (ASR) modeling study to develop and calibrate a regional groundwater flow and transport model.

Documents Reviewed

The document shown below was submitted for IMC review:

- "Draft Groundwater Model Calibration Report Aquifer Storage and Recovery Regional Modeling Study ." US Army Corps of Engineers, April, 2010.

Individual reviewers in some cases reviewed additional documents when certain parts of the report above needed further clarification.

This document is divided into the following two sections: (1) technical comments and (2) general comments.

Technical Comments

The review was limited to the document above, and therefore does not extend to the model code, model input or model output files.

The comments are listed following the table of contents of the review document for ease of reference.

0.0 Executive Summary

1. Paragraph 1: The authors should briefly introduce the "four documents" within the Executive Summary.

Fixed.

2. Paragraph 3: The authors should briefly introduce all performance goals/objectives within the Executive Summary.

Language has been added to the Executive Summary to list the major performance goals that will be discussed in detail in the fourth report. Because the specifics to meet each of the goals are still evolving, only broad descriptions are included. These descriptions are detailed enough to define the scale and accuracy of the model necessary to meet the goals Those objectives which are beyond the ability of the regional model to examine, will be examined using the local scale models.

3. Paragraph 3: The authors should detail "various constraints" in the Executive Summary.

This phrase has been removed from the Executive Summary.

4. Paragraph 3: The authors should quantitatively characterize "well calibrated" in the Executive Summary. The authors state in Paragraph 1 that the objective of the present report is to detail the construction, calibration, and sensitivity of the Phase II Regional Model. The authors should explicitly and quantitatively detail construction and sensitivity in the Executive Summary.

The purpose of the Executive Summary is to provide a quick overview for readers who do not have the background or knowledge to understand the details of the technical report or who do not have the time to read the lengthy report. We believe that the inclusion of detailed quantitative statistics on the calibration quality is unnecessary and undesired in an Executive Summary. The qualitative description of the calibration has been expanded and the reader who is interested in more details is directed to the calibration chapter of the main report.

1.0 Introduction

1. Paragraph 1: The authors should consistently identify the objective of the fourth report as either "The final document in the series will summarize the local scale model development and evaluation of various CERP ASR alternatives." (from the present paragraph) OR " The calibrated model described in this report will be used to evaluate CERP ASR against a variety of performance objectives. This evaluation will be documented in the fourth and final ASR groundwater modeling report." (from the Executive Summary).

The two descriptions are both true. Both descriptions have been expanded to mention both the regional aspect and the local-scale aspects of the planned analysis.

2.0 Regional Modeling Approach

1. Paragraphs 1 and 2: The authors state that "The first and most important step in the modeling process is to define clear, achievable goals and objectives for each stage of the process based on the desired end results." The authors do not explicitly identify model goals within Section 2.0. The authors identify a primary objective in Section 2.0, and allude to "different project objectives". The authors introduce four "large-scale issues". The authors should explicitly identify all goals, objectives, and issues upon introducing these concepts in Section 2.0. Alternatively, if goals, objectives, and issues are formally introduced at another location within the document, the authors may wish to defer introduction of goals, objectives, and issues to the location within the document in which these concepts are discussed.

As mentioned in the comment, four large-scale issues were identified that will be addressed using the regional model. A fifth issue, potential for rock fracturing, has been added to this list. Two smaller scale issues were also identified in the original report. Those are well-to-well interaction within an ASR well cluster and ASR well recovery efficiency. The smaller scale issues will be addressed using the local scale models. Details regarding how these issues are evaluated and the criteria for the evaluation will be provided in the fourth report in this series. The modelers believe that this general definition of the objectives is sufficient for moving forward with the calibration. The PDT is aware that their objectives must not exceed the reliability or resolution of the model.

2. The authors should include a section that details previous studies. For example the USGS Regional Aquifer System Analysis (RASA) program generated a considerable volume of information specifically related to the study area. The authors may want to detail the RASA program, and identify elements of the RASA program that are of use to satisfying the ASR Regional Modeling objectives. Specifically, the authors may find the following reports relevant:

Miller, J.A., 1986, Hydrogeologic framework of the Floridan aquifer system in Florida, and in parts of Georgia, Alabama, and South Carolina: U.S. Geological Survey Professional Paper 1403-B, 91 p. 33 pls.

Bush, P.W., R.H. Johnston, 1988, Ground-water hydraulics, regional flow and ground-water development of the Floridan aquifer system in Florida and in parts of Georgia, South Carolina, and Alabama: U.S. Geological Survey Professional Paper 1403-C, 80 p., 17 pls.

Meyer, F.W., 1989, Hydrogeology, ground-water movement, and subsurface storage in the Floridan aquifer system in southern Florida: U. S. Geological Survey Professional Paper 1403-G, 59 p.

Sprinkle, C.L., 1989, Geochemistry of the Floridan aquifer system in Florida and parts of Georgia, South Carolina, and Alabama: U.S. Geological Survey Professional Paper 1403-I, 105 p, 9 pls.

A summary of previous modeling work was provided by CH2MHill. This report had been included as a reference in the draft report. A few sentences have been added to the Introduction to direct the readers to this report. In addition, aspects of the USGS RASA program that were used to generate the hydrogeologic framework are described in Reese and Richardson (2008), referenced as the major basis for the hydrogeologic construction of this model.

3. The authors should summarize other previous studies in a section that is devoted to previous work.

Same response as for #2 above.

2.1 Modeling Codes

1. Paragraph 1: The authors state that "Substantial density variations in the groundwater (due to variations in temperature and salinity) are observed across the model domain". The authors should replace qualitative statements with quantitative statements throughout the document. For example, the authors should state the numerical variation in density across the model domain in place of the qualitative term "Substantial".

Fixed.

2.1.1 SEAWAT

1. Paragraph 1: The authors may wish to eliminate the bullets, and associated sentence, as this information is not particularly relevant.

Agreed.

2. Paragraph 1: The authors should include Guo and Bennett (1998) in the reference as the first occurrence of SEAWAT within the published literature. (Guo, W., Bennett, G. D., 1998. Simulation of saline/fresh water flows using MODFLOW. In: MODFLOW '98 Conference, Golden, Colorado. pp. 267–274.)

Reference added.

3. Equation 2.1 is not "the variable-density form of Darcy's law for groundwater flow." Equation 2.1 is more correctly characterized as "the governing equation for flow in a porous medium, as a function of freshwater head" (Equation 37, Guo and Langevin, 2001). The authors should appropriately cite Guo and Langevin (2001). The authors should explain the freshwater head concept, and include and reference Equation 3 of Guo and Langevin (2001).

The name of the equation (now 2.3) has been changed with citation. The description of equivalent freshwater head with equations was previously found in Appendix C, but has been moved to this chapter as new Section 2.1.

4. The authors may wish to correctly typeset the denominator of the dimensionless density term for the gamma axis in Equation 2.1. The authors may wish to identify alpha, beta, and gamma as "Orthogonal coordinate axes" following "Where".

Fixed.

5. Equation 2.2 is not "the advective-dispersion equation". Equation 2.2 is more correctly characterized as "the governing equation for fate and transport of contaminants of species k in a three dimensional, transient groundwater flow system". If the authors do not employ reactive species, the authors should eliminate the fourth term on the right-hand side of Equation 2.2. The authors should appropriately cite Zheng and Wang (1999) Equation 1. What is the difference between C in Equation 2.1 and C^k in Equation 2.2? The authors should use a lower case k in Equation 2.2 as is done by Zheng and Wang (1999), to differentiate between this species counter and the use of a capital K symbol for hydraulic conductivity. The authors should identify D_{ij} as the "hydrodynamic dispersion coefficient tensor", as is done by Zheng and Wang (1999). The authors may wish to cast Equations 2.1 and 2.2 in a parallel form, such that the implied summation in i and j on Equation 2.2 is expanded, or such that the implied summation in i and j is employed in Equation 2.1.

The errors in format and definition have been fixed. Equation 2.2 (now 2.4) has been written as found in equation 38 of Guo and Langevin, 2002 in place of the previous form copied from Zheng and Wang, 1999. Both equations are written exactly as found in the 2002 SEAWAT USGS published User's Guide.

2.1.2 WASH123D

1. The authors may wish to cast Equation 2.3 in a form that is parallel to the form chosen for Equations 2.1 and 2.2. Specifically, Equation 2.3 uses a tensor dot product form that is not used by Equations 2.1 and 2.2. The authors may wish to note that it is possible to write Equations 2.1 and 2.2 in a tensor dot product form.

Since Equation 2.2 (now Equation 2.4) is now written in the form of Guo and Langevin, 2002, it is in tensor dot product form and matches Equation 2.3 (now Equation 2.5). Since the USGS SEAWAT User's Guide does not present all equations in parallel form, we have not done so in this project report.

2. The authors should use a bold typeface for hydraulic conductivity K, and for the gradient operator del, to distinguish these elements as tensors, and differentiate them from, for example, an element of K, such as K_{xx}, which would not be typeset with a bold font.

The conductivity tensor K in equation 2.5 (old equation 2.3) has been bolded. The gradient operators have also been bolded.

3. What is the difference between "referenced pressure head" in Equation 2.3 and head? What is the difference between "potential head" z in Equation 2.3 and "elevation at the measurement point" Z in Equation 2.1? What is the difference between "density of source/sink water" rho^star in Equation 2.3 and "fluid density source or sink water" rho_s in Equation 2.1? What is the difference between "volumetric flow rate of source or sink" q in Equation 2.3, "source/sink volumetric flow rate per unit volume of aquifer" q_s in Equation 2.2, and "volumetric flow rate of sources and sinks per unit volume of aquifer" q_s in Equation 2.1?

The original equations were written exactly as found in the respective model documentation. The model documentation is referenced in Section 8.0 so that the reader may research the source document to answer additional questions on the governing equation or model descriptions. In response to this comment, the variables used in the equations have been made to match.

4. The authors define time with the symbol t on both Page 4 and Page 5. The volumetric flow rate of sources and sinks is defined after both Equations 2.1 and 2.2. Throughout the entire document, the authors may wish to define variables once, on first use, and refrain from redefinition throughout the remainder of the document.

The second definition of time and source/sink flow rate has been removed.

5. Paragraph 2: The authors refer to Equation 2.2 as both the "advective-dispersion" equation and the "subsurface transport equation". The authors should use a consistent textual description of this equation.

We see no contradiction between the two terms.

6. Paragraph 2: The authors should explicitly state goals of the Phase II modeling effort.

The purpose of this section is to provide a general overview of the equations solved by each model. The model objectives are summarized at the beginning of Section 2.0.

2.2 Model Extent and Spatial Discretization

1. Figure 2.2: Do surfaces represent the tops of hydrogeologic units? Bottoms of hydrogeologic units? The mid-point of hydrogeologic units? Please explain.

A note has been added to Figure 2.2 indicating that these surfaces represent the tops of each hydrogeologic unit.

2. In the Phase I report, the model domain was rotated 18 degrees counterclockwise. In this Phase II model, the domain appears to have been rotated 38 degrees west of north. Has the rotation been changed from Phases I to II and why?

As stated in Bittner et al (2008), "… it would seem more reasonable for the axis to be similar to that of the gravity anomaly axis… Additional simulations are planned using a grid alignment rotated to correspond with the gravity anomalies direction…" During the construction of the Phase II model grid, several gravity anomaly publications and recent field work performed by SFWMD were reviewed to determine a reasonable average angle for preferential flow paths. The resulting grid angle was N38W. A statement has been added to the new text to explain the change in grid angle. It should be noted that since regional anisotropy was not activated for the final calibration, the angle of the grid has no bearing on the results.

3. Some additional clarification regarding the vertical layering is needed. The authors need to explain the vertical layering. It is clear that they use the major hydrogeologic units (Figure 2.4). However, they should explain the discretization of those layers. The APPZ zone in southwestern Florida is missing or non-productive (Reese and Richardson, 2007) based upon observed data. Similarly, the Boulder zone is also missing or generally non-productive in the northern portion of the model. How these units were dealt with in the model should be discussed.

Additional paragraphs have been added to Section 3.2.1 to describe the subdivision of the hydrogeologic layers into model layers. The missing APPZ zone in SW Florida was modeled by making the layer very thin in that area. The missing BZ zone was modeled

by making the conductivity values similar to the LF in this area. Both of these descriptions are included in the new text in Section 3.2.1.

4. The model's horizontal extent is not sufficiently extensive near the northwestern corner, western, and southern boundaries. These boundaries should be extended to where outcrops of Floridan Aquifers occur. On the Gulf side of the model, the boundaries should be extended as far as possible into the Gulf, with consideration of model run time, to include the estimated position of the saltwater/freshwater interface. Using observed data instead of natural boundaries to specify constant heads and/or concentrations along these boundaries will limit the use of the model for evaluating saltwater intrusion in those areas. It may also create challenges in drawing defensible conclusions if ASR wells are analyzed close to these boundaries.

The current model boundaries were based on the recommendations in the conclusion of the Phase 1 model report (previously reviewed by IMC). Although it would be desirable to extend all layers to their outcrop locations, this would greatly increase the computational time for each model run and the RAM necessary to interact with the model or solution. This would also add vast areas to the model where little or no geologic information is available. The layer outcrops occur over 150 miles west of the Floridan peninsula. Including this area would double the area of the model without adding additional relevant data. Half of the model would be void of any calibration points or data on layer thicknesses, hydraulic conductivity or storage.

The risks inherent in a larger, more unwieldy model with a large uncalibrated zone, have been determined to outweigh the risks that the ASR wells will impact the specified head boundary conditions on either the west or north boundary. We have developed a plan to determine the effect of the ASR pumping on the boundary conditions. The plan is to extract the flux rate for each specified head boundary cell on the north, west and south boundaries of the model and reapply that rate as a specified flux boundary condition during the ASR regional production runs. These solutions can be compared against those solutions obtained using the specified head boundary conditions. If the differences are minimal, we will be assured that the simplification to the model was warranted and that the boundary is not impacted by the CERP ASR pumping. If the differences are significant, the two solutions will allow us to bound the possible effects of the pumping and provide a more probabilistic solution to the decision-makers. This process will be described in detail in the next report, which describes the use of the regional model and the local-scale model to predict the effects of the CERP ASR program.

2.3 Model Time Discretization

1. Both the transient calibration and validation simulation periods are much too short to show any TDS concentration changes in the modeled aquifers if only 10 and 15 monthly stress periods are used. The Kissimmee River ASR project alone will exceed 15 months just for the 4 cycles. In addition, this short of a timeframe does

not address variations in climatic conditions which drive the head in the upper aquifers.

It was not the intent of this model to reproduce TDS concentration changes. There are very few wells with long term TDS data, so calibration of this type of model would be difficult. The TDS and temperature were included in the model only because they impact the flow of groundwater. The PDT is interested in possible long-term effects of the CERP ASR program on saltwater intrusion. To answer these questions, we will be running a much longer-term version of the model and a number of sensitivities or Monte Carlo type simulations will be run because of the uncertainty inherent in the use of the model for something it has not been calibrated to do.

Regarding the shortness of the timeframe for addressing climatic conditions, we have tried to balance the time requirements of an enormous data collection effort with the need to calibrate to a wide variety of hydrologic conditions. Clearly the model would be better with longer or more-varied calibration period, but the time and money required to collect the necessary data is prohibitive. SAJ can, perhaps, provide an estimate of the cost of collection of 27 months of head and pumping data. The data collection effort performed to date involved searches of numerous databases, a QA/QC effort and many phone calls to individual well owners.

2. Discussion of the time steps in Section 2.3 is confusing. Flow time steps are defined in the report as 5 or 6 days, but in each flow timestep, transport timesteps are determined during transport modeling, either using a fixed step or being calculated by transport model. In addition, it is unusual to run a steady state SEAWAT model to obtain steady state solutions directly. It is usual to set up as a transient model with a single stress period of significant duration so that a steady solution is obtained when both heads and concentrations do not change much or approach constant values as time increases.

Section 2.3 (now Section 2.4) has been clarified to indicate that both flow and transport timesteps were approximately 5 days long. (31-day months had timestep sizes of 5.2 days; 30-day months had timstep sizes of 5 days; 29-day months had timestep sizes of 5.6 days; 28-day months had timestep sizes of 5.8 days). The flow and transport timesteps were the same. We believe this to be valid because the TDS and temperature are not expected to change significantly at this scale. For the future local scale models, it is expected that both the flow and transport timesteps will need to be smaller in order to effectively model the freshwater bubble.

There is an option in MT3D to allow the transport simulation to select the timestep size based on the user-specified Courant number. When this option was selected, the model required a very small timestep size (less than 1 day) because of a few cells in the northwest portion of the model with large aspect ratios. This area is far from the proposed ASR locations and not important for the goals of this model, so this timestep selection option was not used. A sensitivity analysis of the selection of timestep size is presented in Appendix B. It indicated very little material improvement in the model with a timestep size less than 5 days.

The reviewer indicates that it is unusual to run a steady state SEAWAT model to obtain steady state solutions, but we believe it is the best option in this case. The purpose of this initial steady state run was to develop a starting condition for the transient model in which the equivalent freshwater heads are at equilibrium. This is done by holding the TDS concentration (and temperature) at the initial conditions and solving for the head condition which matches the boundary conditions, model parameters and initial TDS and temperature fields. In this way, the transient model will be starting with our best estimate for conditions during October 2003 (or October 1993 for the validation period). Otherwise, the initial stress periods (or perhaps all of the stress periods) in the transient model will be taken up with bringing the heads to an equilibrium condition rather than trying to reproduce the heads in the calibration wells.

As mentioned by the reviewer, a true steady state transport condition for TDS or temperature can only be obtained by running the transient model for a long period of time, until the concentrations do not change with time. Tests presented in the Phase 1 report (see Section 5.1) indicate that when allowed to run for 35,000 years, the TDS concentrations increase significantly in all areas of the model other than the recharge area. If this type of steady state starting condition was used for the start of the transient model, the initial conditions would have been nothing like the TDS levels which have been measured in the Floridan peninsula over the last few decades. This model would not have accurately reproduced conditions in 2003 or in any other period for the foreseeable future. The TDS condition in the peninsula does not seem to be in a steady state condition currently, in part due to the variety of significant pumping stresses that are being placed on the Floridan Aquifer.

3. Please explain why the period from October 1993 through July 1994 was chosen for the validation period (page 8). There are fewer observation wells active during this time period.

The period from August 1993 through July 1994 was chosen to reduce the data collection effort. The August 1993 through July 1994 time period is the same time period used for the regional model performed by USGS (Sepulveda, 2002). Choosing the same time period allowed SAJ and the modelers to make use of data collected as part of the USGS study.

4. Paragraph 3: The authors initially use a one-day, steady-state stress period "to provide a starting condition for the rest of the model." This steady-state stress period solves for a steady state head; however, the concentration solution will not instantaneously adjust to this steady-state head solution. The concentration solution may take significantly longer than one day, and in some instances or at some locations, perhaps months, years, or decades, to adjust to the instantaneous, steady-state head solution. This longer-term adjustment to the initial concentration condition may affect the estimation of transport parameters with an automated method like PEST. The authors may wish to include an additional transient stress period after the steady-state period and prior to the start of the time

period of interest. The concentration solution will migrate toward a steady state during this additional stress period. The length of the additional transient stress period is a function of the time needed for the concentration solution to migrate to a steady state, in response to the steady-state head solution.

We do not believe that the salinity is currently in a steady state. The Phase 1 report included some tests of that model running for 35,000 years. At the end of those runs, a significant portion of all aquifers had a larger TDS concentration than what exists currently (based on water quality data for the last few decades). The purpose of the one-day steady state run was to obtain a head condition that agreed with the interpolated TDS field. Put simply, the transient starting condition for the temperature and TDS concentrations was based on an interpolation of the available data while the transient starting condition for the head was based on a steady state calibration of hydraulic conductivity values until the starting condition matched available data.

It is true that a longer period run may require the adjustment of transport parameters. However, there is not enough data to do this type of calibration. Substantial uncertainty exists in estimating the ocean level 35,000 years ago and consequently the boundary heads for a simulation starting 35,000 years ago. The changes to the TDS in this model are expected to be small given the time scale being modeled. The transport parameters are expected to become more important for the local scale models. If the data for the local scale calibration is not available, sensitivity runs will be used to determine the range of possible results.

The inclusion of an additional transient stress period prior to the time period of interest would need to be exceedingly long (perhaps 35,000 years) and there is not sufficient data for calibration or boundary conditions for that length of time.

3.0 Conceptual Model

1. Paragraph 1: It is mentioned that additional conceptualizations of temperature and salinity are required. Has salinity been analyzed in previous model efforts? Please clarify.

The purpose of this sentence was to indicate that while much of the conceptualization for the hydrogeology was available in the Framework (Reese and Richardson, 2008), the TDS and temperature data had not been analyzed in that report. The sentence has been clarified in the report and a new Appendix describing the analyses of the salinity and temperature data has been added.

3.1 Topography

Paragraph 3: How did the authors parse well data where the well is open within more than one hydrogeologic unit?

For monitoring wells, the database was queried to find all wells with more than 50% of the open interval within a single hydrogeologic unit. Some wells were omitted if they were deemed to not represent regional conditions. A table presenting the well names and the reasons for inclusion or removal has been added to the report as Table 4.1.

For pumping wells, the pump rate was prorated among the aquifers tapped by the open interval based on the thickness of each aquifer covered by the well and the approximate conductivity found in each aquifer. Wells which partially tapped confining units had all their pump volume moved to the aquifer portions of the wells. (Rounding occasionally resulted in a small amount of water being pulled from confining unit cells.) For additional details, please see Appendix D Section 2.0 Pumping Rate Assignment in the Regional Model.

3.2.1 Regional Geology

Paragraph 2: The authors should describe briefly the UF and APPZ before describing the LF.

The descriptions of all aquifers are provided in the Hydrogeologic Framework (Reese and Richardson, 2008) and readers are invited to look in that document for additional information. The statement about the LF is made because the Hydrogeologic Framework divides the LF into a number of subunits (LF1, LF2, and LF3). The model does not differentiate between these layers, so the statement in Paragraph 2 is made to address this difference. The statement has been clarified in the report.

3.2.2 Hydrogeologic Properties

1. Paragraph 2: The authors should provide the specific subsection of Section 3, in which the final calibrated parameters are presented. The authors should reference figure numbers.

Fixed

3.2.3 Regional Anisotropy

1. Bittner, Richardson, Langevin, England, and Stevens (2008) concluded that regional anisotropy and the effects of pressure and temperature on fluid density and viscosity improve agreement between head observations in southern Florida, and numerical models of variable density flow and transport. The authors state that "SFWMD performed additional hydrogeologic investigations to quantify the extent and magnitude of regional anisotropy in the FAS. Initial findings from an analysis of flowing fractures in selected wells indicate that evidence may exist for [regional anisotropy in the FAS]. However, further unpublished analysis ultimately concluded that, although there are indications of a preferential flow direction in some areas, this is not a widespread, regional feature. Based on these findings, regional anisotropy was not included." Given the conclusions of Bittner

et al. and the SFWMD field study, the authors should fully detail the unpublished analyses.

Unfortunately, these unpublished results are still not available for inclusion in this report. They are planned for completion in time for inclusion in the TDR for the Regional Study. Conversations with Emily Richardson at SFWMD have given us a clearer understanding of the basics of the study and this section has been clarified. Although Bittner et al (2008) concluded that the inclusion of anisotropy might improve the calibration of the model, there is currently no evidence to support the use of a regional anisotropy, so the model was calibrated without this option. Readers who require additional information on this study are invited to wait for the TDR or to contact Ms. Richardson directly.

2. Paragraph 2. Regional anisotropy may be present due to stratigraphy and the development of higher permeability facies along depositional strike. The direction of this strike would probably be roughly parallel to the axis of the peninsula, which is 10 to 30 degrees west of North. This may be more important in the UF than in the APPZ. Perhaps this could be confirmed by aquifer tests, provided enough monitoring wells in different directions were used in the tests.

This is an interesting theory, but its analysis is outside the scope of this study.

3.3 Boundary Conditions

3.3.1 Surficial Head Boundary Conditions

1. Paragraph 2: The authors detail an assumption that ASR pumping does not affect head in the SAS. The authors may wish to include a table or list, in which all model assumptions are clearly listed. For example, the authors would include a number of standard assumptions in the table or list, such as principal axes of anisotropy are aligned with Cartesian axes of the model grid. The authors may wish to detail methods, such as sensitivity analyses, used to justify all assumptions, including the assumption that ASR pumping or injection does not change SAS head. What happens if ASR pumping or injection occurs for a very long period of time, such that the SAS is potentially drawn down or up in some locations? Is the SAS sufficiently disconnected from the FAS at all locations within the model domain? What if ASR pumping occurred at locations where the FAS and SAS are not sufficiently disconnected? Would the head in the SAS be affected?

We have added Table 2.1 detailing assumptions, their basis and sensitivities in Section 2.0.

Regarding the assumption of principal axes of anisotropy being aligned with the Cartesian axes of the grid, since anisotropy was set to 1.0 on all layers, the orientation of the grid has no effect on the result.

Regarding the assumption with the SAS, we cannot be certain of the validity of this assumption until we have run the production runs with the ASR wells. The modelers are planning a sensitivity run which will extract the calculated fluxes at all specified head boundary cells (other than those on the ocean) and then rerun the model using those fluxes as specified flux boundary conditions. The comparison between the results of these two models will tell us what impact this assumption has had on the ASR analysis. If the impact is important, the two models may help bound the results. The PDT has been kept aware of our assumptions and their possible effects on the ASR analysis.

2. Appendix Page C-3: The authors state that "The calculated flux was compared to available estimates on recharge in the model domain and found to be generally similar." The authors should detail the comparison of calculated flux and available estimates of recharge with a table or graph. The authors should provide documentation to support the available estimates of recharge, such as report reference or well identification information.

This analysis was described in Section 4.1.4 and in Figure 4.18 (now Figure 4.29). The statement from the Appendix has been updated.

3. Paragraph : The authors may wish to detail whether the specified head boundary condition at the surface is transient or steady. If specified boundary conditions at the surface are steady state, the authors may wish to justify the steady state assumption. The authors may wish to provide a table of observed aquifer heads, with associated well or location identification information, and ranges in observed head.

The specified head boundary condition at the surface is transient and based on average monthly heads for a large number of wells. The text has been clarified in several locations to make this clear. Table 4.1 lists all the wells used in the SAS interpolation

3.3.2 Simulation of Ocean Boundary

1. Paragraph 1: The authors state that "the annual variation of monthly mean sea levels is about 0.5 feet, which is much smaller than the variation in nearly every other parameter of the model." The authors may wish to detail how an annual variation in mean sea level, measured in feet, is compared with variation in other model parameters, such as hydraulic conductivity, that are not measured in feet and/or not transient. The authors may wish to re-word this sentence.

The sentence has been revised to clarify the original meaning – that the variation in head at the ocean boundary is smaller than the variation in heads seen at nearly all observation wells in the model.

2. Paragraph 1: The authors should provide a figure that details ocean boundary elevation versus time for both the Virginia Key and Naples gages. The authors should tabulate the phase and amplitude of major tidal constituents at Virginia Key, Naples, and at other tidal gages in Florida, to prove that Virginia Key and Naples are representative time series for the east and west coasts of Florida. The Virginia Key tidal gage is inside Biscayne Bay, at the end of a pier that is near a causeway. Are the phase and amplitude of major tidal constituents at this location equivalent to the phase and amplitude of major tidal constituents 40 miles off the coast of Melbourne Beach, or 15 miles off the coast of Fort Lauderdale?

A figure of the ocean boundary elevation has been added to the report (Figure 3.16). We see no need to tabulate the phase and amplitude of major tidal constituents at the gages in Florida because we are using only the Monthly Average water level in the model. The stress periods in the model are a month long and so, cannot hope to reproduce any tidal signatures. In response to the request that Virginia Key and Naples data be revisited to ensure they are representative, the NOAA Tides and Currents Database was searched for any other tidal gages in the modeling domain with data available for the calibration or validation periods. A number of additional tidal gauges were found. The Trident Pier gage is located just north of the model boundary on the east coast. In the 2003/2004 period, its water level is up to 0.6 feet lower than the modeled boundary condition. If it had been averaged with the only other east coast gage, the head at the eastern boundary would have dropped by approximately 0.25 feet during the spring and summer of 2004. However, since this gage has no available data during the 1993/1994 validation period, it was not used in the selection of boundary conditions. The 0.25 foot change is less than the calibration errors and would have been of minimal impact to the model overall.

Three gauges were found in the Florida Keys. These are beyond the boundary of the model, and so were eliminated from the model. However, the monthly average water level is very close to that measured at Virginia Key. Inclusion of these points in an average would have changed the boundary condition head by perhaps 0.1 feet in some months. This is well within the error inherent in the model.
Finally, a single gauge (Port Manatee) was found on the west coast, about 15 miles from the entrance to Tampa Bay. This gauge had available data only for the calibration period, and generally had water levels similar to those at Naples.

The entire range of all the available data for all months of the calibration and validation periods is less than 1.5 feet. The sea levels do not change significantly over this time period when averaged over each month. The use of the Naples and Virginia Key gauges was sufficiently accurate for the model of this scale. The plots of water levels at each gauge and the locations of the gauges are shown below:

3.3.3 Aquifer Head Boundary Conditions

1. Paragraph 1: The authors should explain whether aquifer head boundary conditions are transient or steady state. If aquifer head boundary conditions are steady state, the authors should justify the steady state assumption. The authors should provide a table of observed aquifer heads shown on Figure 3.10, with associated well or location identification information, and ranges in observed head.

The aquifer head boundary conditions are transient. The head values for each stress period were selected by averaging the available data over the month. A few sentences have been added to the text to emphasize this point. Table C2 (in Appendix C) contains information on all of the wells shown in Figure 3.10 (now Figure 3.17). The table has been expanded to include location information. Since the aquifer boundary conditions are transient (averaged over each month), the inclusion of ranges of observed head is less useful. More useful, might be the inclusion of the ranges of observed heads in each stress period, however, as this would make the size of the table and report unwieldy, the readers are invited to extract the desired data from the appropriate online database (e.g. USGS or DBHydro).

3.3.4 Confining Unit Head Boundary Conditions

1. Paragraph 1: The authors should justify the no-flow boundary condition on boundaries of confining units. The authors should compare the vertical flux between confining unit and aquifer, at the boundary, to the vertical flux between confining unit and aquifer a few cells into the domain. If both vertical fluxes are within 10%, the assumption may be acceptable. Alternately, the authors may wish to use a specified head on confining unit boundaries, which is equivalent to the average of the head used in the bounding aquifers.

A comparison of the model results with and without specified heads assigned on the confining unit boundaries has been added in the sensitivity section (Section 5.5.3) of the report. No appreciable difference was observed, indicating that the assumption is acceptable.

3.3.5TDS and Temperature at the Boundaries

3.4 Initial Conditions

3.4.1 Salinity (TDS) Distribution

1. The TDS along the ocean boundary in BZ was set above sea water at 40,000 mg/l. The report suggests that it could be caused by minerals in BZ and injections of wastewater with high salt, but this high value is still used in the model at the boundaries where these conditions may not exist. Was the selection of this value derived from model calibration? This high concentration will largely increase equivalent freshwater water heads in BZ and thus change flow directions and patterns in upper layers.

This issue was brought up at the February 2010 PDT meeting and was addressed as a sensitivity run in Section 5.5 in the original Draft document. The recommended plan forward was to recalibrate the model using the new lower BZ salinities at the ocean boundary. As planned, the model has been recalibrated for the final version of the modeling report. As such, Section 5.5 was removed as being unnecessary and the TDS interpolation plots were updated.

2. Relating to the previous question, the eastern boundary temperature was set at approximately 4 degrees C in the BZ to account for temperature and density changes observed in the deep ocean. Considering that one of the largest warm water currents runs along the eastern boundary, is there a reference from the coast of SE Florida which supports the standard middle latitude thermocline used to calculate the temperature at depth for the aquifers?

The temperature along the eastern boundary of the BZ varies from approximately 7°C at the northern edge of the Phase II ASR Regional model to 5°C at the southern edge.

The temperature variation was read from Figure 3.19 (now Figure 3.27) of the Draft Groundwater Calibration Model Report based on the variation in the BZ layer depth.

At latitude 27°N, between Jupiter Island and Grand Bahama Island, several studies have been performed to estimate the transport of the Florida Current. Data collection for these studies included temperature along the latitude line from the ocean surface to its floor. The figure below, from Figure 2.3 of Chester, 1989 (which was adapted from Leaman et al., 1987), shows the temperature profile throughout the cross section at latitude 27°N. The temperature at the base of the cross section, approximately 750 m (2,460 ft) deep, is 5°C which is consistent with the temperature values used in the Phase II model at this depth. In 2001, NOAA obtained temperature data from the same site which was reported in a study to determine groundwater flow patterns in the Floridan Aquifer based on isotopic measurements. At a depth of 630 m (2,065 ft), the temperature reported was 7.8°C. (Table 2 of Morrissey and Clark, 2009). In the Phase II model, this location is on the boundary of the LC where the assigned temperature is 8°C. Data from these reports supports the use of the middle latitude thermocline along the Florida coast to assign the temperature boundary condition.

3. Reese (1994) investigated the distribution of TDS in the Floridan aquifer system, in southeastern Florida. The authors do not reference Reese (1994). The following TDS distributions, using the Reese and Richardson (2008) hydrostratigraphic framework, can be generated by interpolating Reese (1994) data to cell centers:

[Figures removed.]

These figures may not be directly quoted or referenced by others, or identified as a personal communication. The information may be useful to the authors in answering specific questions concerning TDS distributions based on Reese (1994).

The 1994 Reese report (WRI 94-4010) referenced in this comment was used in the generation of the salinity distribution for this model. The omission of this reference was corrected in the final modeling report. In addition to the referenced report, a variety of other data sources were used, including more recent USGS publications, data from the Florida Department of Health, the DBhydro on-line data base, data collected for previous modeling efforts, well completion reports, etc.

Based on discussions with the reviewer, the above figures were generated based on Table 7 (WRI 94-4010), which identifies the depth to the brackish and saline water interfaces at 24 locations. These interface depths were primarily based on resistivity curves and not measured water quality data. For the Phase II regional modeling effort, measured water quality data, including data from Tables 2 and 3 of WRI 94-4010, were used to establish the salinity distribution in each model layer. The data used were critically evaluated by both the modelers and SFWMD to ensure that the data were representative and reliable. After the data were interpolated to the model grid/mesh, a variety of error-checking routines were performed to ensure consistency between vertical layers. This was especially important in the confining layers, where the salinity data were more limited than in the aquifers. Appendix E has been added to the final modeling report to more fully describe the procedures used to generate the TDS distribution in the Phase II regional model.

4. The authors TDS distributions are somewhat different at some locations in southeastern Florida than the distributions shown above in Figures 1 – 4 ***[Figures removed]***. The authors show "islands" of high or low TDS concentration at some locations. For example, TDS of less than 5 ppt in the MCU Lower, in northern Miami-Dade County, where the Reese (1994) distribution shows greater than 30 ppt. The authors may wish to explain---at some locations---the transient geologic process that lead to the presence of these "islands" of TDS concentration, or re-contour the TDS distribution such that the islands do not exist, and a classic saltwater wedge shape remains, as is shown in the above Figures 1 – 4 ***[Figures removed]***. The authors may wish to re-order Figures 3.11 through 3.17 in stratigraphic order, such that the reader can progress from top to bottom, or bottom to top, and rationalize TDS distributions that deviate from the classic saltwater wedge shape.

In evaluating this review comment, an error in the DBhydro database was discovered at wells DF-1 and DF-5. These wells were used to generate the TDS distribution for the MC2 and are at the location in northern Miami-Dade County referenced above. The corrected TDS for this location is 34,200 mg/l. This error has been corrected in the DBhydro database and updated in the final calibrated model.

During model construction the "islands" of high TDS concentration were evaluated throughout the model domain. Some are the results of TDS inversions (high TDS overlying lower TDS) which are supported in the data. Prominent examples of this inversion are located at the SFWMD test wells near City of Oakland Park and the Hillsboro ASR Pilot Project.

The City of Oakland Park wells are located in Broward County near the Atlantic coast. The wells in this location where TDS data are available for the UF are designated BF-1, BF-3, and BF-4S. The recorded TDS for these UF wells varies between 7500 mg/l and 8731 mg/l. In addition to these UF wells, there are two wells, BF-2 and BF-4M, that have TDS data for the APPZ. The recorded TDS levels for these wells range from 4810 mg/l to 5520 mg/l, which is noticeably fresher than that observed in the UF.

The Hillsboro ASR Pilot Project wells are located in southern Palm Beach County. The wells in this location where TDS data are available for the UF are PBF-10R and PBF-13. The recorded TDS for these UF wells varies between 2932 mg/l and 6500 mg/l. The corresponding APPZ well at this location, PBF-11, again has a lower TDS range of between 1262 mg/l and 3200 mg/l.

In summary, the TDS data was collected from numerous sources in addition to WRI 94-4010 and critically reviewed during the Phase II model construction and calibration. As discussed during the October 28, 2008, PDT meeting with IMC, observed data was used to the maximum extent possible to set the initial TDS concentrations. The data at the "island" locations referenced in this comment is based on observed data and the lateral extent of elevated TDS is limited within the model. As such, the modelers feel that the TDS representation is reasonable, accurate, and consistent with the approach previously presented to the IMC.

3.4.2 Temperature Distribution

1. Figure 3.24: What causes the 22-28 degree C temperature in the Boulder Zone, within Miami-Dade County, near the county boundary that divides Miami-Dade County and Broward County, within 10 kilometers of the Atlantic Ocean? Is this 22-28 degree C temperature due to injection? If so, are there other locations within the model domain that also would exhibit relatively higher temperature due to injection, such as at the North and South District Wastewater Treatment Plants in Miami-Dade County, where very large volumes of wastewater treatment plant effluent have been injected into the Boulder Zone?

The higher temperature in the Boulder Zone near the Miami-Dade/Broward County boundary is due to injection. This temperature data point should have been removed from the data set. Because injection well temperature data or temperature influences at monitoring wells due to injection wells represent local conditions and do not reflect the regional aquifer temperature, temperature data affected by injection should be omitted. The temperature dataset was reanalyzed for injection impacts and adjustments were made to the temperature distributions in the Boulder Zone and Lower Floridan layers. Appendix E has been added to the report to detail the data used in each layer to construct the temperature distribution and their sources.

3.5 Sources and Sinks

4.0 Calibration/Validation

4.1 Steady State Calibration

1. On page 21, the authors indicate that there is no standard protocol for selecting a calibration range during the calibration process. It should be noted that the calibration statistics are within an acceptable range for previous models developed for the Floridan aquifer (Figures 4.2 through 4.11).

The modelers continue to believe that despite the variety of statistical measures of calibration quality, the decision to accept a calibration is primarily a qualitative one, and is based on numerous considerations, including the intended use of the model and the precision required to answer the questions to be posed. That the calibration statistics for this model are within the ranges deemed acceptable by previous modelers is auspicious, but these previous models were not likely designed for the same purposes, so a comparison of statistical calibration may not be practical.

Figure 4.19: The authors show a saddle feature in the modeled predevelopment head distribution for the 60-foot contour, west of Lake Okeechobee. This region is of particular importance, as it is an area where ASR is being evaluated. The following text may not be directly quoted or referenced by others, or identified as a personal communication. However, the information may be useful to the authors in answering specific questions concerning historic potentiometric surface delineations. The authors may also find it useful to review the cited literature.

> Given the eventual conclusion that "the Floridan aquifer system south of Lake Okeechobee can only be replenished by groundwater flow from central Florida" (Bush and Johnston, 1988), what causes the modeled potentiometric high south of Lake Okeechobee on Figure 4.19 (and also on Figure 4.2, 4.3, 4.6, 4.7)? Is this the result of some assumed initial condition in head, salinity, or temperature? Perhaps some assumed initial condition within the modeled trough, west of Lake Okeechobee? Is the assumed initial condition the result of one of the above-described, historic, superseded hypotheses? Is the existence of this trough in the pre-development model realistic? Given the importance of comparing pre-development conditions in the Lake Okeechobee region to post ASR conditions, the presence of this trough may considerably affect study conclusions, and conclusions about the impact of the ASR program. The authors may wish to specifically, explicitly, and quantitatively explain why the trough exists within the pre-development model, or alter the model to eliminate the trough.

The reviewer has identified a trough feature that occurs between the 50-foot and 60-foot contours in the modeled predevelopment Upper Floridan head contours in the vicinity of Lake Okeechobee as shown on Figure 4.19 of the Draft Groundwater Model Calibration Report (now Figure 4.30). In addition, the reviewer provided a history of the major contributions to the development of the published Upper Floridan potentiometric surface in south Florida. In the earliest cited publications, Stringfield (1936), Parker and others (1955), Healy (1962), the trough is not shown. Two later publications, Healy (1975) and Johnston et al (1981), show a trough based on additional head data in the Lake Okeechobee area. Bush and Johnston (1988) reanalyzed the data and removed the trough from the 1980 potentiometric surface based on three factors (1) some wells used to delineate the trough were open to depths shallower than the Floridan aquifer or not open exclusively to the Floridan aquifer (2) water level fluctuations at Belle Glade (PB-203) suggest replenishment from the recharge area north of the trough and (3) the higher head water south of Lake Okeechobee has not dissipated over time.

The comparison to the predevelopment heads (Bush and Johnston, 1988) in the Draft Groundwater Model Calibration Report was made by running the calibrated 2004 steady state SEAWAT model without any pumping wells. The head boundary conditions on the surface and aquifer side boundaries represent hydraulic conditions for 2004 (i.e. with drawdown from pumping included). It is possible that because the surface heads defining the recharge represent 2004 conditions rather than predevelopment conditions, less recharge is entering the model and it is not sufficient head to push the flow further to the south in the Upper Floridan aquifer. However, in areas other than the trough area, it was surprising how closely the modeled predevelopment contours matched the Bush and Johnston (1988) contours.

The model initial conditions are independent of the data in any of the publications of the Upper Floridan potentiometric surfaces. The initial head condition for each model cell was set arbitrarily at an elevation higher than the bottom of the SEAWAT grid cell. The initial head conditions affect how quickly the model reaches a solution but does not impact the numerical result. The salinity and temperature initial conditions were based on available total dissolved solid and temperature data to determine the native values for the aquifer. In the figures showing the distribution of the salinity and temperature data for the initial conditions (Figures 3.18 to 3.25 and 3.28 to 3.36), the area west of Lake Okeechobee exhibits salinities and temperatures much higher than the surrounding areas in the MC1 and APPZ layers for salinity and in all layers below the UF for temperature. It is possible that these patterns contribute to the formation of the trough, but not enough information is available for salinity and temperature in predevelopment times to know whether the patterns have existed long-term or have developed more recently.

The model can be altered to remove the trough for predevelopment conditions. One way this can be done is to lower the values of the vertical hydraulic conductivity in the ICU and/or IAS in Glades County. The topography and surface heads in the area along Caloosahatchee River up to Lake Okeechobee are lower than those in the UF so to keep the water from discharging to the surface, a tighter ICU/IAS is necessary. Another way to increase the UF heads is to increase the vertical hydraulic conductivities in the confining units below the UF. Although these changes can yield a predevelopment solution without a trough, the computed UF heads for calibration time periods become too high compared to the observed heads or the hydraulic conductivity values necessary to complete the change are beyond reasonable ranges.

A significant problem in deciding whether or not a trough exists is the lack of head data. Even for 2004 calibration conditions, there are only a few well clusters that could be used to determine the direction of flow and none of them are in Glades County, the area where the trough may exist. The well clusters surrounding Glades County (clockwise starting in the north) are ROMP 28 (UF, APPZ, and LF), OKF-100 (UF and APPZ), PBF-7 (UF and LF), L2 (UF and APPZ), and LAB (UF and APPZ). Of these wells, the UF well furthest north and south, ROMP 28, L2 and PBF-7, have heads higher than 55 ft. The UF wells closer to the border of Glades County, OKF-100

and LAB, have values less than 53 ft indicating a shallow trough like that shown in the model results. Of course, with current conditions, the heads are affected by pumping and may not represent the pattern of the heads in predevelopment conditions.

A study that may provide insight regarding the question of whether the Upper Floridan aquifer in south Florida is recharged from areas north of the lake will be published later this year. The study states that analyses of geochemical data indicates that "most of the Upper Floridan aquifer contains groundwater recharged during the last glacial period" rather than from recently recharged groundwater (Morrissey, S. K., et al., 2010). While evidence to show that the higher head water in the south Florida Upper Floridan aquifer is "relic" water doesn't prove that the trough was always present, it doesn't preclude the presence of a trough.

With the predevelopment trough removed from the model or not, the modeled flow directions that occur in the UF are unchanged. At wells PBF-7 and L2 south of Lake Okeechobee, an upward gradient exists that is replicated in the model. At ROMP 28 in Highlands County, a downward gradient exists that is replicated in the model. The location of the gradient direction change varies based on recharge and pumping conditions. This area is the location where many of the proposed ASR wells are planned. Sensitivity and Monte Carlo analyses will be performed for the with-project scenarios to better define the uncertainty and determine the impact of the CERP ASR program for different aquifer pumping conditions.

2. Paragraph 13: The authors use a statement by Anderson (1992) to suggest that "The judgment of when the fit between model and reality is good enough is a subjective one. To date, there is no standard protocol for evaluating the calibration process…" Anderson made this statement almost 20 years ago in 1992. A considerable volume of work has occurred since 1992, in which standard protocols for evaluating calibration are more quantitative than in 1992. For example, the authors may wish to refer to and incorporate concepts available in the vast literature on parameter estimation, and from parameter estimation codes such as UCODE or PEST. The authors may wish to remove the Anderson quote, abandon the position that calibration is entirely subjective, and provide more quantitative calibration methods and metrics.

A considerable volume of work has, indeed, been published since 1992, and there are numerous statistical measures and analyses that have been put forward in an effort to standardize the calibration of models. However, we continue to support Anderson's opinion that the decision to accept a calibration is primarily a subjective one. This decision must take into account the purpose for which the model is designed as well as the data available and the resolution in both time and space. For example, despite its

calibration metrics, this regional model is not calibrated well enough to provide estimates of well-to-well interactions for ASR wells. With the same calibration statistics, this model is calibrated well enough to provide an estimate of the regional impacts of the CERP ASR program as a whole.

4.1.1 SEAWAT

1. Figures 4.20-4.29: The authors may wish to re-order the figures in stratigraphic order, either from top to bottom, or from bottom to top; and to re-order the figures such that WASH123 and SEAWAT figures are adjacent, for identical layers. The reader can then easily confirm that the same distribution is being used for both models. The authors show orders of magnitude changes in regional horizontal hydraulic conductivities across sharp interfaces, at some locations. For example, south of Lake Okeechobee, in the APPZ for the SEAWAT model, horizontal hydraulic conductivity changes from 5-20 feet per day to 400-600 feet per day across a sharp line near the edge of the lake. The authors may wish to offer geologic justification for such a sharp, regional delineation; or, the authors may wish to introduce a more gradual, continuous transition zone, in which regional hydraulic conductivity changes continuously along a continuous gradient. The authors may wish to use pilot points and an interpolation method such as kriging to define hydrogeologic parameters that vary in space, in a reasonable and defensible fashion. Some sharp-change locations under the proposed conductivity distribution are in regions where ASR will be analyzed by the model. The adopted hydraulic conductivity may affect conclusions drawn from the model. The authors may wish to contour all hydrogeologic parameters with a continuous contour method (such as is used on Figure 5.3), as opposed to the method of bins (used on Figures 4.20-4.29).

Figures 4.20 through 4.29 for the SEAWAT model were ordered according to their descriptions in the text, which discussed the aquifers first. They have been reordered according to their stratigraphic order. The WASH123D model has not been recalibrated for the final report. An appendix has been added to show the similarity of the draft calibrations between the SEAWAT model and the WASH123D model. We prefer to keep the SEAWAT and WASH123D figures separate since they are discussed in different sections of the report.

All of the changes in hydraulic conductivity which occur across sharp interfaces are explained in the report. Section 4.1.2 describes both the location of the change from the ICU to IAS based on Miller (1997) and the location of the change from limestone to dolomite in the APPZ, based on the Framework report (Reese and Richardson, 2008). In addition, a sensitivity analysis was run on the location of the APPZ change and the location of this line was found to be unimportant to the calibration. Since this line runs near some of the proposed ASR locations, some additional sensitivities are planned for the regional ASR runs.

The conductivity fields were developed using pilot points and ordinary kriging. (See Section 4.1.1 and the notes on Figures 4.31 through 4.40)

We avoided using a continuous contour method because of the sharp interfaces in hydraulic conductivity seen in layer 3 (IAS/ICU) and the APPZ. A continuous contour method would have placed a number of very close contour lines across that interface and might have given the impression that the conductivity changed gradually (albeit with a sharp slope). The use of bins in the figures makes clear that a sudden change of several orders of magnitude was used in the model and is consistent with the format of numerous existing studies of the Floridan Aquifer.

4.1.1.2 Calibrated Hydraulic Conductivity Fields

1. Please add the APT data to the calibrated horizontal and vertical hydraulic conductivity fields, and provide a discussion about changes between observed data and simulated values.

APT results have been overlain on the calibration conductivity field figures (see Figures 4.34, 4.36 and 4.38).

2. On page 24, the authors state that the boundary between the aquifer and aquitard was based on Miller (1997). Please explain why Reese and Richardson (2007) were not used. On page 27 and Figure 4.12, the authors discuss and illustrate the vertical gradient for the Alligator Alley well. They indicate that if equivalent fresh water heads were used, the water level actually increases with depth (for the simulated wells).

Reese and Richardson (2008) do not include a figure showing the boundary between the aquifer and aquitard in the IAS/ICU layer.

- The authors should show the observed data on the equivalent freshwater head graph. Will the simulated and observed still match?

Equivalent freshwater head is generally not measured in the field. TDS and temperature data are much sparser than head data. In order to show the "observed data" on this figure (4.18) we would need to use the TDS, temperature and head data to calculate the equivalent freshwater head. This would be the same calculation made on the model calculated data, so this exercise does not appear to be relevant. The purpose of the equivalent freshwater head plot in Figure 4.18 was to clear up any confusion that might result from the observed head plot at left. Readers without a clear understanding of equivalent freshwater head or without a clear knowledge of salinity conditions deep below south Florida may be confused by the apparent downward gradient between the APPZ and the Boulder Zone in the observed head plot. The equivalent freshwater head plot is included and discussed in the text as a reminder to the reader that flow conditions are controlled by the equivalent freshwater head, not

by the observed head. Therefore, the head gradient driving the groundwater flow at the Alligator Alley well is upward from the Boulder Zone to the surface.

- The authors should provide the formula for converting to freshwater equivalent heads

The description of the concept of equivalent freshwater heads and the equation have been moved from Appendix C to a new section (2.1) in the main report.

- The authors should demonstrate the vertical flow under transient conditions by doing wet and dry season graphs.

Wet and dry season (May 2004 and October 2004) results have been plotted together on the vertical gradient plots and included in the analysis of the transient calibration. See Figures 4.100 through 4.110.

- A similar graph for ROMP 86A would be helpful. At this well, the observed and simulated data do not provide a good match.

See the response above. Plotting the equivalent freshwater head involves subjecting both the observed and model calculated heads to the same calculations. Further, since the observed heads at ROMP 86A are shallow and because the groundwater in all layers has low salinity in this area, the calculation would have a minimal effect on the results. The purpose of the equivalent freshwater head plot on Figure 4.18 was not to allow comparison of the calculated and observed heads, but to show that the vertical movement of groundwater is governed by the gradient in the equivalent freshwater heads and not that in the measured heads.

3. Figures 3.1 and 4.20, and Section 4.1.1.2, concerning the horizontal hydraulic conductivity field in the UF: The area of high K along the northwest side of Lake Okeechobee in Glades County (> 120 ft/d) is questionable. The only data point that supports this is the Kissimmee River ASR pilot site, and this site is at the far northeastern extent of this area. Is this level of K in the Suwannee and upper Ocala supported by the new test well in Glades County, BREX-1?

The model is quite insensitive to this area of high K except in the immediate vicinity of pumping wells. Since there are no observation points nearby, this K value does not affect the calibration quality. Because this area is so important to the ASR project, a number of sensitivities are planned for the production runs to ensure that the model can bound the possible outcomes of the CERP ASR program.

BREX-1 was not included in the model because it did not meet the standards specified for the project in several ways:

- ***It was a 'natural flow' test with no applied stress***
- ***It was a single well test. (Other single well tests were used, but they were all applied stress tests conducted using conventional methods)***
- ***The test lasted less than an hour***

4. Figures 3.2 and 4.21, and Section 4.1.1.2, concerning the horizontal hydraulic conductivity field in the APPZ: There are some large areas in Figure 3.2 without data that could be important to the model and to the implementation of ASR. These areas are:

- Southern Glades and northern Hendry Counties

- Southern Osceola and northern Okeechobee Counties

K in the APPZ in these areas could be large, for example, in wells GLF-6 and LAB-TW in the first of these areas. However, these areas are not indicated to have high K in Figure 4.21. Has data been collected in test wells drilled in Okeechobee and Osceola Counties since the preliminary framework study concerning the K of the APPZ in the second of these areas? (If not hydraulic tests data, then maybe indications of high K, such as fracturing indicated on geophysical logs and development of thick zones of dolomite.)

There was no APPZ test run during the construction of LAB-TW. However, LAB-PW2 was re-constructed as part of the Regional study and a test of the APPZ was conducted at that time, resulting in a transmissivity of over 560,000 ft2/d in a 100 foot interval. This test result has been included in the latest calibration of the model.

The GLF-6 test was not used because at a discharge rate of 290 gpm, the test would not have stressed that portion of the aquifer, which has large open fractures.

5. Figures 3.3 and 4.22, and Section 4.1.1.2, concerning the horizontal hydraulic conductivity field in the LF: Similar to the APPZ, could an area of high K in the LF extend from northern Osceola County southward down through Okeechobee County? This is a large data gap area. Has data been collected in test wells drilled in Okeechobee and Osceola Counties since the preliminary framework study concerning the K of the LF in this area? (If not hydraulic tests data, then maybe indications of high K, such as fracturing indicated on geophysical logs and the development of thick zones of dolomite.)

According the SFWMD, the Toho Water Authority has done a single-well test in Osceola County in the LF, but the results have not been released yet.

Northeast of OSF-104, there was a test well called LATMAX_B-6, but it was open to both the UF and APPZ. The open hole was long and there was some semi-confinement in the middle and there are no logs to indicate the locations of permeable zones, so there is no way to parse out hydraulic conductivities from the reported transmissivity value.

We are aware of no other data in this area.

6. Figure 4.22: The area of relatively high K (200 to 300 ft/d) in the LF in Sarasota, southern Manatee, and Desoto Counties is not supported by the data shown in

Figure 3.3. Low K in this area is also indicated by the possible presence of pore-filling evaporate at the depth of the LF.

These conductivities have been reduced in the latest calibration of the model.

7. Figures 3.6 and 4.26, concerning vertical K of LC: The moderate K (0.01 to 0.05) of this unit probably does not extend into the northwestern part of the modeled area (west-central Florida). We would expect very low K in this area because of possible or probable presence of pore-filling evaporate at the depth of the LC in this area.

The conductivities have been reduced in the latest calibration of the model.

8. Observed confinement provided by Lower Floridan confining unit (LC) below the Lower Floridan aquifer (LF1) is generally tight. Reese and Richardson (2007) indicate that this unit provides good confinement in areas where there has been infilling of the pore space with gypsum and anhydrite. The Glauconitic bed can also provide tight confinement in some areas. Maliva and Walker (1998) found in southwestern Florida that unfractured dolomite beds provide the primary confinement. Conductivity of dolomite is as low as 3e-5 ft/day. However, calibrated vertical hydraulic conductivity (Kv) of LC presented in the report is globally around 0.01-0.05 ft/day, which is 100 to 1000 times higher than those measured. High Kv values in LC have significant effects on simulated heads in upper layers due to large equivalent freshwater heads in Boulder Zone (BZ) caused by the depth of the aquifer and the high concentrations assigned in the model. Please provide an explanation as to why the observed Kv values were not used in the model to limit upper flow from the boulder zone which has generally not been observed around the deep well injection sites.

In the northwest part of the model (west-central Florida), the LC vertical conductivities have been reduced. In this area the Boulder Zone is not present and the Lower Floridan conductivities have also been reduced to reflect the possible presence of pore-filling evaporate (see the two previous comments). Because the aquifers above and below the LC layer are not present or not very permeable, the model is not very sensitive to changes in the LC conductivity values in this area.

In the remaining portions of the model, the LC vertical conductivities have also been revised as part of the recalibration. The recalibrated LC conductivities in the southwestern portion of the model are in the range from 0.01 to 0.1 ft/d. This is much higher than the conductivity for dolomite shown in Maliva and Walker (1998). However, it is important to remember that for this model, the LF represents the first permeable zone (LF1) of the Lower Floridan Aquifer and the LC represents all of the permeable and confining units between the LF1 and the BZ. As such, the conductivities in the LC are a composite of all of those layers which are made up dolomite as well as many other materials. For these deep zones, not much is known about their combined permeability or continuity. Any discontinuities created by

fractures or facies changes are represented in the model by a higher vertical conductivity.

It is possible that upward migration at injection sites has not been observed because not enough time has passed for the injected fluid to migrate up through the confining layer(s). A MODPATH analysis of the travel time of a particle from the BZ upward through the LC (Kv=0.1 ft/d) to the LF in the model yielded a value on the order of 5,000 years. The monitoring period since injection began is less than 100 years.

For the above reasons, we have maintained the LC vertical conductivities in the 0.01 to 0.1 ft/d range.

9. Figures 3.10 - layer 22, Figure 3.14, and Figure 4.23, concerning extent of BZ: We don't think the BZ extends into the northwestern part of the modeled area. (See Reese and Richardson, 2008, Figure 24). It does appear to be present in east-central Florida, including Oceola and Orange Counties, but it is probably absent in most of west-central Floridan (north of Charlotte County). Can the northwestern boundary of the layer including the BZ be modified to more correctly reflect the extent of the BZ in this area?

See our response to Comment 3 in Section 2.2. The absence of the BZ in the northwest part of the model is accommodated by making the conductivity close to that of the LF.

10. Figure 4.19, the area of high head doesn't extend far enough to the south. Predevelopment heads in the northern Keys was as high as 40 ft, but the modeled head is 30 ft (or less?).

As described in Section 4.1.4, the predevelopment heads were computed by removing all interior pumping in the model. This allows a close comparison to the figure published by Bush and Johnston in 1988 for areas interior of the model boundaries. Unfortunately, because of the nature of the specified head boundary conditions, any pumping which impacts the boundary cannot be removed. The specified heads along the southern boundary are based on measured head values in the 2003/2004 time period, specifically heads at I75-MZ2, BICY-MZ2 and ENP-100, so no comparison near these boundaries should be made for predevelopment conditions.

11. For Figures 3.12, 3.22, 4.19,and 4.21, and maps of the APPZ, there is a correlation between salinity, temperature, head, and possibly K in the APPZ in an area southwest of the Lake along the Caloosahatchee River Basin in southern Glades and northern Hendry Counties. Salinity and temperature are high in this area, head drops down some (see saddle in axis of area of high head extending southeast into southern Florida on Figure 4.19), and K could be high in this area. Can this correlation be explained by the model? One theory might be that there is increased upwelling of saline water in this area. Also, a map that Emily Richardson and Reese created of the altitude of the base of the brackish-water zone (base of the USDW – water with less than 10,000 mg/L dissolved-solids

concentration) indicates a saddle in this same area. This surface approximates the saltwater interface and the depth of this interface is substantially shallower in this area than to the north or south. This would seem to suggest that the low head in the UF in this area was present even before development (pumping) of the Floridan.

Salinity and temperature fields were interpolated from the available data. Conductivity has been tweaked until the heads matched measured field values. There is likely a correlation between these four parameters, but the model cannot explain it. The time scale of the model does not extend far enough back into the past to determine if the upwelling of saline water caused the other parameters to change. This type of explanation is beyond the scope of this model; the model has not been designed to be able to answer this question.

12. P. 23, bottom sentence, Section 4.1.1.2: The 2:1 ratio for horizontal to vertical K of confining units needs to be referenced and better explained. Did this come from Reese and Richardson, 2004, p. 41? What Reese and Richardson (2004, p.41) are saying is that this 2:1 ratio was derived from comparison of horizontal to vertical K values from core analyses, and this ratio was used to estimate the vertical K values from horizontal K values determined from packer or aquifer test in confining units.

The 2:1 ratio was an average based on core data where both vertical and horizontal permeability was measured. Most of the data came from SWFWMD ROMP wells. A sensitivity of this ratio has been run and a new section (Section 5.6) has been added to the report to describe the results.

13. P. 24, middle second paragraph, Figure 4.20, Concerning the greater thickness of UF due to inclusion of Ocala in the northwest portion of the model area, and the lower K values in this area: In most of west-central Florida, Reese and Richardson did not include the Ocala Limestone in the UF because it was considered to be more of a semiconfining unit (MC1) than part of an aquifer. (See Reese and Richardson, 2008, p. 43 and 46, Middle Confining Unit, and Figure 20).

This statement was a mistake. It has been corrected to state that the UF is a combination of the Hawthorn and Suwannee units.

14. P. 24, bottom paragraph and P. 53: The citation for the USGS report is Reese and Richardson, 2008, not 2007. The report came out in 2008.

Agreed

15. P. 25, 3rd paragraph, concerning vertical K values for confining units: Given the importance of the K values for these units in the model, should more work be done to compile, interpret, and review this data. The data was rather hastily

pulled together and perhaps was not as thoroughly reviewed as it should have been.

The compilation of the database of vertical K values was begun as a pre-PMP task. The main body of work occurred over the period of about a year, ending in 2003, but it continued as more data became available.

It is unclear what has convinced the reviewer that the data was "rather hastily pulled together" and "was not as thoroughly reviewed as it should have been." If this is based on the impression that there is not enough data available, this can be explained by the process which was used to evaluate the available data. Most leakance values available are based on partially penetrating or overly penetrating tests, which would not allow for the determination of a representative leakance value and the data had to be omitted. The preliminary framework report provides extensive detail on the criteria used for these analyses and the reviewers are invited to look there for additional detail.

16. After reviewing the steady state calibration maps, it looks like some possible observation wells are missing. An example may be OSF-66. Also, many injection well sites should have monitor wells which monitor the boulder zone and possible 1 or 2 layers above the Boulder Zone. The authors should verify that all observation wells were included. If a well was omitted, the authors should explain why.

An additional look at the monitoring well database has led to the loosening of the criteria for selecting wells for use in calibration. Previously, the well was required to have at least 90% of its screen in a given aquifer layer in order to be selected. Further analysis determined that because the geology is simplified and interpolated, wells with at least 50% of their open intervals in a single aquifer could be included. This necessarily eliminates some useful wells because of simplifications to the model geology. However, it was important to eliminate any wells which did not provide head data representative of a single aquifer layer and an in-depth study of the conditions at each of the thousands of monitoring wells was impossible given the time schedule and budget and out of the scope of the study.

OSF-66, according to the simplified geology of the model, is open entirely in the MC1 confining unit, and so was not used in the calibration.

A table of all wells in the database and the basis for their inclusion or elimination has been added to the report. (Table 4.1)

4.1.1.4 Comparison of Model Result to Some Published Information

1. P. 29, second paragraph, concerning slight drop in head along the Calooshatchee River computed by the model (Figure 4.19): We question that the lower head in this area is the result of the stage in the Calooshatchee River. How about the alternate explanation provided in 4.1.1.2 regarding increased upwelling of saline water in this area?

Although both mechanisms driving flow in this comment, (1) low surface heads, and (2) high equivalent freshwater heads in the APPZ due to high salinities along the Caloosahatchee River in that unit, act to create an upward gradient in the UF, neither provide a full explanation of the reason for the lower head in the UF along the Caloosahatchee River. The reason for the slight drop in head computed by the model for predevelopment conditions along the Caloosahatchee River is dependent on many uncertain factors. A discussion of this "trough" area and its implications for the with-project conditions modeling is found in the response to Comment 4.1 Figure 4.19 above.

4.1.2 WASH123D Comparison to SEAWAT

4.2 Transient Calibration/Validation

1. Please present the simulated TDS concentrations for the transient model in primary aquifers. Little to no discussion on water quality was presented in the report. The report would benefit from a detailed discussion concerning water quality since the model was developed as a variable density tool.

This model was not meant to be used as a water quality tool. The TDS and temperature data was included only because of its impact on groundwater flow. Further, the calibration period was so short that the final TDS was not appreciably different from the initial TDS, except in areas of injection of freshwater. Figures of the final TDS distribution would look quite similar to the figures of initial TDS distribution, and plots of the changing TDS at individual points would be flat lines. Water quality will be addressed in greater detail using the local-scale models. Text has been added to the report to clarify this.

2. The horizontal hydraulic conductivities in layer 3 (IA/ICU) was not presented and should be added to the report.

The horizontal hydraulic conductivities for layer 3 were presented in Figures 4.28 and 4.31. They are now found in Figure 4.32.

3. Please provide vector plots of cross sections through model domain. At least three cross sections from north to south and three from west to east of model domain should be provided. In addition, a 3-D display of saltwater/freshwater interface in the modeled aquifers would also be helpful.

These plots and figures have been added to the report. The cross-sections with vectors are Figure 4.160 and 4.161. The 3-d display of salinity is found in Figure 3.25.

4. The flux exchanges between primary aquifers, and discharges to Atlantic Ocean and the Gulf of Mexico should be summarized and discussed for such a large regional model.

These statistics have been summarized in Figure 4.163.

5. The model report should have a table listing the calibration statistics (ME, MAE, and RMS for each observation well). Also, the authors should provide these metrics for each layer and for the model in its entirety. In addition, the table should include the correlation coefficient (r) and coefficient of determination (r^2), which quantifies the relationship between the observed and simulated water levels (Triola 1993). These comments also apply to the validation and transient WASH123D analyses.

These statistics have been calculated and are presented on maps in new figures added to the report.

6. Page 33: Regarding figures 4.57 through 4.77, what is the output frequency for the model calculated heads? The red squares (symbol for heads) occur more frequently than monthly (stress period length) and seem to vary from well to well.

The output frequency for the model calculated heads is approximately every 5 days. The actual frequency varies from month to month based on the number of days in the month. However, there is no variance in frequency from well to well. It is unclear what wells the reviewer feels have more or less output than others. Additional text has been added to clarify that the output timesteps for observation points are the same as the timestep length.

7. An examination of figures 4.57 through 4.77 indicates that at times there is very little correlation between the observed and simulated data. Some examples are given below:

FIGURE	WELL NAME	PERIOD (M/YR)
4.63	ROMP 39 SWNN	3/2004 – 6/2004
4.64	SARASOTA WELL 9	3/2004 – 7/2004
4.66	ROMP 12 MID UP FLDN	3/2004 – 8/2004
4.74	ROMP 13 AVPK	3/2004 – 9/2004
4.76	PBF-12	3/2004 – 11/2004

Some of the listed wells do represent the poorest locations in the calibration. However, as mentioned in the report, the model stress periods are too coarse to be able to match

the steep drop in head and sudden recovery which occurred in almost all wells during the first week of June 2004. This is the case for both ROMP 39 and ROMP 13.

ROMP 12 and the Sarasota well are examples of locations where the model was unable to exactly match the field measured data, likely because of errors in the pumping estimates or over simplifications of the geology in this area.

We feel that the calibration at PBF-12 is reasonable. With the exception of November 2003, the seasonal changes are reproduced by the model (e.g. the head drop from December 2003 to June 2004 is about 1.5 feet; the head rise from June 2004 to October 2004 is nearly 2 feet). On average the model is over-predicting the heads by only about 0.5 feet.

See Section 4.2.2 for an analysis of the transient calibration in each region of the model.

8. Figures 4.76 and 4.121: Well OSF-98 was included for the steady state calibration but not for the transient calibration. Since data is available for this well, it should be included.

This was an oversight that has been corrected.

9. A review of the water levels from the various simulations for the boulder zone suggests an extremely high water level in Polk County with heads similar to the overlying aquifers. Is there evidence that supports this?

There is no direct evidence to support the high heads on the boundary in Polk County in the BZ. There are, however, a number of minor lines of evidence which were the basis for setting the heads as explained in the report. First, there are a number of wells in Orange County (mostly Cocoa USGS wells and OR wells) which showed a similarity in heads among the BZ, LF and UF. These wells were used in the interpolation of the boundary condition and are marked with red diamonds on Figure 3.17. Next, the TDS data in the BZ in Polk County is generally much fresher than in other areas of the layer. This is only based on 2 or 3 measured TDS data points, but led us to the conclusion that the recharge in Polk County must be impacting the BZ and therefore, be in close connection.

Finally, the assumption seems valid since there is a single observation point from the BZ in Polk County, USGS Core Hole 2 at Polk City. This well does not have very much data and there are no head measurements available for either February 2004 or October 2003, but a measurement in September 2003 indicates a head of 127 ft. The model closely reproduces this head in the October model (see Figure 4.11). Although this cannot be a strong calibration point because of the lack of data at the time of interest, it does indicate that the heads in Polk County in the BZ are being predicted at levels similar to what would be expected in the field.

10. The use of the constant heads for the Surficial Aquifer System (SAS) raises some issues. Although this approach is acceptable for the southern portion of the model where the Hawthorn Group is thick and provides sufficient confinement, this is not the case in the northern portion of the model. The Upper Floridan in the northern portion of the model acts in a semi-confined nature with the SAS and seasonal trends in these two aquifers generally follow each other due to the high connection between them. Water levels in the SAS may change several feet during the year. Without this seasonal representation in the model for the transient simulations, the degree of calibration of the northern wells needs to be tempered.

The specified heads applied to the SAS were transient – they were reinterpolated for each month of the calibration and validation periods. Text has been added to the report in several sections to clarify this.

11. Some of the calibration wells appear to have a series of flat lines for each month. Please provide an explanation as to why this is occurring.

The flat lines indicate that the combination of stress changes, hydraulic conductivity and specific storage allow the model to reach an equilibrium condition at this well very quickly within some or all of the stress periods. The model cannot be expected to match daily head changes at the observation wells when it is designed with monthly stress periods. The PDT was part of the decision to use such coarse time discretization and they are aware of the impact to the model results.

Note that wells located near a boundary often show these flat lines because the boundary effect is felt so quickly.

12. The authors should discuss the volumetric flows from the calibrated model:

- Please provide documentation and graphics for the mass balance and percent discrepancy. Discuss any anomalies that you notice.

- Did all of the stress periods reach closure? If not, please discuss.

This information is presented in Tables 4.3 and 4.4.

13. Figures 4.57-4.77, and 4.86-4.122: The authors may wish to include mean error, mean absolute error, root mean square error, and/or the Nash-Sutcliff model efficiency coefficient for each time series. The authors may wish to provide contour plots of mean error, mean absolute error, root mean square error, and/or the Nash-Sutcliff model efficiency coefficient. These contour plots will allow the reader to judge where the model is more effective in replicating observation, and where the model is less effective. The authors may wish to develop tables of error metrics, for both the steady state and transient models. The authors may wish to

offer conclusions about the quality of the calibration, using quantitative metrics to support each conclusion.

These statistics are now presented on additional maps and tables in the calibration section (Section 4.0) of the report. We disagree with the method of contouring error since there can be no guarantee that the error between observation wells is related to the error at the wells themselves. The maps are provided with colored dots for each observation point (Figures 4.95 through 4.99).

5.0 Sensitivity Simulations

1. Regarding the Sensitivity Analysis, to the extent possible, the authors should follow the ASTM guidelines for conducting a Sensitivity Analysis (ASTM D5611)

The ASTM guidelines indicate that input parameters should be varied to determine the effects of that variation on both the calibration of the model and the question for which the model was designed. The Sensitivity section of this report (Section 5) discusses the first half of that direction (determination of the sensitivity of the calibration to each of the input parameters). The second half of the guidelines (determination of the sensitivity of the impact of the CERP ASR wells on the regional groundwater system) will be included in the next report, discussing the production ASR runs.

2. Regarding the Porosity and Dispersion/Diffusion, it would be beneficial to see the sensitivity results either in tables or as figures. According to the authors, some areas changed as much as 15 ft.

With so many model layers and so many timesteps, it is difficult to show the sensitivity results in figures without greatly multiplying the number of figures in the report. Figures are reserved for those sensitivity analyses that showed an impact on the model. An effort has been made to provide figures, tables, or a detailed analysis of the results so that readers can draw their own conclusions about the sensitivities or each parameter.

3. Figure 5.5 is difficult to analyze. The authors may wish to expand the size of the graphs to make them clearer.

This analysis was deemed unimportant since the north boundary head has been analyzed with a sensitivity analysis. This figure has been removed.

5.5 Boulder Zone Salinity

1. P. 41. We would agree that interior salinity values for the BZ can be higher than ocean values because of long-term buildup of dissolved solids (mineralization of the water). We also think that the salinity at the outcrop points should be about the same as the salinity of seawater (TDS of 35,000 to 36,000 mg/L). In southeastern

Florida (Miami-Dade and Broward Counties) eight samples of water from the BZ had an average TDS of 37,000 mg/L, but the TDS in the Lower Floridan was as high as 40,000 mg/L (Reese, WRIR 94-4010, 1994, p. 40).

The TDS at all ocean outcrops (including the BZ) has been set to 35,000 mg/l. As discussed in the response to comment 3.4.1.1 the model has been recalibrated based on this revision. The TDS distribution within the model domain was based on a variety of data sources, including the referenced report.

6.0 Sources of Uncertainty

1. The report states that the principle error in the model is the pumpage data limitations. The authors may want to rephrase this to the principle stress error in the model is due to the lack of aquifer parameter knowledge throughout the model domain and the uncertainty within each aquifer especially at depth.

We continue to believe that pumping data represents the principal error in the model. It is true that the lack of aquifer knowledge in some areas of the domain, especially at depth, is an important data gap, but this data could be estimated through calibration if other parameters (primarily pumping) were better known. Pumping exerts an enormous effect on the groundwater conditions in south Florida and is quite difficult to obtain.

2. The Floridan aquifer is a karst aquifer, with large solution holes and caverns. However, the SEAWAT and WASH123D models are essentially porous media models. Is it justified to use this type of model when attempting to look at transport phenomena in the Floridan aquifer? Could the conduit flow model developed by the USGS be worth looking into for future ASR modeling? Shoemaker, W.B., Kuniansky, E.L., Birk, S., Bauer, S., and Swain, E.D., 2008, Documentation of a Conduit Flow Process (CFP) for MODFLOW-2005: U.S. Geological Survey Techniques and Methods, Book 6, Chapter A24, 50 p. - http://pubs.usgs.gov/tm/tm6a24/

The selection of the modeling code was outlined in the Benchscale Report (Brown, et al 2006). The IMC had the opportunity to comment on that analysis at that time. Perhaps the use of conduit modeling could be considered in the future, but it is outside the scope of the current modeling project.

7.0 Conclusions/Recommendations

1. Paragraph 2: The authors state that "the calibrated regional models do an excellent job reproducing the FAS flow system." The authors may wish to replace the qualitative "excellent" description with a number of quantitative measures that describe the degree to which model predictions match observations. This is particularly important given that the objective of the report is to describe model calibration. The conclusion should be more scientific than "excellent".

For example, as is detailed above, the authors may wish to provide contour plots of mean error, mean absolute error, root mean square error, and/or the Nash-Sutcliff model efficiency coefficient. These contour plots will allow the reader to judge where the model is more effective in replicating observation, and where the model is less effective.

Quantitative measures of the calibration quality are provided in Section 4.1 and 4.2. The reader is directed to these section and the accompanying tables and figures to draw their own conclusion about the calibration. In the Conclusion section of the report, a quick overview of the results and conclusions drawn during the report is presented. A qualitative analysis is appropriate here.

2. Paragraph 5: The authors state that the "calibrated model not only calibrates to steady state snap shots of the aquifers, but also reasonably replicates the observed flow dynamics in the FAS as the aquifers respond to a variety of stresses." The authors do not discuss, or provide figures or illustrations, that detail flow dynamics. For example, the authors do not provide plots of transient velocity, with vectors. The authors do not detail dynamic flow observations, to which model results could be compared to draw the conclusion. Where do the authors make a comparison of modeled and observed flow dynamics? The authors may wish to substantiate this conclusion with technical model data and observations of flow dynamics, or abandon the claim that flow dynamics are replicated.

This was an unfortunate choice of words. The intent of the sentence was to indicate that the model calibrated well to both steady state and transient conditions. The phrase "flow dynamics" has been removed from the revised sentence.

Editorial Comments

0.0 Executive Summary

1. Paragraph 1: The authors should use quotation marks to identify the following verbatim quote from 114 STAT. 2687 TITLE VI SEC 601 Paragraph (h)(1): "is the restoration, preservation, and protection of the South Florida Ecosystem while providing for other water-related needs of the region, including water supply and flood protection."

Fixed.

2. Paragraph 1: The authors should note that ecosystem is capitalized in TITLE VI.

Fixed.

3. Paragraph 1: The authors may wish to use a verb other than "help".

This sentence was revised in the process of rewriting the Executive Summary

4. Paragraph 1: The authors should replace "of CERP ASR program" with "of the CERP ASR program".

Fixed.

5. Paragraph 2: The authors use an entire paragraph in a three paragraph Executive Summary to describe planned content of another report---a future report. The authors should focus the Executive Summary on the present report.

The Executive Summary has been rewritten and expanded.

6. Paragraph 2: The authors should consistently refer to "the CERP ASR program", in place of "CERP ASR" (at two locations in Paragraph 2 and at other locations within the document).

Fixed

7. Paragraph 2 Line 7: The authors should strike "an".

Fixed.

8. Paragraph 2 Line 8: The authors should consistently identify "analyses" (from Line 7) or "analysis" (from Line 8).

Fixed.

9. Paragraph 3: The authors should consistently identify "performance goals" (this paragraph) or "performance objectives" (previous paragraph); OR clearly differentiate the difference between performance goals and performance objectives.

The phrases "performance goals" and "performance objectives" are used interchangeably in this report. However, during the rewriting of the Executive Summary, the term "performance goals" has been removed.

10. Paragraph 3: The authors defined and used the acronym PDT in the previous paragraph. The authors should use the acronym PDT here, as the acronym is defined and was used in the previous paragraph.

Fixed.

1.0 Introduction

1. Paragraph 1: The authors should eliminate passive voice throughout the document.

We do not feel that passive voice should be entirely eliminated, especially in a technical report. We have made an effort to provide variety of sentence structure while maintaining grammatical accuracy. The inclusion of passive voice is useful for emphasizing results and eliminating first person subjects, as is common in technical writing.

2. Paragraph 1: The authors should consistently identify "the CERP ASR program" (from Executive Summary) or "the CERP ASR system" (this paragraph) throughout the document.

Fixed

3. Paragraph 2: The authors should use a verb other than "help".

Please see our response to Comment #3 in the Executive Summary section above.

4. Paragraph 2: The authors state, “Figure 1.1 shows the study area and Figure 1.2 shows the approximate location of the proposed ASR well clusters envisioned in the CERP”. However, Figures 1.1 and Figure 1.2 do not cover the same area. Moreover, Figure 1.1 is not labeled as the site map and does not include the SFWMD boundary. The authors should clarify.

We do not see any reason that the two figures should cover the same area. Each has a separate purpose. Figure 1.1 shows all of the place names mentioned in the report so that any reader unfamiliar with Florida geography can find the location of a city, county or water body mentioned in the text. Since the text does not discuss the boundary of the SFWMD and does not use this boundary to direct readers to any location, there is no need to include this boundary on Figure 1.1. Figure 1.2 is a map of the propose ASR well locations.

5. Caloosahatchee River is misspelled.

Fixed

2.2 Model Extent and Spatial Discretization

1. Paragraph 2 Line 5: The authors should refer to the Florida peninsula, as is done in Paragraph 2 on Line 8.

Fixed

2. Paragraph 6: The authors may wish to clarify whether "budgets" refers to project funds or water budgets.

Fixed

3.0 Conceptual Model

1. Paragraph 1: The authors may wish to rephrase as "(represented by total dissolved solids [TDS])."

Fixed

2. Paragraph 2: The authors may wish to rephrase as "have greatest effect on groundwater flow and constituent transport."

We see no reason to change this sentence.

3.2.1 Regional Geology

1. Paragraph 2: The authors may wish to refer to the Upper Floridan aquifer and Lower Floridan

The cited paragraph refers to both the Upper Floridan and Lower Floridan as written.

Appendix

1. The appendices are very long (217 pages). A table of contents would be helpful.

A list of appendices has been added to the end of the table of contents. To aid readers, the appendices will be provided in separate pdf files and the pdf files have been set up with bookmarks.

Acronyms

1. The acronym IMC is used for Interagency Modeling Center not Interagency Modeling Commission.

Fixed.

Conclusion

The models may need to be revised if the review comments stated above are taken into consideration. The models are acceptable products that could be improved with the suggestions provided. There is also a need to demonstrate how the rock fracturing potential resulting from increased pressures in the FAS during ASR injection would be addressed. It is not clear from the report how the rock fracturing potential was used to guide model construction and calibration.

Rock fracturing potential will be addressed using an analysis from Nicholas Geibel completed in 2010. His report will be available with the final TDR. The analysis provides a head threshold that should not be exceeded for each ASR well location. The

Appendix H: IMC Comments to Final Report With Responses

Comments on the Final Groundwater Model Calibration Report, Aquifer Storage and Recovery Regional Model Study were provided to the groundwater team at the Philadelphia District, USACE from the IMC reviewers via an email from Mr. Larry Stout, P.E., Chief, Interagency Modeling Section, Water Resources Engineering Branch, Jacksonville District, USACE on December 14, 2010. This appendix contains the text of the email and responses to each comment. The groundwater team would like to thank the IMC for their comprehensive review.

The original text of the IMC email is provided as black text, while the responses to comments are provided as red, italic text.

Thank you for providing the Final Groundwater Model Calibration Report for the ASR Regional Study. The IMC team has reviewed the revised report, and want to commend the authors for their excellent work in addressing the large volume of comments provided by the review team. The text is efficient and the figures are informative. After reviewing the Final report, the IMC review team continues to have the following consensus concerns:

1. With respect to the response to Item Number 4, which begins on Page 10 of Appendix G: the model should reach a quasi-steady equilibrium with respect to TDS, temperature, and head, prior to the beginning of the calibration or verification period. A quasi-steady state is defined as an equilibrium, in which any oscillation of TDS, temperature, and/or head is about some mean value, and the mean value does not change or trend as a function of time. A spin-up period that converges on a quasi-steady state is necessary for conclusions developed with the model to be meaningful and defensible.

We continue to believe that the TDS, temperature and head are not currently in a steady state or quasi-steady state condition and that no benefit would be provided to the model by including a spin-up time. Indications of the likely results of a long spin-up time or short spin-up time are provided by model tests performed during Phase 1 and, more recently, in preparation for the "with project" conditions model.

A long spin-up period would lead to significantly increased TDS concentrations and decreased heads compared to those observed today. These results were found during the Phase I model runs where total run lengths of 10,000 to 35,000 years were tested and the Floridan aquifers became significantly saltier south of Lake Okeechobee. Using these TDS values, which are much higher than those currently observed, as initial conditions would not provide reasonable model results.

Recently, an additional model run has been completed with a total run length of 13-years. This run was used to test the boundary conditions for the future "with-project" regional model but without the proposed ASR wells. No appreciable change in TDS occurred during the 13-year timeframe indicating that a short term spin-up would have no impact on the model results.

2. With respect to the response that begins on Page 27: authors state that the "head boundary conditions on the surface and aquifer side boundaries represent hydraulic conditions for 2004 (i.e. with drawdown from pumping included). It is possible that because the surface heads defining the recharge represent 2004 conditions rather than predevelopment conditions, less recharge is entering the model and it is not sufficient head to push the flow further to the south in the Upper Floridan aquifer." Authors may wish to construct a head boundary condition that initially represents a pre-development condition, and then employ a transient boundary condition that changes to reflect historic development. Authors may, for example, defensibly adopt one of the older head distributions cited in the comment as pre-development---such as Stringfield (1936), Parker and others (1955), or Healy (1962). Some of these head distributions were based on extensive data collection campaigns. A defensible initial boundary condition that changes with historic development is necessary for conclusions developed with the model to be meaningful and defensible.

The construction of a head boundary condition based on previous studies would be difficult, time-consuming, and too inaccurate to provide a defensible boundary condition. The calibration model head boundary condition includes side boundaries for each of the major aquifers identified in Reese and Richardson (2008) – the Upper Floridan, the Avon Park Permeable Zone, the Lower Floridan, and the Boulder Zone. Many of the older publications report head data as a potentiometric surface of the Floridan Aquifer as a whole and additional research would need to be undertaken to determine if the actual data is available and to correlate the data to the Regional ASR model aquifers. Also, the main driver to potentially push additional recharge into the trough area near Lake Okeechobee would be high heads in the Surficial Aquifer. The older publications focused on the Floridan Aquifer and artesian heads rather than the Surficial Aquifer heads. Developing a pre-development boundary condition would involve a large amount of guesswork and would not add much value to the modeling effort.

3. With respect to the response that begins on Page 27: the stated objective of the model is to evaluate a number of ASR related issues near Lake Okeechobee. The model predicts that a trough area will exist near Lake Okeechobee: an area of relatively higher head south of Lake Okeechobee is separated from areas of relatively higher head north of Lake Okeechobee by a depression or trough in head contours near Lake Okeechobee. Authors state that "in areas other than the trough area, it was surprising how closely the modeled predevelopment contours matched the Bush and Johnston (1988) contours." It is also necessary to have a clear understanding of the trough area, and this does not currently exist. A head distribution that is supported by observation data within the area of interest near Lake Okeechobee is necessary for conclusions developed with the model within the area of interest---near Lake Okeechobee---to be meaningful and defensible.

The head distribution provided by the calibration model results is supported by the observation data within the area of interest near Lake Okeechobee for the steady state

calibration time periods of February 2004 and October 2003 and the transient time period from October 2003 to December 2004. Thus, the model conclusions are meaningful and defensible. When comparing the model results representing pre-development conditions to the pre-development heads, the model predicts the pre-development heads closely except that the model shows a depression in the Upper Floridan head contours (i.e. a trough) west of Lake Okeechobee, whereas the estimated pre-development contours do not show a trough. No pre-development observation data exists in the area to determine whether the trough existed during pre-development conditions.

Our purpose in comparing the model results to the pre-development heads was simply to show an additional line of evidence for the accuracy of the model – the fact that the model produces results similar to other published work. The pre-development conditions results will not be used for any of the production runs as the project continues. The calibrated model runs that do match observed data in the area near Lake Okeechobee will be used as the base to construct the "with project" conditions model. Uncertainties in the trough area will be evaluated using sensitivity analyses.

It is the consensus opinion of the IMC Review Team to recommend that the authors take one of the following actions: (a) address the limitations associated with these concerns, with additional analyses, data collection, and appropriate revision to both the model and the report; or (b) prominently acknowledge the limitations associated with these concerns in both the Executive Summary and in Section 7 Conclusions/Recommendations. Acknowledgement of all three concerns may take the following efficient and concise form:

> The model has limitations, which include but are not limited to the following: (1) The model did not achieve a quasi-steady state---with respect to TDS, temperature, and head distributions---prior to the beginning of the calibration period. (2) The boundary condition on the surface and sides of the domain is fixed and represents 2004. Transience that deviates from 2004 may exist on the boundary. (3) The model predicts a trough in the head distribution north and west of Lake Okeechobee. Insufficient data exists in this area to determine whether the trough actually exists. The model may underestimate head in the trough area by as much as 15 feet, with respect to published potentiometric surfaces for the area.

The following sentences have been added to the Executive Summary. "The Interagency Modeling Center (IMC) has reviewed this study and their comments on the draft report are listed in Appendix G with responses from the modeling team. While the modeling team addressed most of their comments with additional analyses or text, there are some differences of opinion between the two groups. The IMC comments on the final report and the modeler responses are provided in Appendix H and illustrate the two sides of each issue."

In addition to the above, the IMC recommends that Appendix G be modified as follows:

4. The following statement is made at the top of Page 21 of Appendix G: "These figures may not be directly quoted or referenced by others, or identified as a personal communication. The information may be useful to the authors in answering specific questions concerning TDS distributions based on Reese (1994)." IMC recommends that the referenced figures be removed from Appendix G. The information was provided to the authors, to assist the authors in addressing specific concerns related to the TDS distribution. The information was not intended for publication by the USACE.

The figures provided in the comments from the IMC have been removed from Appendix G.

5. The following statement is made on Page 23 of Appendix G: "The following text may not be directly quoted or referenced by others, or identified as a personal communication. However, the information may be useful to the authors in answering specific questions concerning historic potentiometric surface delineations." IMC recommends that the referenced text be removed from Appendix G. The information was provided to the authors, to assist the authors in addressing specific concerns related to the saddle feature near Lake Okeechobee. The information was not intended for publication by the USACE.

The referenced text provided in the comments from the IMC has been removed from Appendix G.

In conclusion, it is the opinion of the IMC review team that the authors did a commendable job in developing the referenced model. The hydrogeology of this area is quite complex. The report is clearly written and informative.

EXECUTIVE SUMMARY

This report details the use of a calibrated regional model to analyze the effects of the proposed Comprehensive Everglades Restoration Plan (CERP) Aquifer Storage and Recovery (ASR) system, consisting of 333 ASR wells with the potential to inject or extract 5 mgd each. The model indicated that this number of wells was too large for the established performance measures and instead, recommended a smaller system consisting of 94 ASR wells in the Upper Floridan (UF) Aquifer, 37 wells in the Avon Park Permeable Zone (APPZ), and 101 wells in the Boulder Zone (BZ). Wells in the BZ would have 10 mgd capacity. While this design meets the requirements for pump pressure and protection of the artesian pressure in St. Lucie and Martin Counties, the head impacts of the system are significant and widespread. Further, although the system can support the full amount of recharge envisioned by the CERP, there will be a significant reduction in the recovery potential of the system. A second design recommendation was also presented which removed the BZ wells which would be expensive to install and have little possibility of recovering stored water.

A Monte Carlo analysis was used to investigate the uncertainty in the model results. It concluded that a few sites may need to have a slight reduction in the number of ASR wells in order to meet the pump pressure requirements, but there is very little uncertainty in the ability to protect the artesian pressure in St. Lucie and Martin Counties or in the widespread nature of drawdown and "drawup" impacts from the proposed ASR system.

It is recommended that additional study in the form of field pilot studies and local scale modeling at the proposed sites be used to confirm the assumptions from this model and reduce the uncertainty in the results.

1 INTRODUCTION

The U.S. Army Corps of Engineers (USACE), Philadelphia District (NAP), has prepared this report for the USACE, Jacksonville District (SAJ), and the South Florida Water Management District (SFWMD) in support of the CERP. This report documents the evaluation of CERP ASR scenarios using the regional groundwater model. It is the final installment of a series of four documents describing the multi-phased modeling approach undertaken to evaluate the proposed CERP ASR system. The four documents are:

- ASR Regional Study – Benchscale Modeling (Brown, et al, 2006). This report evaluated several model code options and concluded with the selection of WASH123D and SEAWAT as the best-suited to the ASR regional evaluation.
- Draft ASR Regional Study Phase I – Groundwater Modeling (NAP, 2006). This report described the first phase of the model development, including identification of boundaries and regional flow and salt migration pathways; evaluation of model run times and sensitivity to time step sizes; testing of boundary parameters and the sensitivity of hydraulic and transport parameters; and a comparison of results from WASH123D and SEAWAT.
- Final Groundwater Model Calibration Report, Aquifer Storage and Recovery Regional Modeling Study (NAP, 2011). This document presents the model setup, boundary condition development and calibration for the regional model, which is the basis of the model evaluation of the CERP ASR plan.
- Regional Model Production Scenario Report (this report). This document describes the evaluation of the CERP ASR plan against regional performance objectives including rock fracture potential, pump pressures, and impacts to nearby wells. The evaluations were performed on the calibrated regional model with the addition of the ASR wells described in the South Florida Water Management Model (SFWMM), D13R scenario (SFWMD and USACE, 1999). The number of ASR wells was reduced in order to meet the performance objectives and the final design was subjected to a Monte Carlo sensitivity analysis.

In addition to these modeling reports, an evaluation of the effects of various hydrogeologic theories on groundwater flow in South Florida was presented in the conference paper “Using Density-Dependent Numerical Models to Evaluate Regional Groundwater Flow Patterns in South Florida” (Bittner et al, 2008). This study was also preceded and is supported by “Groundwater Numerical Model Development Support and Data Collection Report” (CH2MHill, 2005).

Simultaneously with work on the regional model, significant effort has been expended developing local-scale SEAWAT models of pilot study sites at Kissimmee River and Hillsboro (Site 1) which have been running since January 2009 and January 2010, respectively. These models were built to investigate near field effects of the ASR wells which cannot be suitably studied on a large, regional scale model. The original plans called for inclusion of the local scale modeling work in this report. However, further discussions among members of the Project Delivery Team (PDT) have determined that this modeling

information would be better suited for the Pilot Study Technical Data Report (TDR) developed by SAJ, which is currently in review.

ASR is one of the alternatives proposed by the CERP to provide fresh water storage in South Florida. The CERP recommends the installation of 333 ASR wells open in the Floridan Aquifer System (FAS) and distributed over a large region with well field clusters near Lake Okeechobee, along the Caloosahatchee River, and at several locations along existing canals in the Lower East Coast Region (Palm Beach and Broward Counties). Figure 1.1 shows the approximate location of the proposed ASR well clusters envisioned in the CERP. The proposed plan, with total recharge and recovery pumping rates of approximately 1.65 billion gallons per day, may be larger than any currently operating ASR project (SFWMD and USACE, 2008). To evaluate the numerous design considerations and the variation in aquifer response on regional, sub-regional, and local scales, density-dependent numerical modeling of the FAS was required as discussed in the ASR Regional Study Project Management Plan (SAJ and SFWMD, 2003).

The focus of this report is the application of the previously calibrated model to answer a variety of questions about the impacts of the CERP ASR system on a regional scale. This report begins with a description of the conversion of the calibration model to allow investigation of the regional impacts of the full CERP ASR system. The CERP design was then scaled back in a series of scenarios until the impacts were within the requirements of a set of performance measures. These performance measures included rock fracture potential, pump pressure, impacts to neighboring users (artesian pressure protection, maximum drawdown, and water quality migration), and the ability to provide the storage and recovery volumes designated in D13R. During the process of scaling back the CERP design, wells were removed and some were added to other aquifers, including the APPZ and the BZ. The final scenario was then subjected to a robust Monte Carlo sensitivity analysis.

1.1 Acknowledgements

This report is part of a study prepared for and in cooperation with the SAJ and SFWMD. Thanks are given to the USACE Engineering Research and Development Center (ERDC) and the United States Geological Survey (USGS) for their cooperation, modeling code development assistance, and technical guidance during this study. Special thanks to the IMC (Interagency Modeling Center) for their cooperation in the review of the various phases of this study.

2 MODEL SETUP

The regional impact of the proposed CERP ASR system was evaluated by applying the storage and recovery rates from the November 1998 D13R simulation on the South Florida Water Management Model (USACE and SFWMD, 1999) to the regional ASR study model described in NAP, 2011. The November 1998 D13R simulation on the SFWMM is the "official" simulation recognized by the IMC and constituted the correction of a few errors found in the CERP Yellow Book document (personal communication, Dan Crawford, SAJ).

After first running the model with the CERP ASR design, the plan was scaled back until limits on the performance measures were met. These performance measures were developed by the Project Delivery Team (PDT). During the process, additional changes were made to the plan based on requests from and discussions with the PDT.

For clarity, some discussion of model names is necessary. 'D13R' refers to the run on either model, which incorporates a set of ASR wells into the area surrounding Lake Okeechobee and extending to the Lower East Coast. This report refers to the implementation of the D13R scenario on two models: The South Florida Water Management Model (SFWMM) and the Regional ASR Study Model (RASRSM). Table 2.1 lists some important information about each of the models.

The SFWMM is a regional-scale, physically-based model which combines hydrology and water management practices in southern Florida. Its development began at SFWMD in the 1970s and it has been through several major revisions in the last 4 decades. Although the SFWMM includes a groundwater component, it looks only at surficial, unconfined flows and it addresses them as 2d, vertically averaged flow. ASR wells are incorporated as reservoirs without the evapotranspiration losses. The model simply keeps track of the volumes of injected water (removed from the modeled system), applies a 70% recovery efficiency and tracks the volume of the bubble (net accumulation of excess water injected). Recovered water is limited to the volume of the bubble. The SFWMM is only able to look at the impacts of the ASR system on the water demands in the surface system. ASR wells are included as an additional management option for removal of excess water or supplementation during periods of water deficiency (SFWMD, 2005). The SFWMM is not able to look at regional-scale hydrogeologic impacts of the ASR wells in the FAS. The RASRSM was developed to investigate these hydrogeologic impacts which the SFWMM was not able to examine.

The SFWMM-D13R included CERP and non-CERP projects and determined the volumes of water that would need to be removed or restored by ASR wells in six different basins. The maximum required rate turned out to be 1.65 billion gallons per day. Assuming that all wells are sized to be able to pump 5 mgd, 333 ASR wells would be required to meet that maximum rate.

The PDT for the Regional ASR Study selected a number of property sites near water sources and divided the 333 ASR wells among the sites. The RASRSM-D13R adds the ASR wells to the selected sites and then investigates the regional hydrogeologic impacts of these wells. The 'calibration model' referenced in

this report is the RASRSM before the addition of the ASR wells, when it was calibrated to field data from 2003 and 2004. The setup and calibration of that model are outlined in NAP, 2011.

The RASRSM-D13R model was built using the same computational grid and geologic layering as the calibration (RASRSM) model. Horizontally, the model extended from Orlando to the Everglades and from the west coast of the Floridan peninsula to the bench outcrop of each unit in the Atlantic Ocean. Vertically, the model extended from the ground surface to the base of the Boulder Zone (BZ) and included the following hydrogeologic units:

- Surficial Aquifer System (SAS) – a combination of all units above and including the Hawthorn unit
- Intermediate Aquifer System (IAS) – a combination of the intermediate aquifer and the intermediate confining unit (ICU)
- Upper Floridan Aquifer (UF)
- Middle Confining Unit 1 (MC1)
- Avon Park Permeable Zone (APPZ)
- Middle Confining Unit 2 (MC2)
- Lower Floridan Aquifer (LF)
- Lower Confining Unit (LC)
- Boulder Zone (BZ)

See the Calibration Report (NAP, 2011) for additional information on the extent of the model domain, these hydrogeologic units and their properties.

2.1 BASINS

SAJ provided the daily volumes of recharge and recovery at ASR wells from the SFWMM-D13R scenario for each of 6 basins: Lake Okeechobee, Caloosahatchee River, L-8, C-51, Central Palm Beach, and Hillsboro. The number of wells required in each basin was determined by dividing the maximum flow rate by the expected individual well capacity of 5 mgd. See Figure 1.1 for the general locations of these basins and numbers of required wells. Based on discussions with the ASR Regional Study PDT, a total of 16 sites were selected for the installation of ASR wells. The L-8, C-51, Central Palm Beach and Hillsboro basins each have only one possible site for ASR wells. The Caloosahatchee River Basin has three sites and the Lake Okeechobee Basin has nine.

The wells in each basin were divided among the available sites based roughly on the perimeter length of the sites. As will be described in Section 4, as additional scenarios were developed, the numbers of wells at each site changed from the original design. Well locations were sometimes altered slightly since SEAWAT only allows the placement of wells in the centers of computational cells. At each proposed site, ASR cells were selected to be as far apart as possible given the property size, number of wells and cell

sizes in order to minimize well-to-well interaction as much as possible. It was occasionally necessary to place two wells in the same cell by doubling the pump rate.

2.2 Choice of Time Period

The SFWMM-D13R scenario covered the 30-year period from 1965 to 1995. File size limitations and run times make it difficult to run the RASRSM for such a long period of time. The input and output files for a single 30-year RASRSM-D13R run required nearly 52 GB of storage space and the run-time was between 18 and 30 hours depending on the machine used and the number of processes being run simultaneously. In addition, some of the input files were too large for the allocation of memory for the file buffer. This problem was solved by dividing the RASRASM-D13R run into separate chunks of 38-40 months, each successive chunk being hot-started from the final solution of the previous chunk. In order to address the problems of run-times and space requirements, additional computer resources were acquired and the decision was made to run a shorter section of the D13R period.

Since recharge flows (injection) greatly exceed recovery flows (extraction) at most of the sites for most of the 30-year period, the D13R plan indicates a gradual build-up of freshwater in the aquifers. (Figures 2.1 through 2.6 show the recharge and recovery rates and available aquifer storage at each basin.) The year 1965 was selected as the start time for the regional model run so that the starting condition would not be impacted by previous injection periods. The year 1977 was selected as the end time for the regional model run to include periods covered by SAJ Lake Okeechobee models and to incorporate the entire first cycle of the Lake Okeechobee basin wells (which return to zero stored volume in 1977). As the following paragraphs will show, this shortened period covers a wide variety of hydrologic conditions similar to what would have been seen with the full 30-year time period.

The annual precipitation data for the proposed time period at 13 sites within and near the model domain was compared to the distribution of precipitation data over a 71-year period (1929-1999) in Figure 2.7, which shows a nice range of conditions (Winsberg, 2011). At most of the sites analyzed, several of the years from the model period lie in each of the quartiles of the larger dataset. Note, for example that 1968 and 1969 were very wet years at most of the sites while 1975 was a very dry year. In order to look at the model domain as a whole, Thiessen polygons were developed for the sites and clipped to the model domain. In this way, the recharge values were area-averaged using the polygon areas. This average is shown at the right end of the plot in Figure 2.7 and shows a similar wide distribution of precipitation conditions during the 13-year period.

As a second analysis of the variability of hydrologic conductions during the 13-year evaluation period, Figures 2.8 and 2.9 show the comparison of the annual extracted/injected volumes in each basin for the 13-year period (used in RASRSM-D13R) to the distribution of extracted/injected volumes for the full 30-year period (from the SFWMM-D13R). Similar to the precipitation analysis described above, the values for the 13-year model period are widely spread across the range of values from the 30-year period. Note, for example, that 1971 has generally low injection rates and high extraction rates, indicating a dry period when ASR water was used to supply surface water needs. Similarly, 1969 has generally high injection rates and low extraction rates, indicating a surplus of water in the system.

Since both of these analyses indicate wide variability in the period from 1965 to 1977, we can be assured that the shortened time period of the RASRSM-D13R will still adequately investigate a variety of hydrologic conditions.

2.3 Model Time steps and Stress Periods

The RASRSM was developed using the USGS density-dependent groundwater code, SEAWAT (Langevin, 2003), which is an extension of MODFLOW. SEAWAT (and MODFLOW) require the division of the simulation time into stress periods and time steps. Sources, sinks and boundary conditions generally are allowed to change only at the end of stress periods, resulting in step-functions for many model inputs. Time steps are smaller than or equal to stress periods. Model results are calculated and output may be generated at the end of each time step. In the RASRSM calibration, stress periods were one month long. All boundary conditions and sources and sinks were averaged over each month and applied as a step function to the model. The RASRSM calibration flow and transport time steps were 5 days long, with full output generated at the end of every other time step. The selection of the 5-day time step was based on the results of model testing described in the Calibration Report (NAP, 2011) which indicated that 5 days would be sufficiently accurate without overpowering data storage limits with unduly large output files.

At the start of development of the RASRSM-D13R simulation, the plan was to continue with month-long stress periods and 5-day time steps for the reasons stated above. Month-long stress periods would require the averaging of ASR pumping over each month. However, the pumping rates obtained from the SFWMM-D13R scenario for the ASR wells were found to vary significantly on a daily basis at most of the basins. Figure 2.10 shows one example when this averaging would have resulted in a significant loss of detail, although the total volume of water entering and leaving the ASR well would have been correct. Instead, 10-day stress periods were used to balance the need for simplicity in this large, regional model with the desire to correctly reproduce the pump rates from the SFWMM-D13R design. To coincide with the monthly boundary condition changes, some of the stress periods were shortened or lengthened by a few days. Each month was divided into 3 stress periods: one from the 1st to the 10th of the month, another from the 11th to the 20th of the month and the final period from the 21st to the last day of the month. The last stress period of the month might be as short as 8 days (for February) or as long as 11 days.

Despite the shortened stress period lengths, boundary conditions and regional (non-ASR) pumping remained on monthly step functions in order to simplify the conversion of the calibration model to the D13R model. Time steps remained at the 5-day length used in the calibration model. The comparison between stress periods and time steps for the RASRSM calibration model and the RASRSM-D13R scenario are shown pictorially in Figure 2.11.

2.4 Boundary Conditions

In the calibration model, the boundary cells on the north, west and south edges of all aquifers were given specified head boundary conditions based on the available head data. All cells in the top layer

(SAS) were also given specified head boundary conditions, which allowed the model to calculate and apply recharge or discharge to the surface, as necessary, to meet observed conditions. These applied head values were based on interpolations of measured head values and the process used to develop these boundary condition values is described in the Calibration Report (NAP, 2011).

Although this methodology worked well for the calibration model, it presented some difficulties in applying the model to a separate time period. There is far less head data available for the D13R model period (1965-1977), especially in the deeper hydrogeologic units, making it impossible to repeat the interpolation process which was used to set the 2003-2004 and 1993-1994 boundary conditions on the calibration model. Instead, a separate method was developed which used the available data to form a correlation between the sparse data from the 1960s and 1970s and the more dense data already used in the calibration periods. This correlation was then applied to the boundary conditions from the calibration model, to produce a new set of specified heads for the D13R model.

The first step in developing this correlation was to find as much data as possible for all of the monitoring wells which had data during any part of the D13R model period (1965-1977) and during the calibration or validation periods. The data collection process for the calibration model was lengthy and tedious (see Appendix A of the Calibration Report, NAP, 2011) and it was not desirable to repeat that process, which would have been magnified by the additional length of the model time period. Since the USGS National Water Information System (NWIS) provides significant data and allows a search of wells by county and time period, this website was used to collect the data. Although, there is likely additional data available from other sources, including DBHYDRO, the NWIS site was used alone to save time and effort. The data obtained at this site seemed sufficient for the task since the goal was to develop correlations between time periods, instead of using the data directly in the model.

A total of 186 wells were found with data for the D13R period and the calibration and validation periods and the records were downloaded and tabulated. Initial, optimistic plans had assumed that there would be sufficient data to develop distinct correlations for each county and aquifer, but not all counties and aquifers were well-represented. Most of these 186 wells were open in the SAS with very few tapping the deepest layers of the model. Because of the insufficient data, separate correlations could not be calculated for each aquifer and county, and all wells were combined for analysis.

The tabulated data was condensed by calculating a monthly average head at each well for each month with available data. The Excel functions RSQ, SLOPE and INTERCEPT were used to calculate a linear correlation between months in the D13R period and months in the calibration datasets. The linear equations were then applied to all boundary conditions on the north, west, south and top boundary of the calibration model. The resulting estimated heads were applied to the regional D13R model. It is important to note that the correlations were always quite good, with the lowest correlation coefficient (r^2) being 0.956.

The details of the process can best be explained by using an example such as January 1974. Of the 186 wells downloaded from the USGS NWIS website, 123 wells have data available for both January 1974

and January 1993 and 111 have data in both January 1974 and January 2004. When a linear correlation is fit to these data points (see Figure 2.12), r^2 is 0.976 between 1974 and 1993 and 0.977 between 1974 and 2004. Since the correlation to the 2004 data is slightly better, the equation for that line was used to convert January 2004 boundary conditions to January 1974.

Boundary conditions were converted cell by cell. To develop the boundary conditions for January 1974, the assigned heads for January 2004 at each model cell were altered by applying the equation: $y=0.95x+1.10$ where x is the assigned head for January 2004 in the calibration model (already interpolated from available January 2004 data points) and y is the head to be assigned for January 1974 in the RASRSM-D13R scenario. This equation is then applied to each specified head cell of the model to create a set of specified head boundary conditions for January 1974 from the January 2004 dataset. The same process was followed for each month of the 13-year period. Two examples of the conversion from the 1993/1994 and 2003/2004 specified heads to the 1965-1977 specified heads are shown in Figures 2.13 and 2.14. Note that the general seasonal trends are preserved, while magnitudes are shifted up and down slightly to reflect annual variations in weather patterns.

2.5 Regional Pumping

A significant effort was expended by SAJ to collect and tabulate the groundwater pumping in the model domain for the calibration and validation periods (see Appendices A and D of NAP, 2011). This data is much more difficult to track using public records than most of the other data used in the model. The collection process involved numerous phone calls to well owners and state agencies and the resulting dataset still had significant gaps, which were filled using estimation processes described in Appendix D of the Calibration Report (NAP, 2011). Repetition of this tiresome process for the period of the D13R scenario was not possible within the budget and schedule. This old data may not even be available any more. Like other data in the model, a method was developed to estimate conditions during the period 1965-1977 using the data already collected for the calibration and validation models.

This analysis was made possible by the Historical Water-Use tables published online (USGS Florida Water Science Center). These tables provide estimates of freshwater withdrawals for each year from 1965 to 2000, separated by county and use type. Missing or unavailable data in the downloaded tables was first estimated by using linear interpolation. Then, a ratio was calculated between each year from 1965 to 1977 and 1993 or 1994 for each county and each water use type. That ratio was applied to each well in that county with that water use type. In this way, the locations of the wells and seasonal variations are preserved but the volumes are altered based on water demand. Table 2.2 lists the well type codes from the SAJ pumping database and the corresponding water use from the USGS tables. Where a match was not possible, this table also provides the methodology for estimating pumping rates for the D13R time period.

This process probably does not accurately capture all groundwater withdrawals. The use of linear interpolation assumes a continuous, predictable trend from year to year and this method does not account for wells that might have been abandoned before 1993. But, it is expected that on a regional scale, the volumes of water extracted will be close to reality.

An example will clarify the process. The USGS tables referenced above indicate that agricultural groundwater withdrawals in Hillsborough County totaled about 44.73 mgd in 1965, 64.20 mgd in 1970, 64.74 mgd in 1993 and 62.79 mgd in 1994. If we want to estimate the 1966 flow rate for an agricultural well in Hillsborough County, we begin by linearly interpolating the 1965 and 1970 data to get an estimate for 1966. The result is 48.62 mgd. We then calculate the ratio between agricultural extraction rates in 1993 and 1966 by dividing 48.62 by 64.74, resulting in a ratio of 0.751. This means that all agricultural wells in Hillsborough County can be converted to 1966 flow rates by multiplying the 1993 rate (from the calibration model) by 0.751. One example Hillsborough County agricultural well is owned by Dooley Groves and is reported to have extracted 0.024 mgd during August 1993. By applying the conversion ratio, the August 1966 extraction rate can be estimated at 0.018 mgd. This is the value that was input into the D13R regional model. Figure 2.15 shows all of the pumping in a portion of Hillsborough County in the calibration model and the D13R regional model.

These estimates are not expected to be accurate at individual wells. It is quite possible that the Dooley Groves well did not exist in 1966 and it is also likely that other wells existed in 1966 which have been abandoned in the decades since then. However, it is expected that generally, the extraction from the groundwater on a regional scale will be sufficient to reproduce groundwater conditions during the 1960s and 1970s. As with the specified heads, the objective is to preserve the seasonal variations in regional pumping, while varying the magnitudes according to estimated demand.

2.6 CERP ASR Wells

The recharge and recovery rates assigned to the ASR wells were obtained from the output from the SFWMM-D13R model. Daily flow rates were extracted from *.dss files provided by SAJ using the structure codes in Table 2.3.

The output from the SFWMM-D13R model consists of daily average flow rates to and from ASR wells in each of the six basins. These were incorporated into the RASRSM using positive values for injection rates and negative values for extraction rates, which is the MODFLOW sign convention. See Figure 2.16 for a plot of three months of D13R data at the C-51 basin with the conversion to positive and negative flow rates for the SEAWAT model.

Generally, this process worked well. One exception was at the Central Palm Beach basin, where the wells were occasionally injecting and extracting at the same time and at the same rates (see Figure 2.17). The reason for this apparent inconsistency was that the injection and extraction rates were not connected by the SFWMM. Injection in this basin was a function of the stage levels in the Palm Beach County Agricultural Reserve reservoir, while extraction depended on water supply demands in central and southern Palm Beach County. It is not clear how this type of condition would be handled in reality once the system is built. For the sake of this model, it was assumed that net flow would be 0 mgd during this period.

As described above, the model was run with 10-day stress periods. This means that source/sink terms can only change once every 10 days. For the ASR wells, this meant averaging flow rates over the 10-day

time periods. As shown in Figure 2.10, this eliminates some of the extremes in the pumping schedules, but it provides a better picture of conditions than monthly stress periods.

2.6.1 Incorporation of ASR Well Recovery Efficiency

Recovery efficiency is a measure of the portion of stored water that can be recovered from an ASR well. Efficiency can be reduced by mixing of fresh water with the native, high concentration total dissolved solids (TDS) water, or movement of the freshwater bubble during storage periods. The RASRSM is not able to estimate recovery efficiency because it is affected by primarily small-scale processes (near-well mixing and near-well water quality). The RASRSM was designed to look at regional questions related to the CERP ASR plan. ASR well recovery efficiency can best be investigated through local scale modeling and local pilot studies (SAJ, in review).

The SFWMM-D13R scenario was also not able to calculate the ASR well recovery efficiency. Instead, it assumed 70% recovery efficiency on the ASR wells. This assumption was incorporated in the model by not allowing the model to remove more than 70% of the previously recharged water. Not all RASRSM-D13R scenarios made this same efficiency assumption, for several reasons. First, early data from the Kissimmee River and Hillsboro Pilot studies indicated that recovery efficiency at Kissimmee River was near 100% because of the low background TDS, while at Hillsboro, recovery efficiency was much lower, near 40%, because of higher background TDS (SAJ, in review). Second, later project scenarios (described in Section 4) involved the addition of ASR wells to the APPZ and BZ, aquifers whose high TDS was expected to preclude high recovery efficiencies.

To accommodate the lower recovery efficiencies at Hillsboro, in the APPZ and in the BZ in the RASRSM-D13R scenario, the volume of available water in the aquifers was tracked through each stress period. Injection rates were applied as delineated by SFWMM-D13R, but extraction rates were set at the minimum of the reported SFWMM-D13R rate or the available volume of previously injected water multiplied by efficiency. Thus, if the full design number of wells is used, injection rates will match D13R-SFWMM rates, but extraction could stop sooner than designed if the recovery efficiency is assumed to be less than 70%. Although pilot testing at the Kissimmee River site indicated nearly 100% recovery efficiency, this high value could not be incorporated into the RASRSM-D13R scenario because there is no way to know how high the extraction rates might have gone had efficiency been assumed to be higher in the SFWMM-D13R scenario. More detailed analysis of recovery efficiency is possible with the local scale models (SAJ, in review).

Based on discussions with the PDT, all recovery efficiencies in the UF were assumed to be 70%, except for Hillsboro, which was set to 40%. All recovery efficiencies in the APPZ were assumed to be 30%, except for Hillsboro, which was set to 40%. All recovery efficiencies in the BZ were assumed to be 0%.

2.7 Initial Conditions

Numeric models require the selection of initial conditions as a starting place for the solver. For this model, three sets of starting conditions were required: head, TDS and temperature.

The initial head conditions were of no importance since the first stress period of the model was set to be steady state and was only 1 day in length. No ASR wells were pumping during the first day of the model, but all boundary conditions and regional pumping were set to January 1965 conditions as described in sections 2.4 and 2.5. The model determined a steady state condition that would meet those conditions and then used it as the starting condition for the following stress period.

The TDS and temperature starting conditions from the calibration model (2003) were used as the starting conditions for this D13R model (beginning in 1965) since the scarcity of TDS and temperature data available for the 1960s makes it unreasonable to attempt a new interpolation of field data to determine the initial TDS and temperature for this simulation. It is not expected that significant, regional changes to TDS concentrations and groundwater temperature would occur on the timescale of several decades in most areas of the model. Significant water quality changes might be expected to occur near the coast or near extraction wells, but large scale changes in the majority of the aquifers would occur only over large (geologic) time periods.

To verify this expectation, an analysis was made of long term water quality data for wells in the model domain. TDS, chlorides and specific conductance data was collected from the National Water Quality Monitoring Council (NWQMC) Water Quality Portal for all wells in counties within or touching the model boundaries with at least 40 years of data. (Forty years was selected since it is the approximate difference between the 2003 starting condition for the calibration model and the 1965 starting condition for the RASRSM-D13R model.)

A Mann Kendall analysis was used to determine if a statistically significant trend existed in the data (using a 95% confidence interval). If the Mann Kendall analysis showed a significant trend, a Sen's slope analysis was used to quantify the slope of the trend (USEPA, 2000). The resulting slope value was then multiplied by 40 years to determine the approximate change in water quality that could be expected between 1965 and 2003. Finally, the approximated water quality change was divided by the estimated seawater value for each characteristic to make possible comparisons among the water quality parameters. The estimated seawater values were 35,000 mg/L TDS, 19,400 mg/L chlorides and 50,000 uS/cm specific conductance. In many cases, this percentage change as related to seawater was similar for the three water quality parameters at a given well.

The wells were divided by aquifer and are presented spatially in Figures 2.18 through 2.24. Note that the majority of the wells had no significant trend or a very small median slope. The majority of the points which had a significant water quality change (greater than 10% of seawater levels) were located in the Biscayne Aquifer near Biscayne Bay. One additional point with significant change was located in the SAS aquifer along the lower east coast of the peninsula. The SAS is used as a boundary for this model and no calculations are made in this layer. Additionally, since the depth is small, the equivalent freshwater head will be similar to the measured head and an error in the starting TDS will have little effect on the results of the model.

The only other point which shows a significant change in water quality over a 40-year period was located in the Floridan Aquifer system in Orange County. However, this well is closely surrounded by a number of other wells from the same aquifer which show no significant trend. This leads to the conclusion that the large water quality change at this well is caused by a local anomaly.

Figures 2.25 through 2.31 show the TDS, chlorides and specific conductance data for each of the wells which showed a significant trend and a median slope whose 40-year water quality change could be more than 10% of the seawater level. Finally Figures 2.32 and 2.33 show the TDS, chlorides and specific conductance data for two example wells which do not show a large change in water quality.

The results of this analysis show that the use of the 2003 starting conditions for the RASRSM model beginning in 1965 will have minimal effects on the final results of the model. TDS changes quite slowly in the majority of the model domain. A similar condition is expected with temperature changes.

2.8 Validation of Boundary Conditions and Initial Conditions

In order to ensure that the methodology presented above was reasonable, the RASRSM-D13R was run without any ASR wells and the results were compared to a few observation wells which had head data available for some part of the period from 1965-1977. These comparisons are shown on Figures 2.34 through 2.79 with summary statistics in Figure 2.80. Although the comparison is not as close as for a well-calibrated model, the correlations are good considering the methodology described above. The majority of the wells have mean errors and mean absolute errors within 5 feet and seasonal changes are nearly always well timed. Unfortunately, since most of these wells are located in the northwest portion of the domain and tap the upper aquifers they may not represent all parts of the model domain, but the close comparisons lend some credibility to the model setup process.

3 PERFORMANCE MEASURES

The PDT developed a number of performance measures for analyzing the D13R scenarios from a regional standpoint. The purpose of these performance measures was to provide decision-makers with the data and information necessary to understand the probable hydrogeologic impact of the proposed ASR program on the region. Local scale models are required to assess near-field issues (SAJ, in review).

3.1 ROCK FRACTURE

One of the initial concerns, expressed early in the regional ASR study process, was that large volume, high pressure injection into the aquifers would cause fracturing of the rock, resulting in significant, permanent changes to the subsurface hydrogeologic conditions of South Florida. The PDT turned to Nick Geibel of USACE Omaha District (NWO) to analyze the strength of the rock and the pressures that would cause rock fracturing (Geibel, 2012).

A thorough explanation of the calculation is given in the Giebel report, but a short overview of the equations (Tensile Method) is presented here.

The rock fracture limit is assumed to be reached when the water pressure, P, reaches the critical water pressure stress level, P_f, at the top of the aquifer due to ASR injection. The critical water pressure is described by Equation 3.1.

$$P_f = \sigma_v K_o - P_o\left(K_o - 1\right) \qquad \text{Equation 3.1}$$

where:

σ_v = Overburden stress, defined by:

$$\sigma_v = \sum \gamma t \qquad \text{Equation 3.2}$$

where:

γ = Specific weight of overlying units

t = Thickness of overlying units

K_o = Coefficient of Lateral Earth Pressure, defined by:

$$K_o = 1 - \sin\phi \qquad \text{Equation 3.3}$$

where:

ϕ = Angle of friction

P_o = Ambient pre-fracture water pressure at top of unit (estimated as pressure head from February 2004 calibration)

The water pressure during injection is described by Equation 3.4:

$$P = \gamma_w h_p \qquad \text{Equation 3.4}$$

where

γ_w = Specific weight of water

h_p = Pressure head, defined by:

$$h_p = h_t - h_e \qquad \text{Equation 3.5}$$

where:

h_e = Elevation head

h_t = Total head

Thus, fracturing would be expected to occur when the pressure caused by pumping (Equation 3.5) meets or exceeds the critical water pressure (Equation 3.1). For analysis in the regional model, Equations 3.1 and 3.4 were set equal and rearranged to determine the limiting total head. After simplification, the result is Equation 3.6:

$$h_t = h_e + \frac{(1-\sin\phi)\sum \gamma t}{\gamma_w} + (h_{to} - h_e)(\sin\phi) \qquad \text{Equation 3.6}$$

where:

h_{to} = Ambient pre-fracture total head

For this analysis, the following constants were used:

γ = 130 lb/ft^3 (for all materials)

γ_w = 62.4 lb/ft^3

ϕ = 28.9°

The pre-fracture total head was taken from the February 2004 calibration model. The elevation head and unit thicknesses were based on the geologic units as incorporated into the calibration model.

This calculation was run on each cell in the UF and APPZ aquifers in the regional model. Figure 3.1 shows the resulting maximum allowable total head to prevent rock fracturing. Note that in the UF, maximum total head values in the areas of the proposed ASR sites range from about 300 feet to 600 feet. In the APPZ they range from 600 feet to nearly 1000 feet. Because these limits were so high, other performance measures become limiting factors. D13R scenarios will not be compared to these limits in this report.

3.2 Pump Pressure

As the PDT discussed the ramifications of early model results, it became clear that a limit should be set on the pressure the ASR pumps were required to overcome. The well package in SEAWAT forces the user-defined fluxes into the model without regard to the size of the pump that would be required to achieve this flux rate. The PDT determined that it would be unlikely that an ASR pump would be able to

overcome more than 100 psi of head. This is also the pressure at which most FAS wells are tested and the pressure at which both the Kissimmee River and Hillsboro Pilot Study ASR wells were tested. This performance measure was used in the first few RASRSM-D13R scenarios to eliminate ASR wells from sites where this pressure would be exceeded.

Figure 3.2 shows a simplified schematic of an ASR well injecting into an artesian aquifer. The source of the injected water is assumed to be a surface water body located near the ASR site. Thus, the head to overcome is approximately equal to the difference between the model-calculated aquifer head and the ground surface elevation at the well, if headlosses and pump efficiency are ignored. This head difference can be converted to pressure using the density of water.

One of the problems with using a regional model to estimate the pressure requirements of the ASR pumps, is that the cells are much too large to accurately portray heads near the well. Figure 3.3 shows the results of a simple injection well model run with three different grid resolutions. These plots were developed by running models with identical well pump schedules and boundary conditions on three different grids. The model computed a much higher head at the well when run on the grid with the smallest grid cells. The results of the three models become more similar as the distance from the well increases. These plots were made using a small, generic model. It was not possible to run the RASRSM-D13R model with cell sizes of two feet with the existing computer resources, schedule and budget. Instead, the Theim equation (Equation 3.7) was used to estimate the result on a two-foot grid using the results from the 2000-ft grid.

$$h_w = h_{i,j} + \frac{Q}{2\pi T}\ln\left(\frac{r_e}{r_w}\right) \qquad \text{Equation 3.7}$$

where

h_w = Head at the well
$h_{i,j}$ = Head computed in the cell by the model
Q = Flow rate to the well (positive for injection)
T = Transmissivity of the aquifer
r_e = Effective radius of the grid cell
r_w = Radius of the well (assumed to be 1 foot)

The effective radius can be calculated as 0.208 times the grid cell size for a uniform grid (Anderson and Woesner,1992, p 147-149). This calculation was used for most of the ASR sites, since the grid is regular with a cell size of 200 feet for most proposed sites and their surrounding areas. A few sites, notably Lakeside Ranch and Riverbend had some ASR wells assigned to irregularly sized grid cells. The relationship between the effective radius and the cell size was rederived, but it was found to be only slightly different from multiplying the average of the cell size in each Cartesian direction by 0.208.

Equation 3.7 was applied to the aquifer heads calculated by the model at each ASR well. The head was compared to the ground surface elevation and converted to pressure. The maximum well pump pressure was reported at each ASR site for each scenario on the RASRSM-D13R.

3.3 Artesian Pressure Protection Area (APPA)

Another performance measure requested by the PDT had to do with the impact of ASR on the artesian pressure in the UF and APPZ aquifers in Saint Lucie and Martin Counties. Water users in that area depend on the artesian heads for water withdrawal and the permits for ASR sites will require that the flow from artesian aquifers not be reduced by more than 10% as a result of the project.

Merritt (1997) presents an equation to estimate the flow from an artesian aquifer as shown in Equation 3.8.

$$Q = \left(\log_{10}\left(\frac{2.25Tt}{r_w^2 S} \right) \right)^{-1} \left(\frac{4\pi s_w T}{2.3} \right) \quad \text{Equation 3.8}$$

where

Q = Flow from the artesian well
T = Transmissivity
t = Time
r_w = Well radius
S = Storage coefficient
s_w = Difference between aquifer head and height of spigot

If we wish to use this equation to compare the artesian flows before and after the construction of the D13R ASR system, the only variable which will change with the addition of ASR wells is s_w since the head in the aquifer will change. All other parameters are constant characteristics of either the aquifer or the well. Therefore, we can define a variable, *A*, as follows and simplify the equation.

$$A = \left(\log_{10}\left(\frac{2.25Tt}{r_w^2 S} \right) \right)^{-1} \left(\frac{4\pi T}{2.3} \right) \quad \text{Equation 3.9}$$

$$Q = As_w \quad \text{Equation 3.10}$$

$$Q = A\left(h_{aq} - gse\right) \quad \text{Equation 3.11}$$

where

h_{aq} = Model-calculated aquifer head
gse = Ground surface elevation (estimation of spigot elevation)

The comparison between artesian flow before and after ASR installation can be computed as follows:

$$\%QR = \frac{Q_{noASR} - Q_{ASR}}{Q_{noASR}} \quad \text{Equation 3.12}$$

$$\%QR = \frac{A\left(H_{aq-noASR} - gse\right) - A\left(H_{aq-ASR} - gse\right)}{A\left(H_{aq-noASR} - gse\right)} \quad \text{Equation 3.13}$$

$$\%QR = \frac{H_{aq-noASR} - H_{aq-ASR}}{H_{aq-noASR} - gse} \quad \text{Equation 3.14}$$

where

$\%QR$	=	Percent flow reduction from artesian well
$Q_{no\text{-}ASR}$	=	Flow rate with D13R ASR system
Q_{ASR}	=	Flow rate without D13R ASR system
$H_{aq\text{-}noASR}$	=	Head in the aquifer without D13R ASR system
$H_{aq\text{-}ASR}$	=	Head in the aquifer with D13R ASR system

The results from the D13R scenarios were analyzed for the impact to the artesian conditions in Saint Lucie and Martin Counties by comparing the head results at each output timestep for the RASRSM covering 1965-1977 without ASR wells and the RASRSM covering the same period with ASR wells using Equation 3.14. The result was reported with maps of the UF and APPZ layers with the cells colored by the maximum percent flow reduction across the time period. A second set of maps is provided where the cells are colored based on the number of days out of the 13 year period that the 10% rule is exceeded.

It is important to remember that although the rule apparently applies to the two counties in their entirety, there is one section of Saint Lucie County that (according to the RASRSM) does not have artesian groundwater conditions even before the installation of the ASR wells. This is caused by a ridge coming down from the northwest, which increases the ground surface elevation, but does not significantly increase the head in the aquifers. Figure 3.4 shows the ground surface elevations in Saint Lucie and Martin Counties with the surrounding areas. The ridge comes down through Okeechobee County and extends into the corner of Saint Lucie County. The calibrated models did not predict artesian conditions on the spine of this ridge, and only predicted slightly artesian conditions on the side slopes. Even tiny ASR pumping rates can affect these areas significantly enough to exceed the 10% rule. In the analysis that follows here, areas around the ridge were removed from the analysis.

3.4 Head Impacts

Another matter of importance in analyzing the regional effects of the CERP ASR program is the drawdown which might be experienced by neighboring water users due to the extraction cycles on the ASR wells. Head impacts, which vary spatially (horizontally and vertically) and with time, are difficult to show in a 2-dimensional static figure such as those provided with this report. In an effort to better illustrate these effects on neighboring users, head impacts for each RASRSM-D13R scenario are presented in two different ways.

For permitting purposes, it is important to know the extent of the 1-foot and 5-foot drawdown contours. Since each basin of CERP ASR wells has a different pumping schedule and varying rates, it is not reasonable to select a specific time period during the 13-year model run, at which maximum drawdown would be expected for the entire model. Instead, the drawdown was calculated for each cell of the model at each output time step by subtracting the head in the no project run from that in the ASR simulation. Then, at each cell, the maximum drawdown was extracted and combined with the maximums in other cells into a single dataset representing the maximum drawdown over the model run period (1965-1977). Note that the maximum drawdown may not occur at the same time in each cell of

the model. The 1-foot contour and the 5-foot contour were delineated for each aquifer and these contours are plotted in output figures.

Although neighboring users may, at some periods, experience reductions in water levels due to ASR recovery, they will also, at other periods, experience increases in water levels due to ASR recharge. In this report, we refer to this increase in water level due to ASR pumping as "drawup," which is calculated by subtracting the head in the ASR simulation from the head in the no-project run in each cell. Similar to the drawdown analysis, the maximum "drawup" in each cell was combined into a single dataset and the 1-foot and 5-foot "drawup" contours for each aquifer are presented on maps. Note again that the maximum "drawup" may not occur at the same time in each cell of the model.

The maximum drawdown and "drawup" figures give a good picture of the worst-case scenario for head impacts. However, this worst case may be a rare occurrence over the 13-year simulation. In addition, the "drawup" is generally greater and longer lasting than the drawdown. These details are not evident in the previously described maximum drawdown and "drawup" map figures. To give an idea of the temporal component of head impacts to neighboring users, additional figures are provided for each scenario that show time plots of drawdown and "drawup" at numerous locations near the ASR sites. These locations are located at distances of five, 15 and 25 miles from the proposed ASR well sites and have been chosen in all radial directions.

Although the drawdown/"drawup" analysis is listed here as a performance measure, the PDT has not selected a drawdown/"drawup" limit beyond which the ASR scenario would be rejected. Although these results did not impact scenario selection in the same way that the other performance measures did, they are believed to be important to stakeholders and decision-makers.

In Section 4, the results of the D13R scenarios will be presented and will show that in many of the scenarios, ASR pumping causes significant head changes throughout the model, including adjacent to the north, west and southern boundaries of the model. These boundaries were defined as specified heads based on available head measurements. An assumption inherent in this boundary condition was that the ASR pumping effects would not reach the boundary. Appendix A addresses this assumption and concludes that the boundary effects on the performance measures are minimal.

3.5 Water Quality Migration and Saltwater Intrusion

Because the ASR wells will be injecting high quality water to mostly saline aquifers, and because the injection volumes will exceed extraction volumes, it is reasonable to expect that the CERP ASR plan will have a beneficial impact on seawater intrusion and overall water quality in the Floridan peninsula. The PDT wished to be able to quantify this impact since it is an advantage of ASR system over some other components of CERP. Other members of the PDT expressed some concern that the ASR systems might push low quality water into the zone of influence of a water supply well and requested that this possible impact be investigated.

Unfortunately, this regional model is not well-suited to answering these questions for at least two reasons. First, the cells are too large to accurately portray TDS transport, especially near the wells.

Second, impacts to salinity at locations far from the ASR wells are highly dependent on transport parameters such as dispersion, which could not be calibrated due to lack of TDS time series data and the short time period of the calibration models.

Investigations of water quality migration are better suited to pilot study cycle testing with associated local-scale models (SAJ, in review).

3.6 Ability to Provide Storage/Recovery Designated in SFWMM-D13R

SFWMM-D13R was developed to be able to meet urban, agricultural and ecological water supply requirements. It also provides storage for excess water that may be required later. Many of the scenarios tested in the RASRSM-D13R involved a reduction in the number of ASR wells from the SFWMM-D13R design, or a reduction in the volume pumped. The amount of storage and extracted water that can be provided by each scenario will be important for decision-makers.

Like the drawdown performance measure, the PDT defined no limit beyond which the scenario would be rejected based on storage and recovery rates. Instead, plots are provided showing the total annual injected and extracted volumes for each scenario compared to the volumes defined by SFWMM-D13R. This allows decision makers to quickly analyze the water volumes that would need to be made up using other components of CERP.

4 PROJECT SCENARIOS

After the calibrated RASRSM model had been adjusted to reflect the 1965-1977 period as described in Section 2, the model was first set up to run the entire suite of 333 ASR wells as designated in SFWMM-D13R. The locations of these wells are shown on Figure 1.1. The results were compared to the full suite of performance measures and then the PDT designed a number of follow-up simulations, which were also analyzed against the performance measures. The following section will present the scenario descriptions and their results when compared to important performance measures.

4.1 DESCRIPTIONS OF SELECTED SCENARIOS

The following scenarios were run using the regional model and are discussed below:

1. Full D13R design from SFWMM
2. Scale back Scenario 1 to meet pump pressure requirement by successively removing wells from the model until pump pressures are near or below 100 psi. This is not a unique design – there may be other arrangements of the wells that will meet this requirement, but will have more or fewer wells or a different distribution of the same number of wells.
3. Add all wells that were removed for Scenario 2 to the APPZ. This simulation allows for full injection capacity, but because of lower recovery efficiency in the APPZ, the extraction volumes are often lower than the original SFWMM-D13R design.
4. Scale back Scenario 3 to meet pump pressure requirement by successively removing wells from the model (APPZ layer) until pump pressures are near or below 100 psi. This is not a unique design– there may be other arrangements of the wells that will meet this requirement, but will have more or fewer wells or a different distribution of the same number of wells.
9. Add all wells that were removed for Scenario 4 to the BZ. These wells are to have capacities of 10 mgd and 0% efficiency. Because of the doubled capacity, the number of wells in the BZ is half what had been removed from Scenario 4. Some well counts in upper layers were adjusted slightly to prevent the inclusion of "half wells."
10. Scale back Scenario 9 to meet APPA performance measure and to eliminate drawdown greater than one foot at a distance of one mile from each site.
11. Scale back Scenario 9 to meet APPA performance measure (allow drawdown of any magnitude outside the APPA.)
12. Remove BZ wells from Scenario 11.

Simulation 5 was similar to Simulation 9 and was removed from this analysis because it added no unique information. Simulations 6 through 8 investigated the possibility of using gravity drainage to extract water during recovery periods. The application of the RASRSM to these scenarios was questionable and the PDT ultimately decided to eliminate these runs from the analysis.

Figures 4.1 through 4.12 show the injection and extraction flow rates in the SFWMM-D13R and in each of the RASRSM-D13R scenario runs, providing a visual description of each scenario.

4.2 Scenario 1 – Full Design

Scenario 1 followed the injection and extraction schedules used in the SFWMM-D13R as closely as possible. Some small differences in flow rates were caused by the need to average pump rates over 10-day periods. This averaging did not affect the total volume added or removed from the aquifer. Scenario 1 included all 333 recommended ASR wells, which were distributed among the proposed sites as shown in Figure 4.13. All wells were placed in the UF aquifer and were assumed to be fully penetrating. The SFWMM-D13R scenario assumed 70% recovery efficiency for all wells. However, since data at the Hillsboro pilot site has indicated much lower recovery efficiency, the RASRSM assumed 40% efficiency at that site. Because of this reduction in efficiency, some extraction at this site was removed to ensure sufficient water quality on the extracted water. The results from this simulation are presented in Figures 4.13 through 4.31.

The addition of all these ASR wells to the UF aquifer clearly has some very significant effects on the regional hydrogeology. The head rise is so great, that pumps at all sites would need to be able to overcome pressures much greater than 100 psi (see Figure 4.17). The greatest pressure requirements occur at L-63N and Taylor Creek where hydraulic conductivities are lower and the pressure to overcome is over 800 psi and over 400 psi, respectively.

The effect on the artesian conditions in St. Lucie and Martin Counties is also significant. Figure 4.18 shows that a large portion of the two counties loses all artesian pressure at least once during the 13-year model period. Figure 4.19 indicates that most of this area loses more than 10% of artesian flow for more than 40% of the model time period. All areas of the counties are predicted to lose at least 20% of the artesian flow capacity at some point during the model.

The maximum drawdown experienced due to the ASR wells is greater than one foot in the majority of the model (see Figure 4.20). The 5-foot drawdown area is only slightly smaller. Significant impacts are felt in all layers of the model and across the whole domain from boundary to boundary. The time series plots of drawdown and “drawup” at individual points (Figures 4.21 through 4.28) support the conclusion that this scenario would cause excessive head changes at numerous locations for extended and repeated time periods.

This scenario allows for nearly all of the recommended injection and extraction flows defined in D13R (see Figure 4.29 through 4.31) but the regional effects of the system are widespread and significant and all performance measures are exceeded.

4.3 Scenario 2 – Original Design, Scaled Back for Pump Pressures

Scenario 2, a scaled back version of Scenario 1, was developed by removing wells until the pump pressure requirement of 100 psi was met at each site. The process of removing wells was a trial-and-error process where wells were removed from areas of the highest pump pressure. This would naturally result in the removal of wells from areas of low hydraulic conductivity or high density of ASR wells. Because of the arbitrary nature of the procedure to remove wells, the resulting arrangement of wells

(shown in Figure 4.32) is not the only design that would work. Like Scenario 1, all wells were screened across the UF aquifer. This run reduced the total number of wells from 333 to 97.

Results from Scenario 2 are presented in Figures 4.33 through 4.50. In this scenario, the model estimated that the pumps would need to overcome 80 to 100 psi for most sites (See Figure 4.36). Note that the pressure predicted at the C-41 Canal site is slightly over 100 psi. However, the difference (1 psi) is well within the error tolerance of the model. Interestingly, no ASR wells were placed at the Nicodemus Slough, Taylor Creek and L-63N sites in this scenario. Because of the low hydraulic conductivity at these sites the model predicted that pump pressures would exceed the 100 psi limit even with just a single well.

The preservation of artesian conditions in St. Lucie and Martin Counties is slightly better than Scenario 1 (see Figures 4.37 and 4.38). Only areas right around the ridge and near the well sites lose artesian conditions altogether at any time during the model run. Areas near the coast preserve artesian conditions and the reduction in flow is estimated to be less than 10%. More than 10% artesian pressure loss is predicted to occur in about half the area for more than 11% of the 13-year model run period.

For all aquifers, the area impacted by significant drawdown is slightly smaller for Scenario 2 than it was for Scenario 1 (see Figure 4.39). The "drawup" contours extend slightly further in all aquifers. Time series plots of drawdown and "drawup" (Figures 4.40 through 4.47) show a significant reduction in impact, but sites within 15 miles of the ASR wells still show significant head impacts over long periods of time.

Although this run results in an improvement in all of the performance measures, it also is unable to meet the storage and recovery needs specified in the SFWMM-D13R design (see Figures 4.48 through 4.50). All basins see significant reductions in their ability to store and provide recovered water. This scenario can provide 30% - 56% of designed storage volume and 23% - 78% of designed recovery volume.

4.4 Scenario 3 – Add Remainder of Wells to APPZ

Since the results of Scenarios 1 and 2 indicated that the SFWMM-D13R design cannot be entirely incorporated into the UF, Scenario 3 was developed to try to put the rest of the wells into the APPZ. This well distribution is shown in Figure 4.51. Because of higher TDS concentrations, the recovery efficiency for wells in the APPZ is expected to be much lower than the 70% assumed by the SFWMM-D13R for UF wells. Although neither of the pilot studies looked at APPZ ASR wells, the PDT estimated a recovery efficiency of 30% in the APPZ, except at Hillsboro, where the recovery efficiency was assumed to be 40%. These lower efficiencies were incorporated into the RASRSM by cumulatively tracking the volumes of water injected and extracted and stopping extraction once the volume stored in the aquifer had been recovered. This reduced recovery efficiency means that the addition of ASR wells to the APPZ will provide additional storage capacity, but will not be able to fully provide the recovery volumes designated by the SFWMM-D13R design. Results are shown in Figures 4.52 through 4.69.

The addition to the APPZ of all 236 wells which had been removed from Scenario 2 resulted in a significant increase in the required pump pressures at most of the APPZ sites (see Figure 4.55). This is especially true at Hillsboro, which is located in the limestone portion of the unit. It is also noteworthy that the addition of ASR wells to the APPZ resulted in an increase in the pressures that must be overcome by pumps in the UF layer. Many of these UF sites were already near the 100 psi limit with Scenario 2 and the addition of even one APPZ well pushed the UF pressure over the limit, although the APPZ pressure may remain below the limit.

The effects of the ASR system on the APPA in St. Lucie and Martin Counties are shown in Figures 4.56 and 4.57. Although there is little change in the land area which meets the 10% limit, the area that loses artesian pressure completely is much larger in Scenario 3 than in Scenario 2 for both the UF and APPZ aquifers. Model results indicate that most of the water users in the two counties will experience significant reductions in artesian flow during ASR extraction periods.

The areas affected by significant drawdown and "drawup" for Scenario 3 are shown in Figure 4.58 and the time series plots are in Figures 4.59 through 4.66. Generally, the "drawup" is similar to Scenario 1 since there is a close connection between the UF and APPZ and both scenarios inject the same volume of water. Drawdown is slightly less than Scenario 1 due to the reduced extraction volumes in the APPZ wells.

The comparisons of the injection and extraction flow rates to the design rates (Figures 4.67 through 4.69) show, as expected, that this scenario allows for a full injection capacity. Extraction volumes are lessened, however, due to the lower assumed recovery efficiency in the APPZ. Reductions in flow tend to increase towards the end of the simulation as stored water is gradually used up. This simulation is able to extract between 40% and 98% of the annual volumes designated by SFWMM-D13R.

4.5 Scenario 4 – UF and APPZ Wells, Meeting Pump Pressure Requirements

To develop Scenario 4, the number of wells in the APPZ was reduced until pump pressures again met the 100 psi requirement. The results of Scenario 3 and Scenario 4 indicate communication between the UF and APPZ layers at many of the proposed ASR sites. Since the UF ASR wells had already put the UF pump pressures close to the limit, it was often impossible to add any APPZ wells without causing the UF pump pressure to again exceed the limit. In most cases, only a few APPZ wells could remain. Most of the APPZ wells in this scenario were at sites that had no UF wells, such as Nicodemus Slough, Taylor Creek, and L-63 N. All three of these sites have low conductivities in the UF, but much higher conductivities in the APPZ. In total, this scenario included 41 wells in the APPZ. When combined with the 95 UF wells, this resulted in a total of 136 ASR wells for this scenario. The full details of the design are provided in Figure 4.70 with the results shown in Figures 4.71 through 4.88.

Pump pressure requirements are shown in Figure 4.74. Although the maximum pressures in the UF at Kissimmee River / Paradise Run and Lakeside Ranch are slightly over the 100 psi limit, the exceedance is within the error of the model.

The effects of ASR extraction on the artesian pressure in St. Lucie and Martin Counties are shown in Figures 4.75 and 4.76. These effects are quite similar to those for Scenario 2. Coastal areas meet the requirement that artesian flow be reduced by no more than 10%. Inland areas near the Lakeside Ranch and Port Mayaca ASR well sites and near the ridge in St. Lucie County lose all artesian flow for more than 40% of the 13-year simulation.

Drawdown and "drawup" impacts (Figures 4.77 through 4.85) show a slightly smaller impact than Scenario 3, but not as small as Scenario 2.

Because of the smaller total number of ASR wells, the amount of water recharged or recovered in all basins has been reduced, often by significant percentages. Injection volumes have been reduced to 43-64% of the design because of the diminished number of ASR wells. Extraction volumes have shrunk to 26-83% of SFWMM-D13R volumes because of the reduced number of ASR wells, but also because of the lower assumed recovery efficiency at Hillsboro and at all APPZ sites.

4.6 Scenario 9 – Larger, Less Efficient BZ Wells

Scenario 9 was developed by using the same well distribution from Scenario 4 and adding the remaining wells from the SFWMM-D13R design to the BZ. BZ wells were assumed to have capacities of 10 mgd, so only half as many wells were added to Scenario 9 as had been removed from Scenario 4. The design of this scenario is shown on Figure 4.89. The recovery efficiency of the BZ wells was assumed to be 0%, making these wells more like disposal wells than ASR wells. Although the use of the term ASR for these BZ wells may not be appropriate because there is no recovery cycle, these wells are able to provide removal of excess water during wet seasons, preventing flooding and helping keep the salinity of coastal estuaries at appropriate levels. Figures 4.90 through 4.107 show the results of this scenario.

Pump pressure requirements in the UF and APPZ have remained approximately the same as for Scenario 4, but there has been an increase in pump pressures in the BZ, although the levels remain well below the 100 psi limit (see Figure 4.93).

This scenario represents a slight improvement over Scenario 4 in terms of artesian pressure in the APPA (see Figure 4.94 and 4.95).

The zones of significant "drawup" have expanded slightly but areas of significant drawdown have shrunk due to the additional injected water (Figures 4.96 through 4.104).

Because of the additional injection in the BZ, this scenario is able to meet the D13R volumes for storage (injection). Extraction volumes are smaller for this scenario than for Scenario 4 because of the 0% recovery efficiency in the BZ. This scenario was able to extract between 28% and 60% of the D13R annual volumes (Figures 4.124 through 4.126).

4.7 Scenario 10 – Eliminating Drawdown Beyond 1 Mile and Meeting APPA Requirements

Scenario 10 was developed to meet both performance measures and greatly reduce drawdown impacts of the system. It began with the set up for Scenario 9 (which already met the pump pressure requirements) and then the extraction was gradually reduced until the artesian pressure loss in the APPA was less than 10% and maximum drawdown 1 mile from each site was less than or equal to 1 foot. This scenario was designed to virtually eliminate all impacts to neighboring users (other than increased head).

The reduction in extraction was accomplished by applying a percentage to the extraction volumes used in Scenario 9. The percentages used at each site are listed in the second table on Figure 4.108. Note that this is not the recovery efficiency. Recovery efficiency (shown in the upper table) was still applied to the pump rates, but this extraction percentage was applied additionally to further reduce the drawdown (see Section 4.10).

The results for this scenario are presented in Figures 4.109 through 4.126. This scenario allows for full injection capacity, but the allowable extraction is much smaller than that required by SFWMM-D13R. In some areas, nearly all extraction was eliminated from the model.

As expected, there is little impact to the pump pressures since injection volumes are unchanged. (See Figure 4.112.) Artesian pressure remains within the 10% limit in all areas of Saint Lucie and Martin Counties for both the UF and APPZ. (See Figures 4.113 and 4.114) Large losses in artesian pressure occur only in the immediate vicinity of ASR wells. Most of both counties lose less than 5% of the existing artesian pressure.

There was no major change in areas of "drawup" compared to Scenario 9. As expected, however, the areas of significant drawdown have changed greatly. Drawdown greater than 1 foot is now only found in the immediate vicinity of the ASR wells. Note that the apparent drawdown in the BZ is not due to extraction, but is caused by salinity changes which impact the equivalent freshwater head. There is no extraction from the BZ ASR wells in this scenario. Drawdown and "drawup" data are shown in Figures 4.115 through 4.123.

Although this run was able to meet the SFWMM-D13R scenario requirements for storage, recovery was reduced to between 1% and 4% of the SFWMM-D13R extraction volumes in each year of the simulation. (See Figures 4.124 through 4.126.)

4.8 Scenario 11 – Final Selected Scenario

When the PDT analyzed the results of Scenario 10, it was determined that the requirement to reduce drawdown below 1 foot at locations more than 1 mile from the ASR wells was likely too stringent. Scenario 10 is more like an expensive water disposal system than an ASR system. Some informal research indicated that other ASR sites in Florida are not held to that standard. Therefore, Scenario 11 was designed to meet all performance measures other than the 1 foot drawdown at 1 mile requirement.

It was developed by starting with Scenario 10 and gradually increasing extraction volumes until just before the APPA requirement was exceeded. The resulting design is shown in Figure 4.127. Note that most sites have their full extraction capacity (already decreased by recovery efficiencies) except for those that are near St. Lucie and Martin Counties, where the artesian pressure protection rules are in force.

Because injection volumes are unchanged, the pump pressures that must be overcome during injection are quite similar to results from Scenarios 9 and 10 (Figure 4.131). Artesian pressure reductions in Saint Lucie and Martin counties are greater than they were for Scenario 10, but still meet the 10% requirement in both the UF and APPZ. Areas outside these counties see greater loss of artesian pressure during the extraction periods of the ASR pumping schedule.

"Drawup" areas and magnitudes are similar to those seen in both Scenario 9 and Scenario 10. (See Figures 4.134 through 4.142.) Drawdown areas are somewhat similar in size to those seen in Scenario 9 but the shape of the maximum drawdown contours have shifted slightly to avoid St. Lucie and Martin Counties. Time series plots show drawdown magnitudes similar to Scenario 9 for points away from the APPA, but they are smaller in the APPA.

Annual extraction volumes are still not able to meet SFWMM-D13R levels, but they can provide between 12% and 60% of the recovery water volumes during each year of the 13-year simulation, which is an improvement over Scenario 10. (See Figures 4.143 through 4.145.)

This simulation was selected by the PDT as the final recommendation and it was used in all of the analyses of Sections 5 and 6 including the Monte Carlo simulation.

4.9 Scenario 12 – Selected Scenario Without BZ Wells

After the completion of all the production scenario analyses and the Monte Carlo simulation (presented in Section 6) discussions with the PDT and the IMC model reviewers revealed some concerns about the BZ ASR wells from people not originally involved in the scenario decisions. Concerns included:

- Drilling to BZ depths is quite expensive, perhaps prohibitively so,
- With no recovery cycle, these wells are not truly "ASR wells,"
- Despite the ecological and flood-protection advantages of disposing of excess water through these BZ wells, this water is desperately needed in the Everglades and although there is no current mechanism to transport it there, the idea of disposing of needed water is not palatable to some.

To address these concerns, an additional scenario was added which was identical to Scenario 11, except it did not include any BZ wells. The design is summarized on Figure 4.146. Note that the reduction in extraction which was used to prevent significant loss of artesian pressure in St. Lucie and Martin Counties is still included. The results of this scenario are shown in Figures 4.147 to 4.164.

Pump pressures (shown on Figure 4.150) are similar to the results of Scenario 4 and are slightly lower in the BZ than the results of Scenarios 9, 10 and 11 because of the removal of BZ wells.

The reduction of artesian flow in the APPA for this scenario is shown in Figures 4.151 and 4.152. A few small areas exceed the 10% limit slightly. Extraction impacts are increased because there was less injection previously. This performance measure exceedance could easily be eliminated with a slight additional reduction to recovery rates in the ASR wells near these counties.

Drawdown and "drawup" results are shown on Figures 4.153 through 4.161. The area of significant "drawup" has been reduced slightly due to the removal of the BZ wells. Drawdown areas have changed only trivially.

Unlike Scenario 11, this scenario cannot meet the storage volumes defined by D13R. As shown in Figures 4.162 through 4.164, annual injection volumes for this scenario are between 42% and 62% of the D13R volumes from the SFWMM. Extraction volumes have increased slightly and range from 12% to 82%.

4.10 Recovery Efficiency, Extraction Percentage, and Comparison to Designed Flow Rates

In the above subsections, a number of percentages are reported for each of the scenarios. During conversations with members of the PDT, presentations to various groups and the IMC and internal reviews of the draft report, the authors noted that many had difficulty understanding the differences between these reported percentages. Although the text has been clarified as much as possible to explain their meanings, this section is provided as an additional aid to understanding.

- **Recovery Efficiency**: The recovery efficiency is a comparison between the amount of water injected into the ASR well and the volume which can be recovered. This percentage is generally less than 100% due to water quality, uncertainties regarding heterogeneities in the rock, movement of the freshwater bubble, density stratification, etc. Section 2.6.1 explains how recovery efficiency was incorporated into this model. The SFWMM-D13R assumed 70% recovery efficiency for all ASR wells. Thus, the extracted volumes never exceed 70% of what has already been injected. The recovery efficiency is also an assumption and an input for the RASRSM-D13R. When the assumed recovery efficiency is less than 70% (such as in the APPZ), the extraction rates are set to zero in the MODFLOW well package as soon as the recovered volumes reach 30% of the previously injected volumes. Once additional injection periods had added to the volume of stored water, extraction was again allowed. The inclusion of recovery efficiencies usually impacted the length of time for extraction and not flow rates. Until the stored volume in the aquifer reached zero, extraction rates matched those designated by SFWMM-D13R. Recovery efficiencies for each proposed ASR site are provided on the upper tables of the design figures for each scenario (Figures 4.13, 4.32, 4.51, 4.70, 4.89, 4.108, 4.127, and 4.146).
- Extraction Percentage: In order to meet the performance measure requiring that artesian flows not be reduced by more than 10% in the APPA (St. Lucie and Martin Counties), extraction rates at some proposed ASR sites were reduced beyond the recovery efficiency for Scenarios 10, 11 and 12. In Scenario 10, these extraction percentages were also used to reduce the drawdown at

distances more than 1 mile from the proposed ASR sites. Unlike recovery efficiency, these extraction percentages were added as a reduction in flow rate for all extraction periods during the modeled period regardless of the volumes of stored water in the aquifer. These percentage, which range from 0% to 100% are shown on the lower tables of the design figures for Scenarios 10, 11 and 12 (Figures 4.108, 4.127, and 4.146).

- Comparison to Designed Flow Rates: In order to analyze the success of each scenario at meeting the storage and recovery volumes defined by SFWMM-D13R, tables of percentages are provided for each scenario listing the comparison of annual volumes injected and extracted as a percentage of the SFWMM-D13R volumes. These are not inputs to the model, but are analyses of the scenario for its ability to meet the designated volumes. These percentages are shown on three figures for each scenario and are accompanied by bar charts showing the actual volumes each year. If the percentage reported is 100%, this means the scenario was able to exactly meet the volumes designated in SFWMM-D13R. Lower percentages mean a reduction in the ability of the scenario to storage or recovery needs of the basin. See Figures 4.29-4.31, 4.48-4.50, 4.67-4.69, 4.86-4.88, 4.105-4.107, 4.124-4.126, 4.143-4.145, and 4.162-4.164.

A short example may help clarify these three reported percentages. Assume that the SFWMM-D13R design for a given basin defined 30 days of injection at 20 mgd followed by 30 days of extraction at 14 mgd. This rate could be met by using four ASR wells. The injected volume would be 600 million gallons. Assuming 70% recovery efficiency, 420 million gallons would be available for recovery. This is exactly the volume that is removed during the second 30-day period.

In one scenario, this flow rate might be achieved in the RASRSM-D13R by using 4 UF wells with 70% recovery efficiency. This allows us to exactly match the designated flow rates from the SFWMM-D13R design. Now, let us assume that this site is near St. Lucie or Martin Counties and that its extraction percentage is set to 50% to prevent a loss of artesian pressure. This would mean reducing the extraction rate during the second 30 days from 14 mgd to 7 mgd, with a resulting extracted volume of 210 million gallons. When we compare this to the D13R design, this is 100% of the designed injection volume but only 50% of the designed extraction volume.

Let us assume that in a second scenario, this flow rate is to be divided evenly between two UF wells at 70% recovery efficiency and 2 APPZ wells at 30% recovery efficiency. The two UF wells would be set to inject at a total rate of 10 mgd for the first 30 days of the scenario. During the second 30 days, the extraction rate would be 7 mgd (3.5 mgd per well). If we continue with the assumption that the extraction percentage is 50% for protection of the APPA, the extraction rate would be further reduced to 3.5 mgd (1.75 mgd per well). This is a total injection volume of 300 million gallons and a total extraction volume of 105 million gallons.

In order to add the two APPZ wells, we begin with 30 days of injection at a rate of 10 mgd. This is a total injected volume of 300 million gallons, but since the recovery efficiency is only 30% in the APPZ, only 90 million gallons are available for recovery. During the first 10 days of extraction, the extraction rate is set to 7 mgd to match the requirements from the SFWMM-D13R design. This removes a volume of 70

million gallons and reduces the stored available volume to only 20 million gallons. Thus, during the second 10 days of extraction, the maximum possible rate is 2 mgd (1 mgd per well). This extraction period removes the last of the available stored freshwater so the extraction rate during the final 10 days of the scenario is 0 mgd. Then, if we apply the 50% reduction required to protect artesian pressure, the three extraction rates for the last 30 days of the scenario are reduced to: 3.5 mgd, 1 mgd, and 0 mgd, divided evenly between the two wells. This is a total extracted volume of 45 million gallons.

In order to compare to the SFWMM-D13R design, the volumes from the UF and APPZ are added together and divided by the design volume. For the injection comparison, we add the 300 million gallons injected into the UF to the 300 million gallons injected into the APPZ and divide by the 600 million gallons in the D13R design. The result is 100%, meaning that this scenario is able to fully meet the injection requirements of D13R. For the extraction comparison, we add the 105 million gallons removed from the UF to the 45 million gallons removed from the APPZ. The result (150 million gallons) is divided by the design volume of 420 million gallons and we can show that this scenario provides only 36% of the extracted volumes designated by SFWMM-D13R.

4.11 Validity of Drawdown Plots

The maximum drawdown plots shown on Figures 4.20, 4.39, 4.58, 4.77, 4.96, 4.115, 4.134, and 4.153 show widespread impacts caused by the ASR pumping. Some might question the validity of a model that indicates ASR impacts occurring many tens of miles away in aquifers not tapped by the ASR wells. There are three reasons that the modeling team feels that these results are valid.

1. First, impacts to groundwater conditions are already being felt on a regional scale. Figure 4.165 shows the measured heads during the calibration period at six monitoring wells scattered throughout the regional domain and found in all four aquifers. Each one experienced a steep decline in head, with a minimum occurring between June 2 and June 4, 2004, followed by an abrupt increase in head. Each well has a different magnitude of head and the ranges vary, but the shape of the head plot for each well is startlingly similar. This same signature is seen at nearly every observation well in the model domain. (See Figures 4.41 through 4.94 in the Calibration Report, NAP, 2011.)

   To more closely evaluate the head signature, heads at 74 wells were normalized to their head range where 1.0 is the maximum measured head and 0.0 is the minimum measured head (over the 14-month calibration period of November 2003 to December 2004). These 74 wells were located in all areas of the model domain and in all aquifers. They were selected only when more than 400 daily observations were reported during the calibration period. To prevent the over-selection of wells containing the head signature, no wells were removed from the analysis for unexplained anomalies or possible data errors. Figure 4.166 shows these normalized heads distributed into bins of 10% of the wells with data for that day (between 6 and 8 wells). Note that while the outer bands are quite large, the inner bands are extremely narrow. For example,

if the outer two bands (lightest blue and lightest red bands) are removed, 80% of the observation wells would fall into the remaining envelope, which is very thin. Note also that at the beginning of June 2004, all but the outermost (light blue) band are small, indicating nearly universal head minimums occurring within a few days of each other at all observation wells.

The main cause of this head signature is likely the regional pumping occurring in the FAS. Figure 4.167 compares this normalized head distribution to the monthly averaged extraction pumping in the model domain. When the extraction pumping is compared to the head (upper plot on Figure 4.167), there is a close correlation with a slight lag in the head changes. In the lower plot on Figure 4.167, the extraction pumping has been adjusted by summing 80% of the previous month's pumping rate with 20% of the current month's pumping rate. (The 80% and 20% multipliers were selected by trial and error in a search for a good correlation.) These two plots show a close relationship between FAS withdrawals and groundwater levels.

Some may argue that precipitation would be the main driver for head changes. Figure 4.168 shows the same normalized head distribution plots overlain with daily precipitation data for four sites. This precipitation data has been smoothed by summing the previous 30 days of precipitation. The lower plot on Figure 4.168 shows the average 30-day precipitation calculated using relative areas of Thiessen polygons clipped to the model domain. Both plots show poor correlation between precipitation and groundwater heads during the fall, winter and spring seasons. Precipitation is the likely cause of the sharp dip in heads which reached a low point between June 2, 2004 and June 4, 2004 at the vast majority of the observation points. Although the heads were already dropping due to increased extraction pumping, the descent was sharpened by approximately 2 weeks of dry weather. All four weather stations reported several days of rain beginning between June 2, 2004 and June 5, 2004, which caused the water levels to begin to rise.

Because the majority of the groundwater withdrawals from the FAS in the model domain are for agricultural purposes, there is some relationship between precipitation and groundwater withdrawals during the growing season. During the spring and early summer of 2004, when agricultural demands were high, extraction pumping also increased because precipitation remained low. Precipitation then increased during the summer and early fall and so agricultural water demands were largely met by rainfall and groundwater extraction diminished. Although precipitation rates were quite low during the late fall and winter of both 2003 and 2004, agricultural water demands were also low, so pumping did not need to be increased.

The groundwater extraction is not evenly distributed across the model domain. (See Figures 3.37 to 3.41 of the Calibration Report, NAP, 2011). The greatest rates are generally near Lake Okeechobee and the vast majority of the wells are located in the northern half of the model. Despite this irregular distribution, the effects of the pumping are felt nearly uniformly in all parts of the model domain with very little delay. This seems to support the data from the RASRSM-

D13R model which shows head impacts at great distances within short periods of time from the ASR wells.

2. Secondly, as shown in Figure 4.169, the proposed ASR pumping is enormous. This plot shows the sum of all existing extraction wells within the model domain based on the SAJ-developed pumping database and separated into the months of the calibration period. (Details on the development of this database are available in NAP, 2011, especially Appendix A.) At 5 mgd each, 333 ASR wells could remove a maximum of 1.67 billion gallons each day. This is more than the total volume of water removed from the entire model domain during any month of the calibration period other than April and May 2004. The volumes of water being considered for CERP ASR are large and beyond anything that has previously been seen on this peninsula. It is reasonable that its impact might be larger than what has been seen previously.

3. Finally, critics of the drawdown plots might argue that the impacts of the pilot ASR systems were not felt very far away. The left image on Figure 4.170 shows the results from the RASRSM with the pumping from the Kissimmee pilot test applied and calibrated to available field data. The contours show the location of 0.01 feet of maximum drawdown for each aquifer. The right image is an early RASRSM-D13R simulation which included 97 wells scattered throughout the proposed ASR sites, all screened in the UF. In this figure, the contour line is set at 1 foot of maximum drawdown. Thus, the figure on the right has almost 100 times as many wells as the figure on the left and the drawdown shown is 100 times that shown on the left. The area of impact for the two images is strikingly similar. Differences in the shape of the contours are due to the placement of the ASR wells in the D13R run, not all of which were located near the Kissimmee River pilot site.

   Although the Kissimmee cycle test model is calibrated fairly well to the measured data, all of that data is located very close to the ASR well where the drawdown magnitudes are large enough to be measured. Because a drawdown of 0.01 feet is far too small to be measured or noticed in any outlying well, the location of the 0.01 feet maximum drawdown shown in the model output cannot be validated against field data. But, the model results lend some credence to the idea that the placement of about 100 ASR wells would have the impact shown on the right. Note that this is from an early simulation and does not exactly match the results presented previously in this report.

Bredehoeft (2011) discusses the possible reason for this large-area impact. He states that the distance at which cyclical signals from pumping wells can be detected increases with aquifer transmissivity and artesian conditions. The conditions in the FAS are artesian in nearly all areas and the transmissivity is quite large compared to other aquifer systems.

For these three reasons, it is reasonable to believe that impacts from the CERP ASR system might be felt throughout the Floridan peninsula. It is important to remember that these impacts represent the movement of a pressure wave and not the movement of individual molecules of water or the movement

of the freshwater bubble. Pressure can move rapidly through an aquifer without impacting the locations of many water molecules in the same way that a person pushing on one end of an air mattress or water bed can see an immediate movement at the other end of the bed although it is not expected that the molecules of air or water have traveled across the bed instantaneously.

5 TVD Model Run

As explained in the Calibration Report (NAP, 2011), SEAWAT is equipped with several advection solvers. Most of the model runs described in this and other reports, were run using the standard finite difference method (FDM) using upstream weighting. This method is quite fast, though it is not considered to be as accurate as the third order Total-Variation-Diminishing (TVD) method, which is also supported by SEAWAT. The TVD method is significantly slower and so, was not a reasonable choice for the majority of the model runs for this project.

Section 5.1 of the Calibration Report (NAP, 2011) presents the results of a sensitivity analysis which involved running the model using the TVD method and then comparing the results to determine what, if anything, was lost by using the more efficient FDM solver. The results indicated that differences were minor, but were most pronounced for areas impacted by significant, sudden changes in pumping. Because the ASR design includes this type of a pumping signature, the team decided to make intermediate D13R scenarios using the standard FDM solver, but that the final run would be made using the TVD solver. This was considered to be a good compromise between necessary computational speed and desired accuracy.

Accordingly, when Scenario 11 was selected as the final D13R scenario run, it was repeated using the TVD method. Unfortunately, the problem was beyond the capabilities of the TVD method and the simulation repeatedly crashed before completing even one-quarter of the 13-year simulation. The TVD solver requires the user to enter a desired Courant number and then the model automatically sizes the time steps to meet that requirement. Although a full range of Courant numbers were tried, the model was never able to get beyond 983 days into the simulation before crashing due to a severely non-diagonally dominant matrix.

The reason for this failure is probably due to the fact that grid cells near the ASR wells were too large. Generally, small cells are required in areas where sudden, drastic changes to the head or constituent concentrations are expected. The ASR pumping scenarios include numerous sudden changes in pump rates, often changing from full injection to full extraction (or vice versa) in subsequent time steps. While the TVD solver can reduce the time step size to mitigate these changes, it is powerless to change the cell sizes.

Although the existing grid had its smallest cells at the locations of most ASR wells, they were still 2000 feet on a side and were probably not small enough to handle the pumping schedules for D13R. The cells could not be made any smaller because of computational requirements of the computers used to run the models. The grid, as it was, was already taxing the limits of the computers and time constraints with over 1 million cells and requiring more than 12 hours for a single RASRSM-D13R run using the FDM solver. Further, changes to the grid at this point would have required recalibration and rerunning of all 8 RASRSM-D13R scenarios, which was beyond the scope and budget for the project. Fortunately, the comparison of the first 983 days of the results indicated that the differences were minor and the standard FDM solution was sufficient for the needs of the project.

Comparisons of the results are presented for three example areas in Figures 5.1 through 5.3. In each case, the model calculated heads are presented as a time series for a set of points located at increasing distances from the ASR wells. Plots at right show the calculated heads from each of the two solution methods and the difference (TVD solution minus standard FDM solution).

The greatest differences between the two solutions are in the ICU (layer 4) directly above the Moorehaven ASR site, which includes six UF ASR wells and 4 BZ ASR wells in Scenario 11 (See Figure 5.1). During the first 983 days of the D13R simulation, the TVD solution exceeds the FDM solution by greater than 2 feet at only two times, both when the ASR wells switch suddenly from extraction to injection. In addition, the TVD solution head is less than the FDM solution head by more than 2 feet about a half dozen times during the two and a half year simulation when the ASR Wells switch suddenly from injection to extraction. Although the head impact of the pumping continues through the period of pumping, the difference between the two solution methods is only significant for a few weeks or months after the change in pumping. The TVD solution is more accurate during these sudden changes, but only for a short period. Once the model begins to equilibrate to the new condition, both solution techniques are similar with differences well within the error tolerance of the model. In addition, differences between the two solutions are greatest at the ASR site and quickly drop off as distance from the site increases. In fact, differences are within error tolerances when the distance exceeds a few miles.

Comparable results are shown in Figures 5.2 and 5.3, though the differences are smaller and more minor. Similar conditions are seen throughout the model when sudden changes impact the model.

The purpose of the RASRSM-D13R scenarios was to estimate the ability of the CERP system to meet regional performance measures, as described in previous sections. There are two reasons that the use of the standard FDM solution is sufficient for this purpose despite its differences from the TVD solution:

- The performance measure results are presented as worst-case, or maximum conditions. These conditions generally occur at the ends of long periods of either injection or extraction at the ASR wells. Since the differences between the two solutions occur at the beginning of an injection or extraction period, and quickly drop to acceptable levels, the use of the more accurate TVD solution would not significantly affect the performance measure results.
- Most of the performance measures are meant to measure regional impacts of the ASR pumping. Although the differences between the two solution techniques can be significant, the differences are seen only in the immediate vicinity of the ASR wells (usually within a mile or two). This is a regional model, whose purpose is to show the regional effects of D13R over a long time period. It was never expected that this model would be able to reproduce near-well effects. The local scale models (SAJ, in review) were developed for these purposes. The standard FDM solution is considered sufficiently accurate on a regional scale.

This analysis showed that the FDM solutions are sufficiently accurate for the analysis of the performance measures on the regional scale model. All solutions presented in this report were computed using the standard FDM method.

6 MONTE CARLO SENSITIVITY ANALYSIS

Often, numerical groundwater modeling is treated in a deterministic way – i.e. the modeler inputs his best guess for all parameters and treats the result as the "correct answer." In reality, there is uncertainty in all models. Model uncertainty can stem from uncertainty in the input parameters, simplifications made to force the system to fit a mathematical model, error caused by spatial and temporal discretization, etc. It is often more advisable to approach groundwater modeling from a probabilistic standpoint and use the uncertainty in the input parameters to estimate the uncertainly in the output. In a probabilistic model, there is not just one "correct answer;" instead there are a range of possible answers. The decision makers can then provide for a range of possible results in their planning.

A Monte Carlo sensitivity analysis is one way to quantify the uncertainty in the output. In this type of analysis, the input parameters are given probability distributions instead of discrete values. The range and distribution of the values should be an indication of the uncertainty in the parameter. Parameters that are well known or have been measured at the site might be given a narrower range of values than parameters that are unknown or obtained from the literature. The model is then run multiple times with different sets of randomized parameter values selected from those distributions. Assuming that the input distributions are valid, this methodology results in a number of equally probable model results. Instead of reporting a single answer, modelers can report the range and distribution of the model results and planners can design for contingencies based on those distributions. Also, if the results of the Monte Carlo analysis indicate a wide variability in output, it can signal the need to collect more data to reduce the uncertainty and tighten the variability of the model output. See Figure 6.1 for a schematic of a Monte Carlo analysis.

During the Monte Carlo analysis of the RASRSM, the input parameters for Scenario 11 were randomized and the ASR and no project scenarios were run on each randomized set of parameters. The results were then analyzed in comparison to the performance measures. The entire process was automated so that the computer could run a large number of randomized scenarios and provide statistics on output without user intervention.

6.1 INPUT PARAMETER DISTRIBUTIONS

The designation of probability distributions for the input parameters is often a challenge. If sufficient samples or measurements have been taken, distributions of the results can be applied to the model parameters. However, there is seldom that much data available for groundwater models. Testing for parameters such as hydraulic conductivity and storage parameters or analyzing geology can be expensive. Often, information is known at just a few points and must be interpolated to other areas of the model. In some cases, including the present model, probability distributions are simply estimated based on a range of values that would be considered acceptable by the engineer's judgment.

The parameters that were varied for this Monte Carlo analysis were porosity, dispersivity, molecular diffusion, hydraulic conductivity, specific storage, starting TDS concentrations, starting temperature, the thickness of the BZ and horizontal anisotropy. A total of five different methods were used to vary these

parameters during the randomized Monte Carlo runs. In all, 2894 different sets of parameters were developed using the techniques described here.

6.1.1 Uniform Distribution of Values

The first group of parameters was varied uniformly within a range considered acceptable. This group included porosity, longitudinal dispersivity and molecular diffusion for TDS and temperature. These parameters are transport parameters which could not be calibrated due to the short time period of the calibration model and the lack of sufficient time varying TDS and temperature data. The parameter values used in the calibration model were best guesses with little basis in field data, so the best option was to allow the Monte Carlo scenarios to use any value within plausible limits.

Each layer of the model was given a different random value for porosity and longitudinal dispersivity, but a single diffusion value for each constituent was selected to be applied to the entire model. The random numbers were generated using the RANDOM_NUMBER function in FORTRAN. Each random number was generated independently; there was no assumed correlation between the parameters. The allowable ranges for these parameters are shown in Table 6.1. The range was incorporated using the following formula:

$$Random\ Parameter\ Value = R \times (UB - LB) + LB \qquad \text{Equation 6.1}$$

where

R = Random number generated by FORTRAN (between 0.0 and 1.0)
UB = Upper bound of acceptable values
LB = Lower bound of acceptable values

Randomized distributions of a few of these parameters are shown in Figure 6.2. It is beyond the scope of this report to show all of them. These examples are indicative of all of the parameters in this group. Notice that each plot divides the range into 20 bins. Therefore, if an infinite number of simulations had been run, 5% of the values would have fallen into each bin. Because of the random nature of the parameter selection, there is some variation among the bins, but generally, all are between 4% and 6%.

6.1.2 Log Distribution of Values

The second group of parameters was varied using a log distribution with the range set according to acceptable values. This group included the ratio of longitudinal to transverse dispersivity, the ratio of longitudinal to vertical dispersivity and the ratios of horizontal to vertical conductivity for each geologic unit. These distributions placed the greatest probability on the lower bound of the acceptable range.

The allowable ranges for these parameters are listed in Table 6.2. The random numbers were generated using the RANDOM_NUMBER function in FORTRAN and then adjusted using the following formula. All random parameters were developed independently without any assumed correlation between parameters.

$$Random\ Parameter\ Value = 10\text{^}\left(R \times \left(log(UB) - log(LB)\right) + log(LB)\right)$$ Equation 6.2

where

R = Random number generated by FORTRAN (between 0.0 and 1.0)
UB = Upper bound of acceptable values
LB = Lower bound of acceptable values

Distributions of a few of these parameters are shown in Figure 6.3. It is beyond the scope of this report to show all of them. Notice that the applied distribution made it more likely that a value would be selected from the low end of each range. For example, more than 16% of the 2892 Monte Carlo selections applied a longitudinal to transverse dispersivity ratio between 0.1 and 0.15 while only 2% of the simulations applied a ratio close to 1.0. This is in keeping with general rules of thumb for this ratio.

For the hydraulic conductivity ratios in the aquifers (UF, APPZ, LF, BZ), the calibrated model used a value of 0.1. This was assumed to be the most likely value and the log scale was set up to place most random selections close to this value.

Unfortunately, an error was made in the setup for the hydraulic conductivity ratios for the confining units (MC1, MC2, LC). Here, the model calibration used a value of 0.5, and this should have been the most common value in the Monte Carlo selections. However, the same distribution was used here as with the other log scale parameters and the most likely value was again, 0.1. Similar situations occurred for the IAS and ICU. Although this error is unfortunate, it is believed to have a minimal impact on the results of the analysis. The hydraulic conductivity ratios were not used as calibration parameters so the 0.5 value is the initial guess made as the model was being set up, not a calibrated value. Further, as will be described below, each Monte Carlo simulation was tested against the calibration data before being added to the set. Thus, if the calibration was sensitive to these parameter values, bad values would have automatically been removed from the set before continuing. See Section 6.2.3 for additional information on this issue.

6.1.3 Parameter Distributions Applied to Pilot Points

Two of the most sensitive calibration parameters (hydraulic conductivity and specific storage) were included in the calibration model as pilot points. As described in Section 4.1.1 of the Calibration Report (NAP, 2011), the parameter values were applied to a set of mostly randomly placed points. Then these parameters were interpolated to the computational grid using a kriging technique.

In order to apply the Monte Carlo analysis to these parameters, a distribution was applied to the pilot point values and the interpolation was regenerated to produce a new conductivity or storage field for each run. Since hydraulic conductivity was closely calibrated and based on significant field data, itsr uncertainty was considered to be somewhat low and the values were not allowed to vary as much as more uncertain parameters. Each pilot point hydraulic conductivity value was allowed to vary between half of the calibrated value and twice the calibrated value. Uniform distributions were applied using Equation 6.1. A few examples of the conductivity fields for the UF are shown in Figures 6.4 and 6.5.

This method allowed each randomized hydraulic conductivity distribution to remain true to any measured data and close to calibrated values. General trends and orders of magnitude are preserved, but subtle changes are introduced in each randomization. The Monte Carlo simulation can investigate the sensitivity of some of these values while remaining true to known information.

The distributions for specific storage were set in a similar manner. Again, random values were selected for each pilot point, but a log distribution was used spanning four orders of magnitude, ranging from one hundredth of the calibrated value to 100 times the calibrated value. The larger range was selected because there was less data for selecting storage values and therefore, more uncertainty. Also, selection of the best calibration was more difficult for the transient model because of the additional parameters and the difficulty in defining a "well-calibrated" scenario. The log distribution was selected because of the large range and the fact that these parameters tend to fall along a log scale. Figures similar to Figures 6.4 and 6.5 could be supplied but are omitted for simplicity since they would provide no new information.

6.1.4 Invertible Distributions Applied to Pilot Points

Another type of distribution was developed for parameters whose ranges straddled unity, but were not appropriately distributed with either a uniform or log distribution. Horizontal anisotropy in the UF and APPZ were varied in the Monte Carlo simulation using this type of invertible distribution. MODFLOW and SEAWAT incorporate this parameter by applying a ratio to each cell of the model, representing the ratio of hydraulic conductivity along the columns to hydraulic conductivity along the rows.

Early work on the regional ASR study demonstrated the existence of a preferential flow direction along the spine of the Floridan peninsula based on some lineament studies (Fries, 2004). It was this information that led to the rotation of the grid by 38°. Later study (Bittner, et al, 2008) indicated that this anisotropy did not affect calibration and so it was removed from the RASRSM. The PDT asked that it be re-introduced in the Monte Carlo simulation. At that time, some early information at the Kissimmee River pilot site seemed to indicate localized preferential flow to the east and west, nearly perpendicular to that indicated by the SFWMD work. This issue has continued to progress and is described in greater detail in the cycle test report (SAJ, in review). Here, it is sufficient to mention that at the time the Monte Carlo simulations were being set up, it was unclear if there was any anisotropy and which direction it might go. Further, there were theories that localized effects might not match regional effects. So the Monte Carlo simulations were developed to include preferential flows in both directions with anisotropy values varying spatially (rather than being constant across the model). Horizontal anisotropy was varied in the UF and APPZ layers – all other layers had anisotropy values of 1.0, meaning equal conductivity in both directions.

The range selected for horizontal anisotropy was 0.1 to 10.0. This allows the conductivity in either direction to be as much as 10 times or as little as one tenth of the conductivity in the perpendicular direction. If a uniform distribution had been applied across this range, the likelihood of selection of a value between 1.0 and 10.0 would have been ten times the likelihood of selection of a value between 0.1 and 1.0, placing an undue emphasis on values above 1, where the conductivity along the columns is

greater than that along the rows. If a log distribution had been applied, the opposite would have occurred. Instead, the range was set to 1 to 10 and a uniform distribution was applied as in Equation 6.1. Then, a second random value was selected between 0 and 1. If the second number was greater than 0.5, the original random value was inverted. This puts half of the selected values on each side of unity making anisotropy in each direction equally likely.

Figure 6.6 shows the resulting distribution. Note that in the plot at left, the inverted bins are sized at 0.1, while the bins for the non-inverted values are sized at 0.9. This makes the distribution look uniform for the upper values and logarithmic for the lower values. If we think of these values in terms of ratios instead of decimals, the distribution becomes uniform as in the plot at right. Thus, for this Monte Carlo simulation, it is just as likely that the preferential flow is along the columns as along the rows.

To provide spatially varying horizontal anisotropy, the randomized values were applied to a small set of pilot points and interpolated to the surface. A few example anisotropy distributions are shown in Figure 6.7. There is quite a bit of variability in these values due to the uncertainty, but, as will be described in section 6.2, the algorithm for developing these scenarios was set up to eliminate randomizations that could not match the calibration.

6.1.5 Multiplier distributions applied to Pilot Points

As described in Section 2.7, the starting conditions for TDS and temperature on the RASRSM-D13R model matched the starting conditions from the calibration model. The development of the starting conditions for TDS concentration and temperature for the calibration model is described in the Calibration Report (NAP, 2011). The process entailed interpolation of available data, but also involved some engineering judgment and comparison to underlying layers to ensure consistency. Because this method required user intervention, it could not easily be automated for the Monte Carlo simulations like all of the other parameter selection processes. Thus, a separate process was employed to vary the starting conditions.

A set of pilot points was created and values associated with each point were randomized with a range of 0.8 to 1.2 and a uniform distribution (Equation 6.1). The narrow range was used because there was a significant amount of field data employed, so the uncertainty was considered to be somewhat low. The values assigned to these pilot points were interpolated to the grid using the kriging method to apply a value to each cell. The interpolated values on each grid cell were then multiplied by the starting condition value for TDS and temperature from the calibration model for that cell. The final starting TDS concentrations and temperatures varied between 80% and 120% of the values developed for the calibration model. In this way, the resulting randomized starting values remained close to available data and were consistent with other layers and surrounding areas.

Figures 6.8 and 6.9 show a few example randomizations for TDS starting values. Note that all randomizations remain true to the available data and consistent with surrounding data, but subtle differences have been introduced to each randomization. A similar process was followed for setting the initial temperature condition.

Multiplier distributions were also used to change the thickness of the BZ. In the calibration model, the BZ was 500 ft thick over the entire model domain. For the Monte Carlo runs, the multipliers were set from a range of 0.5 to 2.0, resulting in a BZ thickness varying from 250 ft to 1000 ft. An invertible distribution (see Section 6.1.4) was used to prevent the random numbers from favoring one end or the other of the range.

6.2 Selection of Monte Carlo Simulations

For each Monte Carlo simulation, the above processes were used to obtain random values for the 1485 parameters. Every random value was developed independently with no pre-conceived correlations between parameters. Next, any necessary kriging was performed and model input files were developed. Then, the calibration simulations were run with the new set of randomized data to compare the results against the calibration data. Only those scenarios that met minimum calibration requirements were run through the D13R scenarios and the post-processing routines to compare the results to the performance measures. See the flow chart in Figure 6.10 for a visual summary of the process.

6.2.1 Steady State Calibration Check

To test the steady state calibration, the October 2003 and February 2004 calibration models were run with the randomized parameter sets described in Section 6.1. See the Calibration Report (NAP, 2011) for details on these two calibration periods. In the original calibration, some calibration points were considered to be less important than others due to model simplifications, local effects, etc. For this calibration check, everything had to be automated, so all calibration points were given the same weight. The residual error at each point was calculated and the root mean square for the entire calibration set was calculated using Equation 6.3 for each of the two models.

$$RMS = \sqrt{\frac{\sum_{i=1}^{n} c_i - o_i}{n}} \qquad \text{Equation 6.3}$$

where:

c_i = Model calculated head at observation point, i
o_i = Observed head at observation point, i
n = Number of observation points

When the calibrated parameters were used, the RMS for October 2003 was 2.08 and for February 2004 was 1.78. The percentage change for each RMS value was calculated as follows:

$$\%chng = \frac{\left|RMS_c - RMS_m\right|}{RMS_c} \times 100 \qquad \text{Equation 6.4}$$

where

RMS_c = Calibrated RMS
RMS_m = Monte Carlo scenario RMS

Only those scenarios that had a percent change less than 150% were used in the Monte Carlo analysis (RMS less than 5.20 for October 2003 and less than 4.44 for February 2004). Figure 6.11 shows the February 2004 and October 2003 RMS values for each of the randomized parameter sets compared to the calibrated values and the cutoff points for the Monte Carlo analysis. Approximately 55% of the parameter sets passed the steady state calibration test and continued to the next step of the analysis. Those parameter sets which did not pass this test were eliminated from the analysis.

6.2.2 Transient Calibration Check

The calibration check for the transient model was based on the Nash-Sutcliffe statistic (Nash and Sutcliffe, 1970). The 15-month transient calibration model (October 2003 – December 2004) was run with the Monte Carlo randomizations and then the Nash-Sutcliffe statistic was calculated using Equation 6.5 for each observation point.

$$E = 1 - \frac{\sum (o_i - c_i)^2}{\sum (o_i - \bar{o})^2}$$ Equation 6.5

where

E = Nash-Sutcliffe statistic
o_i = Observed head for given time step
c_i = Model calculated head for given time step
$\bar{o}$ = Average observed head across all time steps

When the Nash-Sutcliffe statistic is greater than zero, variation in the model output is smaller than the variation in observed data. When it is less than zero, the model is inefficient, i.e. the variation between calculated and observed values is greater than the variance in the observed data. The optimum value is 1.0. The negative values can be much greater than the positive numbers, so a simple summation would put far too much emphasis on the few poorly calibrated points. To prevent this, points were awarded to each observation point based on the system shown in Table 6.3.

The points awarded to each observation point were summed and a score was assigned to each randomization. The calibration model score was 180. Higher numbers indicate a better calibration. For the Monte Carlo randomization to be selected, the score needed to be higher than 153, 85% of the calibrated value.

Figure 6.12 shows the results of the transient calibration test when compared to the steady state calibration results. It is interesting to note that there are a number of Monte Carlo randomizations with apparently better transient calibrations than the accepted calibration model described in the Calibration Report (NAP, 2011). This is due to the fact that during calibration, the quality of each transient test run was assessed both quantitatively, using a suite of statistical measures, and qualitatively, using the engineering judgment of the modeling team. In order to automate the Monte Carlo analysis, only the quantitative analyses could be used and in this case, only one of the statistical measures was employed.

About 53% of the randomizations that passed the steady state test also passed the transient test and continued to the next step of the Monte Carlo analysis. All other parameter sets were eliminated from the analysis.

6.2.3 Effects of Removing Poorly Calibrated Scenarios

As explained earlier, it is often difficult to select the probability distributions for input parameters, especially when there is minimal data available. In this analysis, the best effort has been made to select reasonable ranges for the input parameters and to develop reasonable distributions that placed greater emphasis on more likely values. But it was also important to ensure that the model results for each simulation matched available calibration data to a reasonable degree. In many cases, when the calibration data was used to whittle down the simulations, the distribution of the parameters was affected. One example of this phenomenon is shown in Figure 6.13. The plot on the left shows the distribution of a parameter whose distribution was not affected by the Monte Carlo selection process. Note that the distribution of all randomized scenarios is quite similar to the distribution of the selected scenarios. The plot on the right shows the distribution for a parameter that was affected by the selection process. Here, a greater percentage of the randomized scenarios with low ratios were not selected because of poor calibration. Thus the distribution has changed as a result of the selection process. During analysis of the input for this report, a few errors were found in the setup of the randomization algorithm, including that described in Section 6.1.2. This method of selecting the scenarios helps mitigate the effect of these errors in setup.

6.3 Monte Carlo Analysis Results

Once the calibration tests had been used to select the best of the randomized scenarios, the results of the RASRSM-D13R runs were compared to the performance measures. Instead of a single, deterministic answer, like those presented in Section 4, this method resulted in a distribution of results, helping to quantify the uncertainty in the model.

In all, 825 full Monte Carlo iterations were run. These had been whittled down from 2836 randomizations of the input parameters. About 55% (1551 randomizations) passed the steady state calibration test and, of those, 53% of those passed the transient calibration test.

The time required to make these runs was significant. It took about 4 to 7 minutes to make the steady state calibration check and 60 to 90 minutes to make the transient calibration check. If those tests were passed, it took 10 to 15 hours to run the D13R scenario and an additional 9 to 14 hours to run a no project scenario for comparison. Another 10 to 30 minutes were required to run the post processing codes and update the running pass rates. In total, a complete Monte Carlo scenario would take 20-30 hours to run to completion.

Variations in run times are due to differences in computer speeds. A total of 14 different computers were used for varying amounts of time over a period of 3 months to complete the simulation.

6.3.1 Monte Carlo Output and Performance Measure Statistics

Because of storage limitations, it was not possible to save the entire set of output files for each Monte Carlo run. On average, the output files totaled nearly 26 GB for a single run of the D13R scenario. Much of that space (39% for flow files, 30% for concentration results and 23% for text output files) was not used for any of the performance measure analyses. But there was still a large amount of disk space needed to store just the head output files - 2 GB for each run. And the results of the no project scenario were of similar size. For 825 runs, that would require over 3 TB just to store the head output files.

Instead of storing the actual output files, each scenario was compared to the performance measures and either passed or failed each one. The number of passing scenarios was summed up as the scenarios finished and new scenarios overwrote the previous solution files. In the case of APPA and drawdown results, this summation was done for each cell in the model. In the case of the pump pressure requirement, the summation was done for each proposed ASR site. Since there were so few sites (16) compared to grid cells (1.2 million), the actual maximum pump pressures were also tabulated.

The final result of the Monte Carlo simulation included:

- A grid dataset showing the number of Monte Carlo simulations with a loss of more than 10% of the artesian pressure at each cell,
- A grid dataset showing the number of Monte Carlo simulations with less than 1 foot of maximum drawdown at each cell,
- A grid dataset showing the number of Monte Carlo simulations with less than 5 feet of maximum drawdown at each cell, and
- A list of the maximum pump pressures encountered at each proposed ASR site for each Monte Carlo iteration.

This space-saving output setup precludes the ability to present distributions of output data such as the maximum drawdown or the percent artesian pressure loss. Instead, we can present the percentage of Monte Carlo simulations meeting each performance measure. If the percentage is close to 100%, we can be fairly certain that the Scenario 11 ASR system design will meet the given performance measure. Conversely, if the percentage is close to 0%, we can be fairly certain that the performance measure will not be met at that location. If the percentage is in the middle, near 50%, we cannot say one way or the other what will happen. If the area of middle percentages is unreasonably large or covers an important area, additional data collection or modeling work are required to tighten up the uncertainty in the output.

One important decision for this type of analysis was how many iterations to run. In reality, the decision was made based on available computers and time allotted, but it was important to be able to determine the accuracy of the results. It was desirable to stop the Monte Carlo simulation only when it was determined that additional iterations would not appreciably improve the reliability of the results. This was done by computing the 95% confidence interval using the following equations:

First, the equation for the sample mean is:

$$\overline{Y} = \frac{1}{N}\sum_{i=1}^{N} Y_i$$ Equation 6.6

where

$\overline{Y}$ = Mean

N = Number of Monte Carlo simulations

Y_i = Result of simulation i

Because the results for this Monte Carlo simulation are binary (either pass or fail), Equation 6.6 can be reworked with $\overline{Y}$ becoming the percent of the runs passing the performance measure:

$$\overline{Y} = \frac{1}{N}\left(P \times 1 + F \times 0\right)$$

$$\overline{Y} = \frac{P}{N}$$ Equation 6.7

where

N = Total number of Monte Carlo simulations

P = Number of passing simulations

F = Number of failing simulations

Second, the variance is computed using Equation 6.8:

$$S^2 = \frac{1}{N-1}\sum_{i=1}^{N}\left(Y_i - \overline{Y}\right)^2$$ Equation 6.8

where

S^2 = Variance (note that S is the standard deviation)

Then, the half-width of the confidence interval is computed as:

$$HW = z_{1-\alpha/2}\frac{S}{\sqrt{N}}$$ Equation 6.9

where

HW = Half-width of the confidence interval

$Z_{1-\alpha/2}$ = Z statistic where α is 5% (1.96)

Equation 6.8 can be inserted into Equation 6.9 and because of the binary nature of the results, it can be reworked as:

$$HW = \frac{1.96}{N}\sqrt{\frac{P\left(N-P\right)}{\left(N-1\right)}}$$ Equation 6.10

Note that the half-width of the 95% confidence interval is dependent only on the number of Monte Carlo simulations and on the number of passing simulations. Figure 6.14 shows how the confidence interval changes as the number of simulations increases for different pass rates. The half-width of the 95% confidence interval is greatest when the pass rate is 50%. As the number of Monte Carlo simulations increases, the effect of the pass rate on the confidence interval lessens. At 825 simulations, the half width of the 95% confidence interval is 3.41% at most. To reduce the half-width of the 95% confidence interval by one percentage point (from 3.4% to 2.4%) an additional 825 simulations would be required and the same set of computers would require about three more months to reach this point. The advantages from the improvement in the confidence interval are outweighed by the time required to achieve these improvements.

6.3.2 Pump Pressure

The method for calculating the pressure that would need to be overcome by the ASR pumps to inject the required flows is explained in Section 3.2. The same method was applied to each of the 825 selected Monte Carlo simulations. Figures 6.15 through 6.26 show the histograms of the results at each ASR site. Bars for pressure values meeting the 100 psi requirement are blue; bars for values not meeting the requirement are red.

For all of the UF sites, the majority of the Monte Carlo runs met the pressure requirements. The percentages and the spread of the results vary significantly, however. For example, at Hillsboro in the UF (Figure 6.15), 66% of the Monte Carlo runs met the 100 psi requirement. But there was a wide range of maximum pressures, from 46 psi to 195 psi. The maximum value of 195 is nearly twice the requirement. This indicates that the uncertainty in the input parameters has led to significant uncertainty in this output parameter. Conversely, at Flaghole in the UF (Figure 6.18), 86% of the Monte Carlo runs met the 100 psi requirement and the range is a bit narrower, from 58 psi to 140 psi. The uncertainty in the input parameters has a lesser impact on this performance measure. Note that all Monte Carlo simulations met the pump pressure requirement at all sites in the APPZ and BZ.

Figure 6.27 shows the change in percentage of passing simulations for the UF site at Lakeside Ranch as the number of simulations increases. The 95% confidence interval (calculated using Equation 6.10) is also plotted on this figure. Note that there is significant variation in the percentage when the number of Monte Carlo simulations is less than 200. After that point, there is less variation and the width of the 95% confidence interval gradually decreases. By the time the Monte Carlo analysis was stopped (at 825 iterations) the improvement in confidence with each additional iteration was trivial. The “return on investment” of time and computational power had become very small.

Figure 6.28 shows the percentage of Monte Carlo simulations that met the pump pressure requirement at each proposed ASR site in the UF with the 95% confidence interval shown as error bars. Note that, as expected, the largest confidence intervals are on the points where the percentage passing is closest to 50%.

Only four sites passed the criteria for every Monte Carlo run, but these are the four sites that have no ASR wells assigned to the UF in Scenario 11. All other sites failed the criteria at least part of the time, so there is a possibility that the number of ASR wells would need to be reduced at some or all of the sites. The most critical sites are Kissimmee River and Lakeside Ranch, both of which slightly exceeded the 100 psi requirement in Scenario 11. Hillsboro is the third most critical site, although it was below the limit in Scenario 11. (See Figure 4.131.)

6.3.3 Artesian Pressure Protection Area (APPA)

The results of the Monte Carlo analysis on the loss of artesian pressure are shown in Figures 6.29 and 6.30. As explained in Section 3.3, one of the performance criteria was that not more than 10% of artesian well flow be lost in the APPA, which consists of Saint Lucie and Martin Counties. As the Monte Carlo simulations finished, each cell was investigated and the loss of artesian pressure was calculated. The number of simulations where more than 10% of the artesian pressure was lost was summed up for each cell in the model. Figures 6.29 and 6.30 each show the percentage of Monte Carlo runs where more than 10% was lost (see upper left images). Note that in both the UF and APPZ, both St. Lucie and Martin Counties are completely blue, indicating fewer than 5% of the runs exceeded the 10% limit. There are a few cells that exceed 5% slightly, but they are not visible with the existing color ramp and at the existing scale. These cells are mostly in the northwest of Martin County and southwest of St. Lucie County. These results show that the distribution of ASR wells in Scenario 11 is very likely to be able to meet this performance measure.

The other three images on each of Figure 6.29 and Figure 6.30 show that the 95% confidence interval is quite small, with the maximum being about 3.4%. In St. Lucie and Martin Counties, the maximum 95% confidence interval is even smaller, less than 2%. The bottom two images on each figure show the upper and lower bound of this 95% confidence interval. The differences between the two are nearly impossible to discern. This is an indication that the number of Monte Carlo simulations was sufficient for the regional nature of the model. Additional simulations would have made little impact to the result.

It is important to remember that this plot represents the worst time step of the 13-year period. The areas in red will lose more than 10% of their artesian pressure at least once during the period. At other times, the head will actually rise and artesian flow will increase.

6.3.4 Drawdown

Drawdown was not a specific performance measure, since there was no specific limit on how much drawdown would be allowable or the distance at which impacts could be felt. However, the drawdown impacts to the neighboring areas were investigated and incorporated into the Monte Carlo simulation. After each Monte Carlo run, the maximum drawdown was computed for each cell of the grid. It is important to note that this magnitude of drawdown is a worst-case condition and would not be found during most of the run period. In fact the figures in Section 4 show that the water table actually rises during much of the period. As the Monte Carlo analysis progressed, the scenarios with greater than 1 foot drawdown, and greater than 5 feet drawdown, were counted for each cell.

Figures 6.31 through 6.34 include an image (top left) of the percentage of Monte Carlo scenarios that had a maximum drawdown greater than 1 foot. Similarly, Figures 6.35 through 6.38 include an image (top left) of the percentage of Monte Carlo scenarios that had a maximum drawdown greater than 5 feet. Like the APPA figures described in the previous section, each figure also shows the half width of the 95% confidence interval and the upper and lower bounds of that confidence interval. There is very little difference between the upper and lower bounds. The half width of the confidence interval is less than 3.5% everywhere. This indicates that a sufficient number of Monte Carlo simulations were run to provide the accuracy desired for a regional model of this scale.

Impacts to the head surrounding the ASR sites are significant. Red areas, indicating nearly all Monte Carlo simulations exceeded 1-foot or 5-foot drawdown, are large. It is likely that maximum drawdown across Glades County, Palm Beach County, Broward County and Lake Okeechobee will exceed 1 foot, with a large part of the area also exceeding 5 feet of drawdown in the UF. Impacts to the APPZ will be similar. Impacts to the LF are centered around the southeast corner of Palm Beach County – most of the county will likely see more than 1 foot drawdown, while only the southeast quadrant will be likely to see 5 feet.

7 SOURCES OF UNCERTAINTY

As with all models, there are numerous sources of uncertainty. Every effort has been made to minimize uncertainty, and where that was impossible, we have endeavored to quantify the impact of the uncertainties on the goals of the model. The purpose of the RASRSM was to investigate the regional effects of the CERP ASR plan. This model was meant to give a broad-brushed, order-of-magnitude estimate of the number of ASR wells which could be placed in the FAS. It cannot be used to look at near-field well effects or at small-scale TDS transport. Local scale modeling and pilot studies (SAJ, in review) are better tools for those types of investigations.

Here we discuss some of the sources of uncertainty in the RASRSM and the possible impact on the model results.

7.1 MODEL SETUP

As discussed in Section 6 of the Calibration Report (NAP, 2011) the model set up introduced a number of uncertainties including,

- time and spatial discretization,
- simplification of the geology,
- interpolation of starting TDS and temperature conditions,
- interpolation of specified head boundary conditions to the SAS and aquifer sides,
- data gaps in regional pumping data,
- inability to calibrate to transport parameters,
- non-uniqueness of calibration (hydraulic conductivity and specific storage).

All of these uncertainties were discussed in detail in the Calibration Report (NAP, 2011). Despite these uncertainties, the calibration of the RASRSM to field data was good and many of these parameters were included in the Monte Carlo analysis, which showed very little variability in the output.

7.2 CONVERSION OF CALIBRATION MODEL TO D13R MODEL

In order to set up the RASRSM-D13R model, the boundary conditions, source/sink terms (regional pumping) and initial conditions were converted from the 2003/2004 or 1993/1994 time periods of the calibration and validation models to the 1965-1977 time period required for the D13R analysis. Generalized data and statistical trends were used to ensure that the conditions in the aquifers were similar to those that existed in the 1960s and 1970s and which informed the selection of ASR pumping rates in the SFWMM-D13R model. The resulting model (run without ASR) was compared to available head data from the 1965-1977 period and found to match fairly well, though not as well as would be required of a calibrated model. The available data was mostly from upper sections of the aquifer system and from the north and west areas of the model domain. The paucity of data in some areas of the model and the fact that model did not always match the data as well as would be desired adds some additional uncertainty to the model results.

7.3 ASR Pumping Data

The SFWMM-D13R model provided daily pumping data for each of the proposed ASR basins. Implementation of daily pumping changes was beyond the scope of this regional model, so the pumping data was averaged over 10-day periods. The averages were calculated so that the total volumes of water injected into or extracted from the aquifers were correct, but the averaging can cause a loss of some high pumping rates, when they are short-lived. Since the performance measures all look at worst-case conditions which generally occur at the end of a long period of injection or extraction, this averaging is unlikely to significantly impact the performance measure results.

The SFWMM-D13R simulation assumed 70% recovery efficiency on injected water. In the RASRSM-D13R, smaller recovery efficiencies were assumed at Hillsboro and in the APPZ and BZ layers. Recovery efficiency is a local-scale effect caused by such processes as mixing of fresh water with the native high-TDS water in the aquifer, buoyancy stratification, local groundwater gradients, etc. Only a highly detailed local scale model could adequately investigate these processes. Field verification of these assumptions can only be effected by pilot studies at the specific site in question.

Recovery efficiency affects the volumes of water which could be removed at each site. However, the APPA performance measure is already a limiting factor on extraction volumes at many sites, so the use of an assumed recovery efficiency will have little impact on the model results. At sites far from St. Lucie and Martin Counties, errors in the recovery efficiency assumptions will impact the volumes that can be removed during dry periods. It is expected that additional near-field study to investigate recovery efficiency will be necessary at each site before construction of the ASR system. This study should include both field pilot studies and local scale numerical modeling as was done for the Kissimmee and Hillsboro pilot sites (SAJ, in review).

7.4 Performance Measures

The use of the RASRSM to investigate the performance measures involved some additional uncertainties. The estimate of the pressures which a pump would be required to overcome assumes that the elevation of the source water is equal to the ground surface elevation at the well location. Pressure calculations ignore headlosses (from pipe flow, pumps, and the treatment system), and skin effects at the well. The use of the Theim equation to account for large grid cells assumes homogeneous, isotropic conditions with an infinite, uniform-thickness aquifer.

The use of the Merritt equation to estimate the percent loss of artesian flow in the APPA also assumes homogeneous, isotropic conditions with an infinite, uniform-thickness aquifer.

The errors introduced by these analyses are probably minor and within the error of the model. Since the purpose of the model is to obtain an order-of-magnitude level accuracy on the number of ASR wells which can be constructed, these estimates and calculations are sufficient. Readers should remember that the recommended numbers of ASR wells may need to be slightly altered as additional study continues.

8 CONCLUSIONS/RECOMMENDATIONS

The RASRSM calibration model was broadened to include the D13R scenario with ASR pumping rates and schedules drawn from SFWMM-D13R. Changes to the design were made to meet PDT-developed performance measures, including the pressure that well pumps would be required to overcome and the effect of the ASR system on the APPA in St. Lucie and Martin Counties. The results show that pump pressure requirements and protection of the APPA can be met with approximately 94 ASR wells in the UF, 37 ASR wells in the APPZ and 101 ASR wells in the BZ if the extraction at sites near the APPA is significantly reduced (Scenario 11). (UF and APPZ wells will have a 5 mgd capacity; BZ wells will have a 10 mgd capacity.) The suggested arrangement of these wells is indicated in Figure 4.127. Although full recharge potential will be available, a significant reduction in the available water for recovery will limit the effectiveness of the system. The model also indicates that this arrangement of wells will result in significant head impacts over a large area of the Floridan peninsula.

Due to the depth and poor water quality in the BZ, it is unlikely that so many BZ wells could be built. Scenario 12 was developed to simulate a more likely scenario including only the UF and APPZ wells (see Figure 1.146). The comparison of these results to the performance measures is only slightly different from Scenario 11 but it involves a significant reduction in storage capacity for the system.

A Monte Carlo analysis of the results of Scenario 11 showed that some additional reduction in the number of wells or the extraction rates may be necessary at a few sites due to pump pressure limitations. The sites most likely to require a small reduction in ASR wells are Lakeside Ranch, Kissimmee River/Paradise Run and Hillsboro (Site 1). It is unlikely that any further reduction will be necessary in protection of artesian conditions in St. Lucie or Martin Counties, though the design for Scenario 11 already includes significant reductions in extraction volumes for several sites around the northeast shore of Lake Okeechobee.

This regional model run makes assumptions about the conditions of the aquifer, the seasonal variations during the 1960s and 1970s and the recovery efficiencies expected from the aquifers. All of these assumptions will need to be closely analyzed through pilot studies at the proposed ASR sites and local scale models to predict the local effects of the ASR well system.

Notes:

The SFWMM-D13R design for the CERP ASR plan divides the system into 6 basins and assigns flows to each basin. The proposed distribution of ASR wells among the basins is shown in the table below.

The CERP ASR Regional Study PDT developed a suite of proposed ASR sites which were selected to be close to water sources and near plots of land owned by SFWMD. The wells for each basin were then parsed out to each of the proposed sites based on the size of property at each site.

Number of CERP D13R ASR Wells Planned for Each Basin	
Caloosahatchee River	44
Lake Okeechobee	200
L-8	10
C-51	34
Central Palm Beach	15
Hillsboro	30
Total	**333**

Notes:

This figure shows the ASR flow rates defined by the SFWMM-D13R scenario for the Caloosahatchee River Basin.

Blue and red bars indicate monthly flow rates in mgd (see left axis).

The black line indicates the available storage volume (in billion gallons) in the aquifer assuming 70% recovery efficiency (see right axis). This line is calculated by cumulatively adding 70% of recharge volumes and subtracting recovery volumes. In the SFWMM-D13R scenario, extraction was not allowed if this volume was less than or equal to zero.

Note that the RASRSM-D13R scenarios used 10-day averages of daily flow rates, not the monthly averages shown here.

The maximum flow rate in this basin is 220 mgd. Since each ASR well is to have a 5 mgd capacity, there are 44 ASR wells assigned to this basin.

Notes:

This figure compares total annual precipitation for the years of the RASRSM-D13R scenario (1965-1977) to the distribution of data for the period 1929-1999. The data for the D13R scenario are well spread across the range of data for the larger period. There are wet and dry years represented in the D13R scenario period.

The Thiessen Sum was calculated by constructing Thiessen polygons for each site and clipping them to the model boundaries. The percentage area represented by each polygon was computed and applied to the annual precipitation to obtain an area-weighted sum of all precipitation in the model area. Polygons for Tarpon Springs and Key West did not intersect the model area and were given a weight of 0% resulting in no impact to the Thiessen Sum.

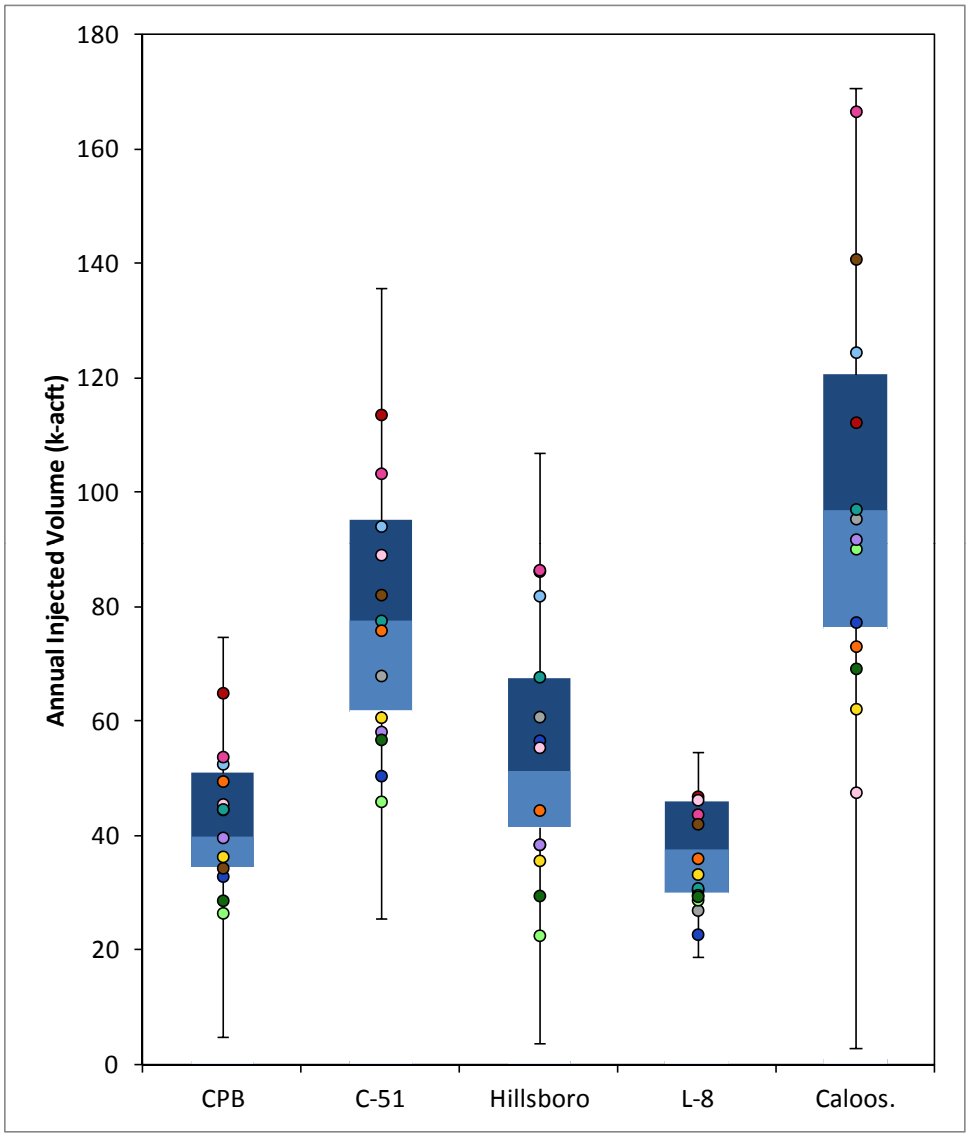
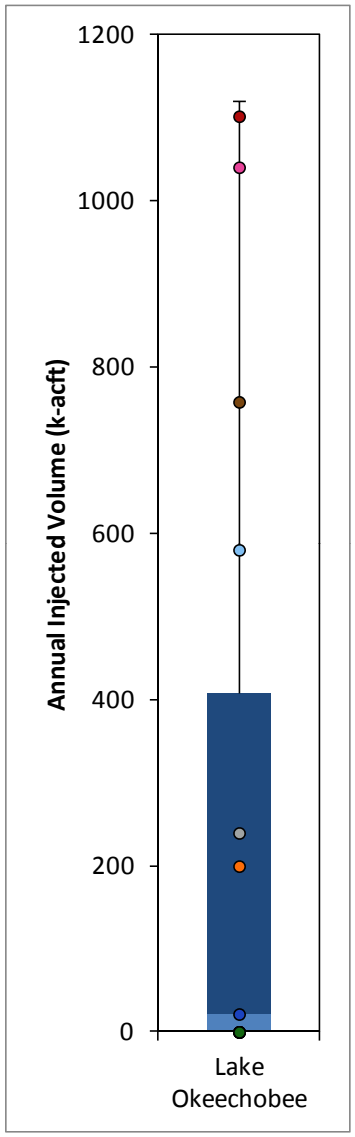
JUNE 2013





Legend

- Daily Average Flow Rate
- 10-Day Average Flow Rate
- Monthly Average Flow Rate

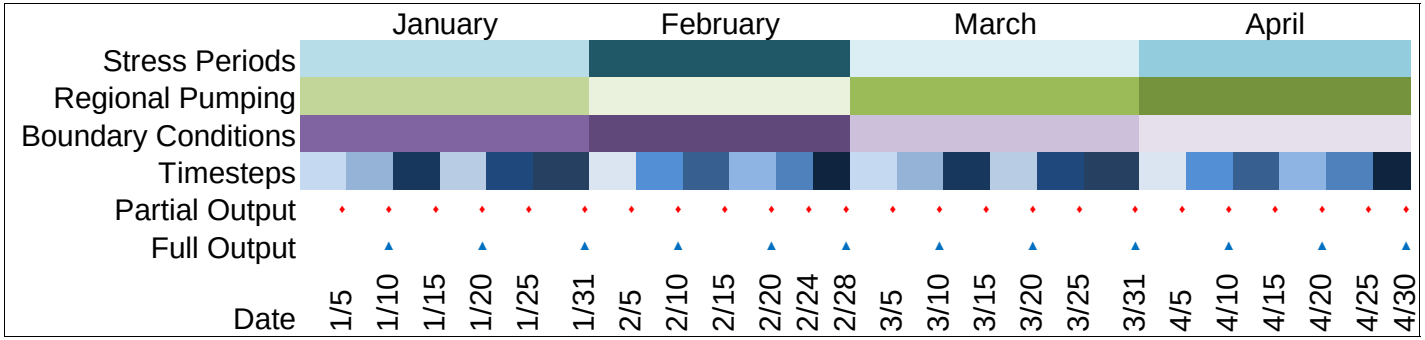
Notes:

Here, an example of the daily SFWMM-D13R output for ASR pumping (injection and extraction) is shown for a three month period with the 10-day and monthly averaged values superimposed.

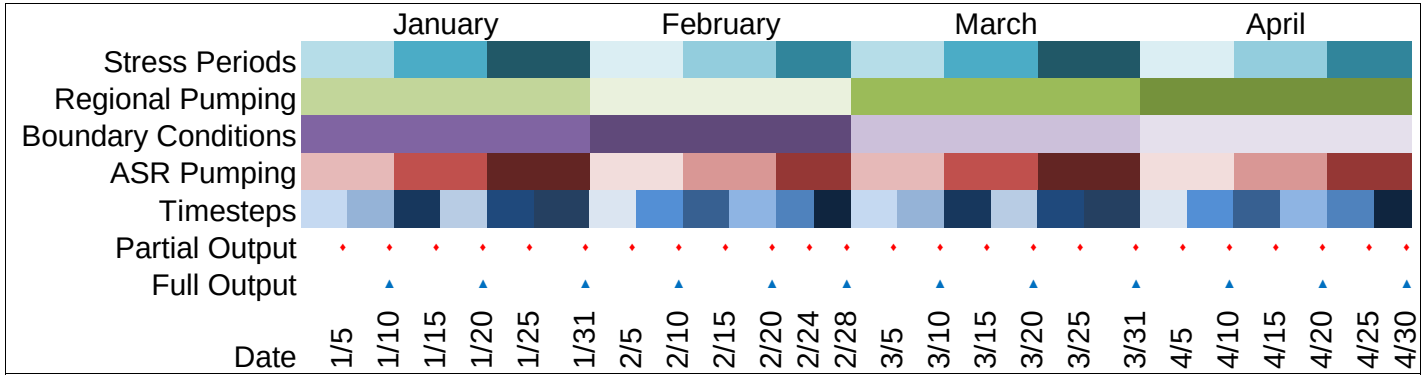
The 10-day stress period was selected for this model because it balances the need to incorporate this detailed data with limitations of computer resources and time constraints.

Generally, the 10-day average does a good job of estimating the flow rates when there are not too many switches between injection and extraction.

Calibration Model (RASRSM)



RASRSM-D13R



Partial Output: Heads at observation points, TDS at all grid cells
Full Output: Heads, fluxes and TDS at all grid cells

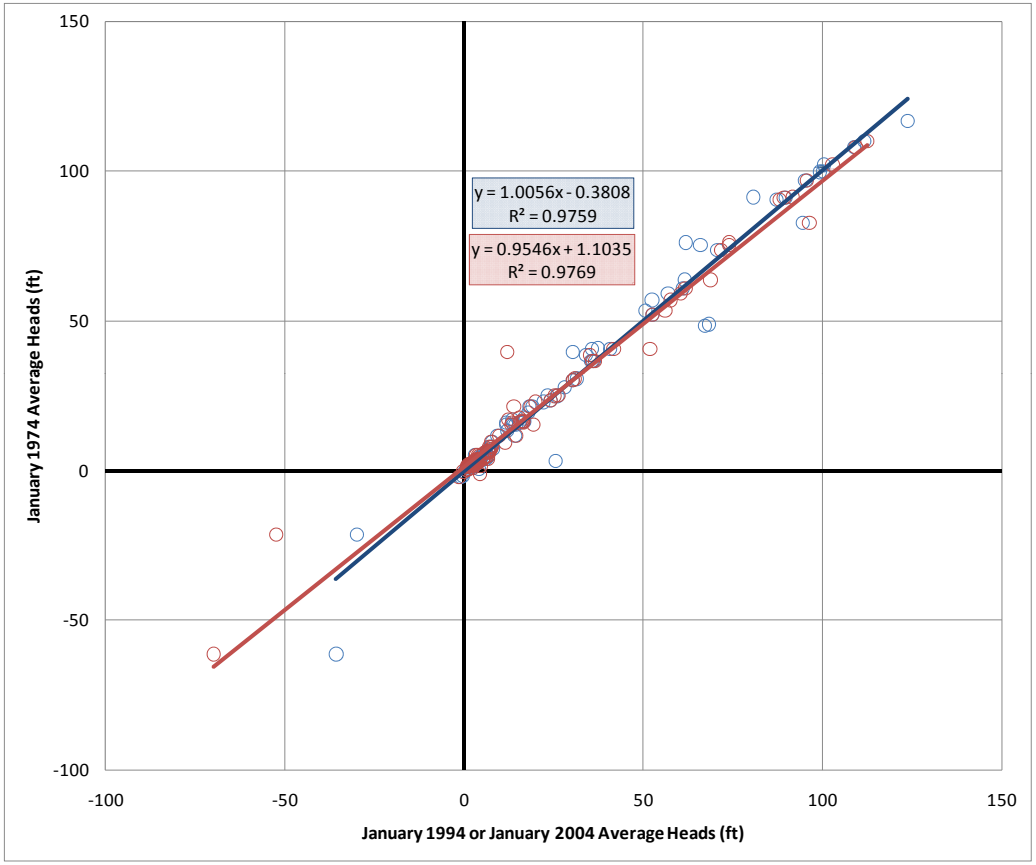
Notes:

These figures indicate, with colored boxes, the lengths of stress periods and time steps for the RASRSM model during calibration and during the D13R runs.

In the calibration model (top figure) stress periods were one month long. Thus, regional pumping and boundary condition heads were averaged over each month and input as step functions. Time steps were 5 days long with full output printed every 10 days.

In the D13R scenarios (lower figure), the daily variation in the ASR pumping was not sufficiently captured by the month-long stress periods. Instead, stress periods of 10 days were implemented and the ASR pumping was averaged over each 10-day period. In order to make use of the boundary condition and regional pumping data used in the calibration model, these parameters continued to be averaged over each month and input as month-long step functions. In this model, the 5-day timesteps were retained along with full output every 10 days.

Note that variations in the lengths of the months necessitate slight variations in the lengths of stress periods and time steps. For example, the last stress period and the last two time steps of February are slightly shorter than others since February is a shorter month.



Legend

- 1994/1974 Average Monthly Heads
- 2004/1974 Average Monthly Heads
- 1994/1974 Trendline
- 2004/1974 Trendline

Notes:

A plot like this was used to determine the best way to estimate the specified head boundary condition for the period 1965 to 1977 when very little head data was available.

The available data for the area of the model was compiled and each month was compared to the same month in the calibration and validation periods.

In this example, January 1974 is compared to both January 1994 and January 2004, when boundary conditions have already been developed by interpolation of the available data. In this case, the correlation to 2004 is better, so the equation y=0.95x+1.1 was applied to the January 2004 boundary condition to estimate conditions in January 1974.

This same process was followed for each month of the 13-year period.

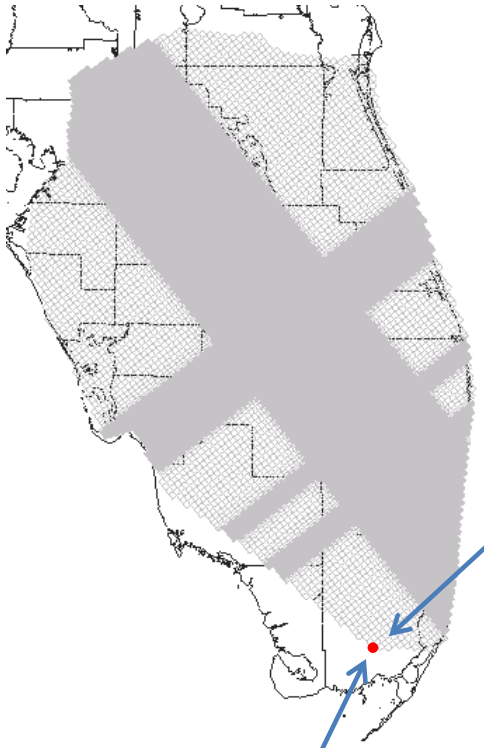
Because of sparse data, all available wells with long term data were combined for this analysis, without accounting for aquifer or location.

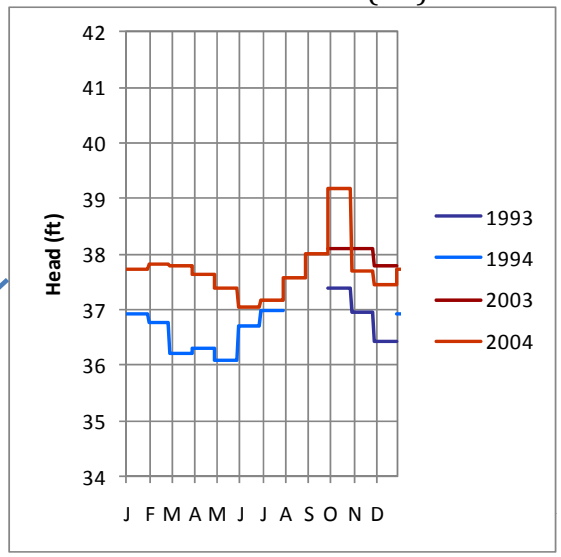
D13R Boundary Conditions: Correlation Example – January 1974

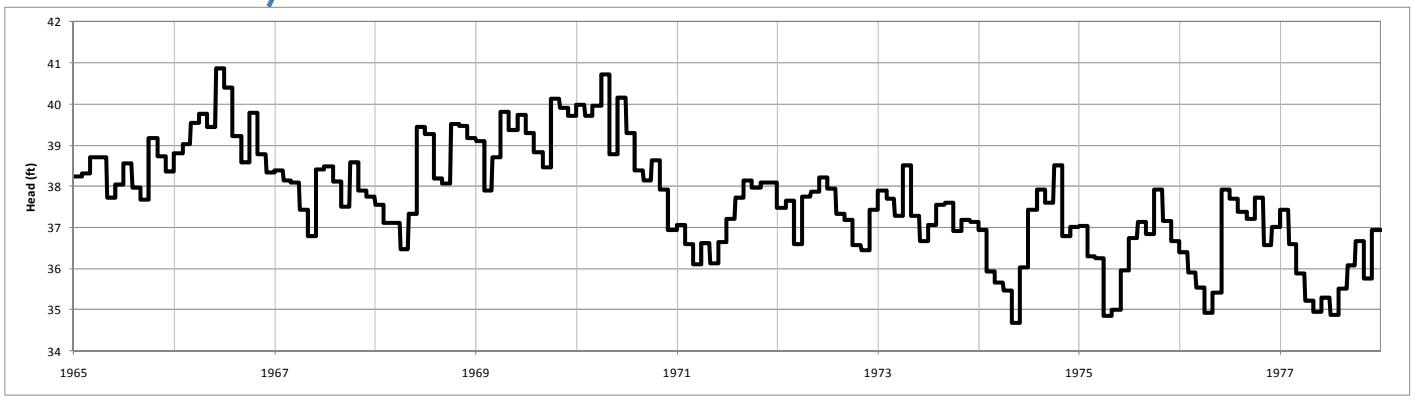
Regional Model Production Scenario Report

Figure 2.12

June 2013







Notes:

The monthly correlations between heads in the RASRSM calibration and validation and the D13R models (see Figure 2.12) were used to estimate the boundary heads between 1965 and 1977 based on the calibration and validation specified heads, which were interpolated from data.

The upper plot shows the boundary conditions applied to the indicated cell for the calibration and validation models. These heads were based on interpolations of available measured head data for the calibration and validation periods (see NAP, 2011).

The lower plot shows the boundary conditions applied to the indicated cell for the RASRSM-D13R. Here, correlations between the heads from periods of calibration and validation and the D13R model period were used to convert the calibration/validation data to estimated head levels during the 1960s and 1970s.

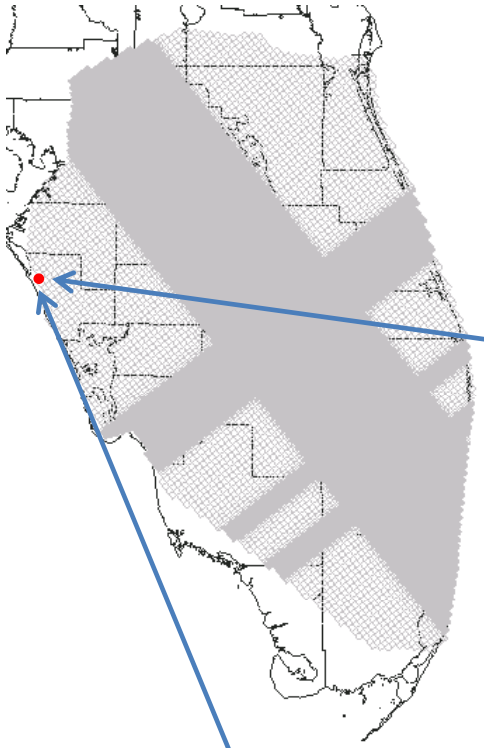
Note that general seasonal trends are retained, but variations are added to reflect wet or dry years

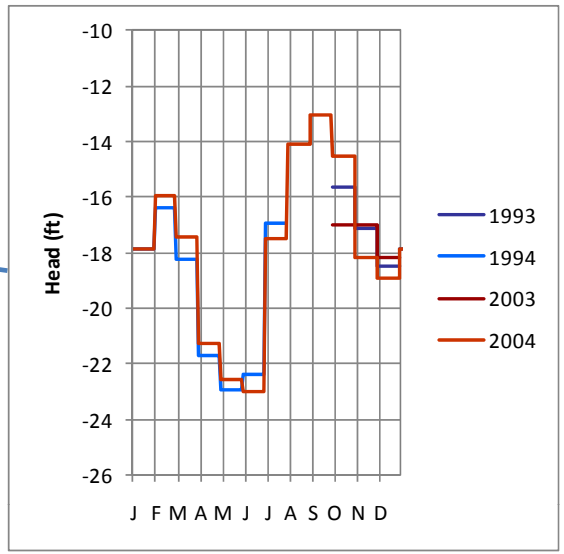
ESTIMATION OF SPECIFIED HEAD BOUNDARY CONDITIONS - EXAMPLE

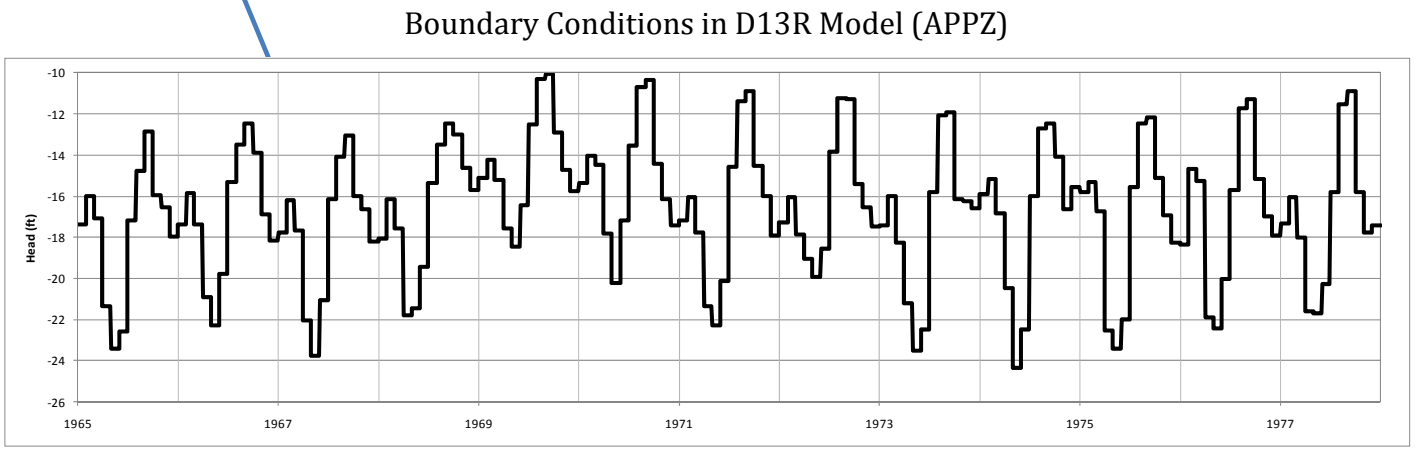
REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE 2.13

JUNE 2013







Notes:

The correlations between heads in months of the RASRSM calibration and validation and the D13R models (see Figure 2.12) were used to estimate the boundary heads between 1965 and 1977 based on the calibration and validation specified heads, which were interpolated from data.

The upper plot shows the boundary conditions applied to the indicated cell for the calibration and validation models. These heads were based on interpolations of available measured head data for the calibration and validation periods (see NAP, 2011).

The lower plot shows the boundary conditions applied to the indicated cell for the RASRSM-D13R. Here, correlations between the periods of calibration and validation and the D13R model period were used to convert the interpolated data to estimated head levels during the 1960s and 1970s.

Note that general seasonal trends are retained, but variations are added to reflect wet or dry years

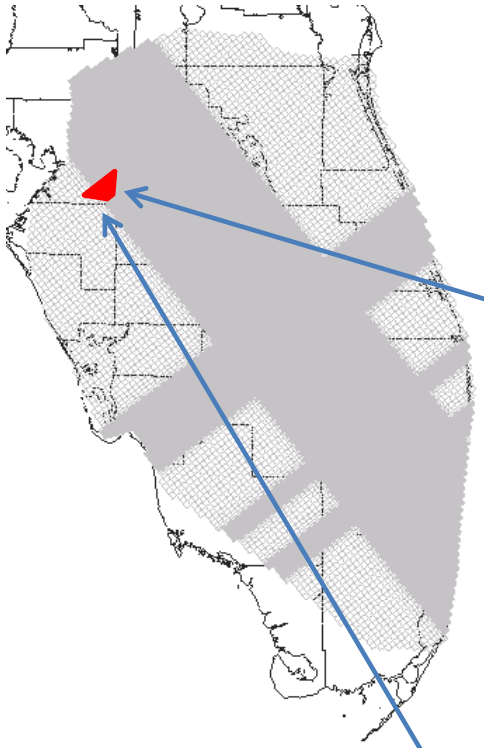
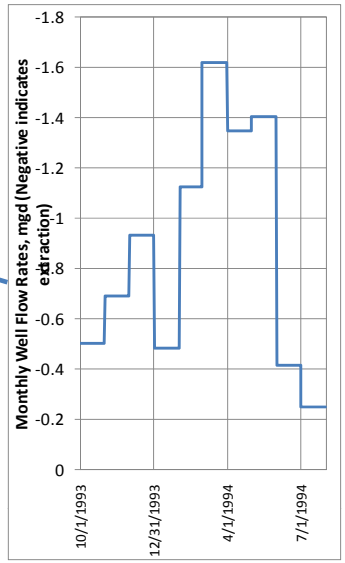
REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE 2.14

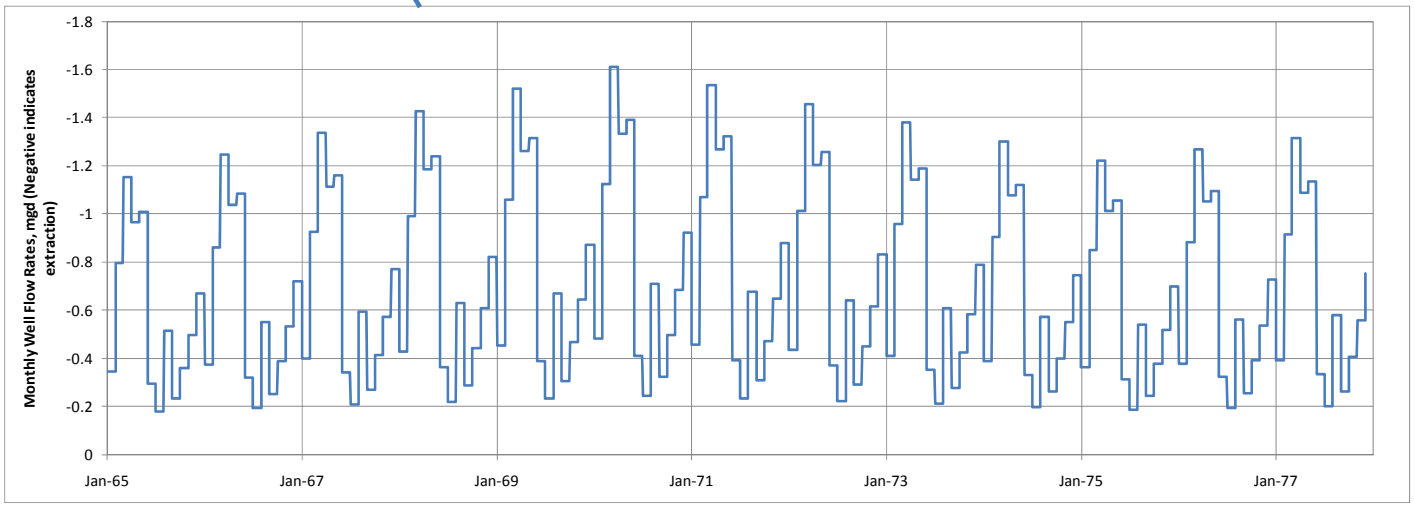
JUNE 2013



Pumping in Validation Model (UF)



Pumping in D13R Model (UF)



Notes:

The upper plot shows the monthly averaged groundwater extraction for a small section of Hillsborough County used in the RASRSM validation model, which covered the period from October 1993 to September 1994.

The pumping from the validation modeling was used with some long term pumping data provided by the USGS Florida Water Science Center to estimate the groundwater extraction for the RASRSM-D13R model for the period from 1965 to 1977. This result is shown in the lower plot for the same section of Hillsborough County.

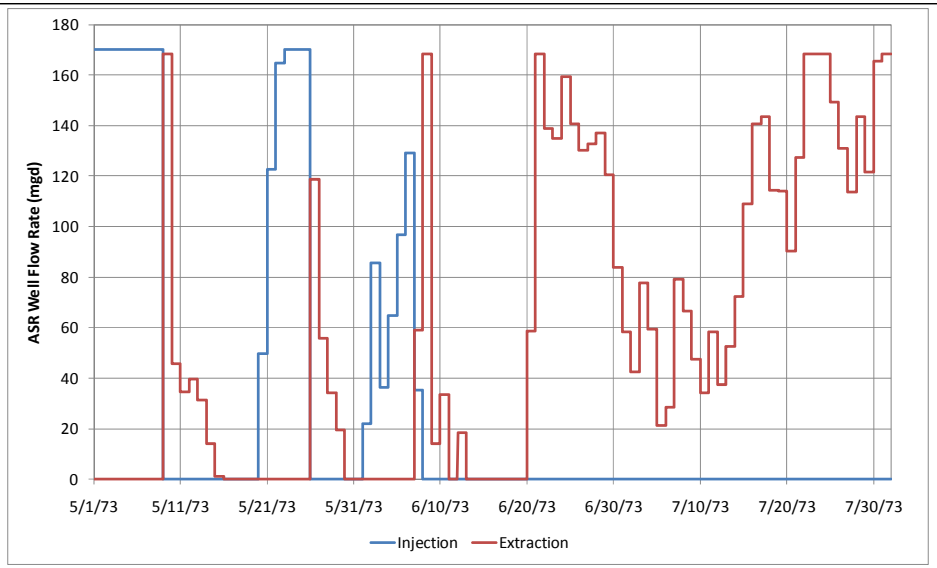
Note that general seasonal trends are retained, but variations are added to reflect wet or dry years

ESTIMATION OF REGIONAL PUMPING - EXAMPLE

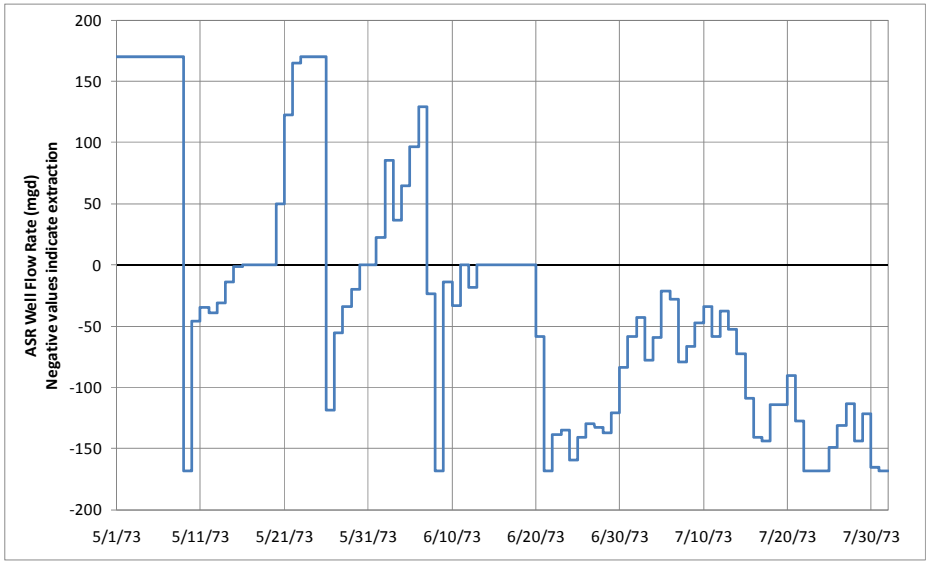
REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE 2.15

JUNE 2013



(a)



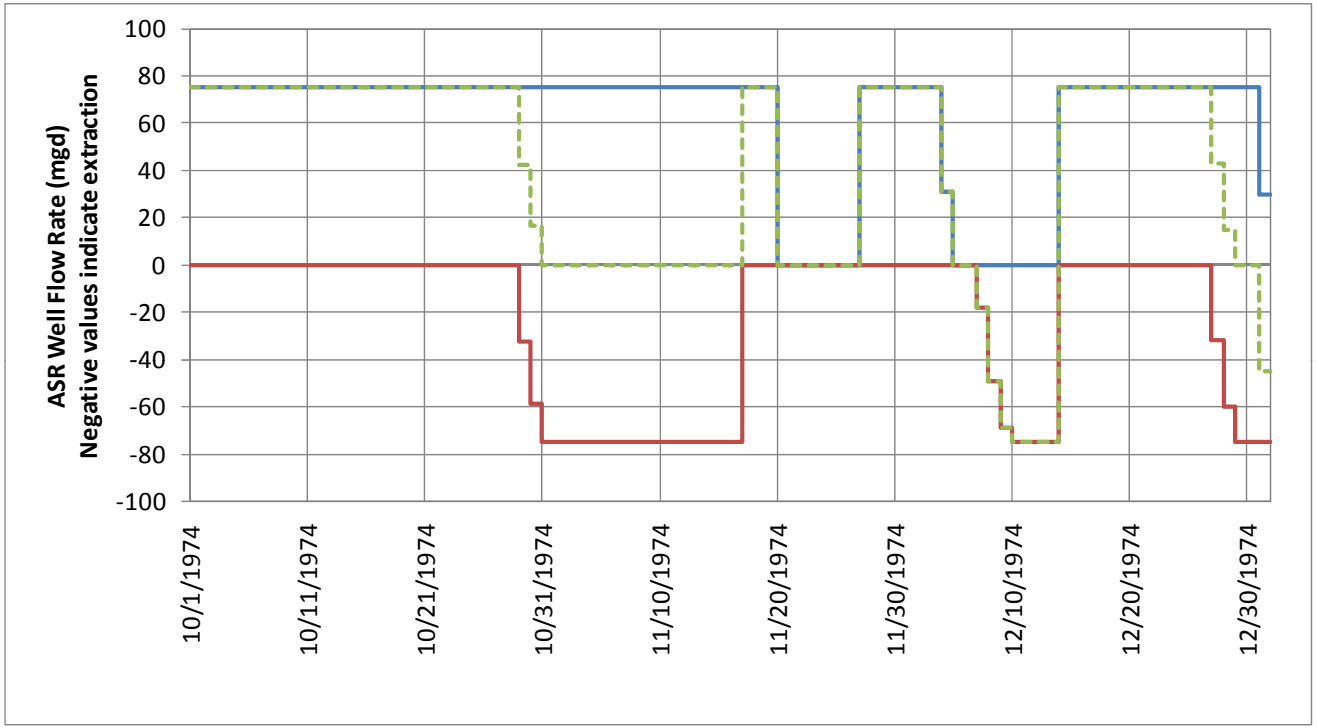
(b)

Notes:

Plot (a) shows the output from SFWMM-D13R for three months at the C-51 ASR basin.

To prepare the data for the regional model, extraction rates were subtracted from injection rates to obtain plot (b), which can be applied to the model.

Notice that on one day (June 7) there is both injection and extraction occurring on the same day.



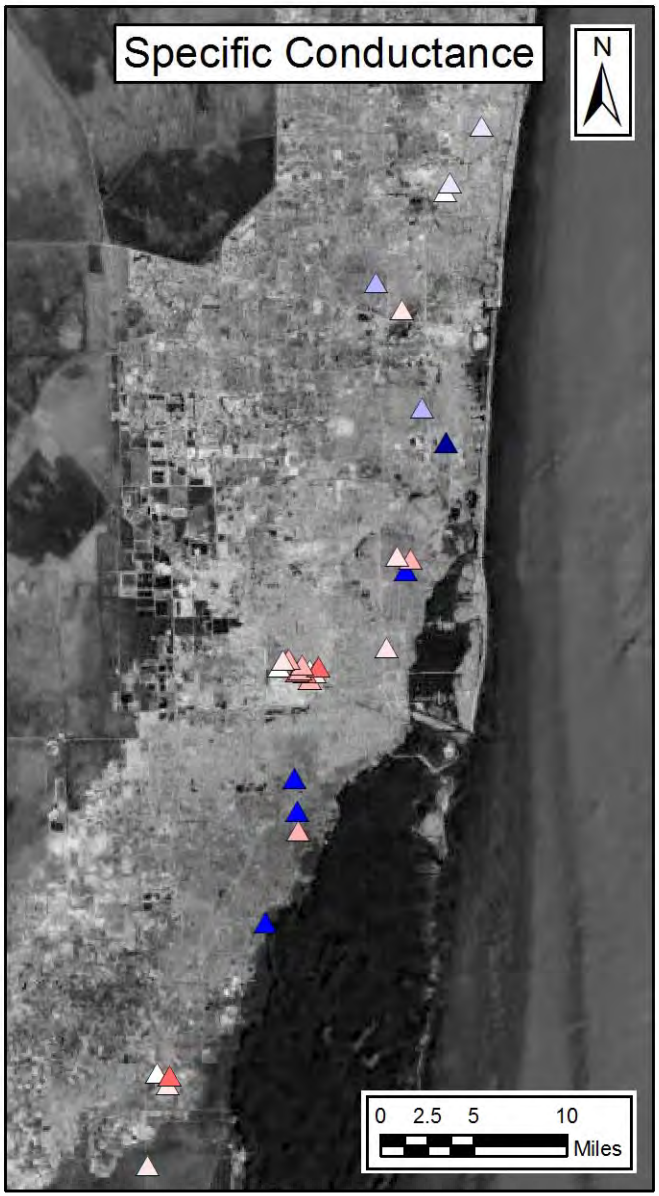
Legend

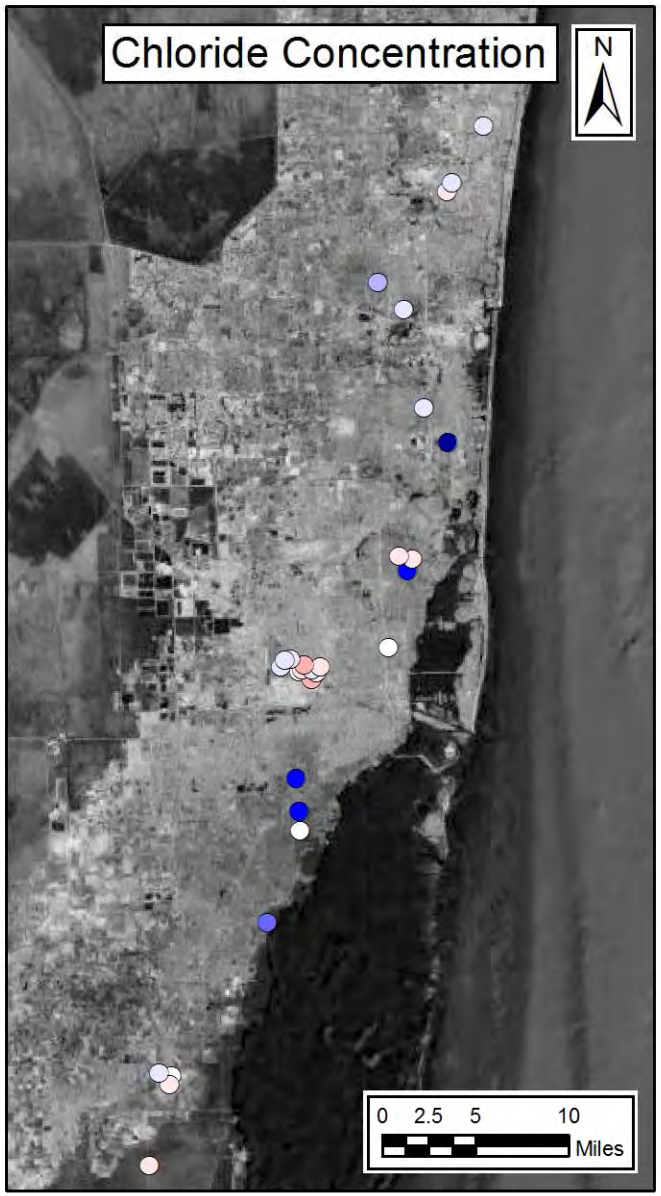
- Injection Rate (positive)
- Extraction Rate (negative)
- Modeled Rate

Notes:

This plot illustrates the problems caused when an ASR well is injecting and extracting at the same rate in the D13R model output. The plot shows the flow rates for a three-month period in the Central Palm Beach ASR basin.

Between October 31 and November 16, the D13R output shows that all wells in this basin were both injecting and extracting at their full capacity (15 wells at 5mgd each). It is unclear how this would be handled in reality. In the model, this results in a net zero flow rate.





40-year Change as a Percentage of Seawater Characteristics

- No significant slope
- -10% to -5%
- -5% to -1%
- -1% to 0%
- 0% to 1%
- 1% to 5%
- 5% to 10%
- 10% to 50%
- > 50%

Mann Kendall analysis was used to determine if a significant slope (confidence 95%) exists.

Sen's slope analysis was used to calculate the median slope in the data.

The median slope (change per year) was multiplied by 40 and then divided by the seawater value to determine the 40-year change as a percentage of seawater. Negative percentages indicate falling values.

Specific conductance of seawater was assumed to be 50,000 uS/cm. Chloride concentration of seawater was assumed to be 19,400 mg/L.

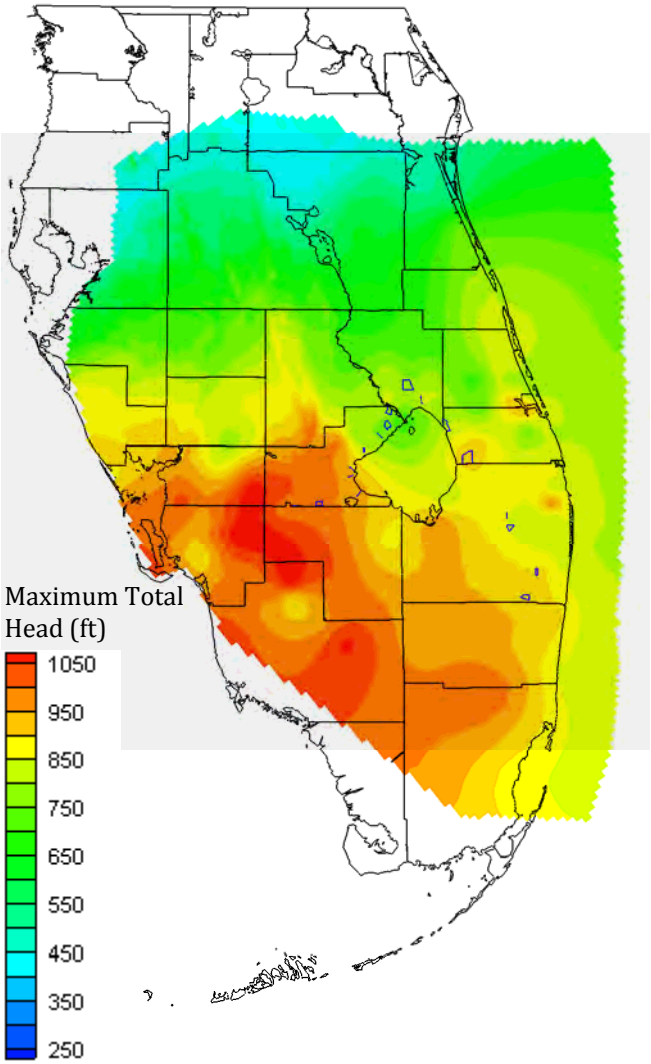
Upper Floridan Aquifer



Avon Park Permeable Zone

Proposed ASR Sites

Notes:

These maps show the maximum allowable total head in the UF and APPZ which will preclude rock fracturing. The calculations are based on the Tensile Method in Geibel, 2012.

Assumptions:

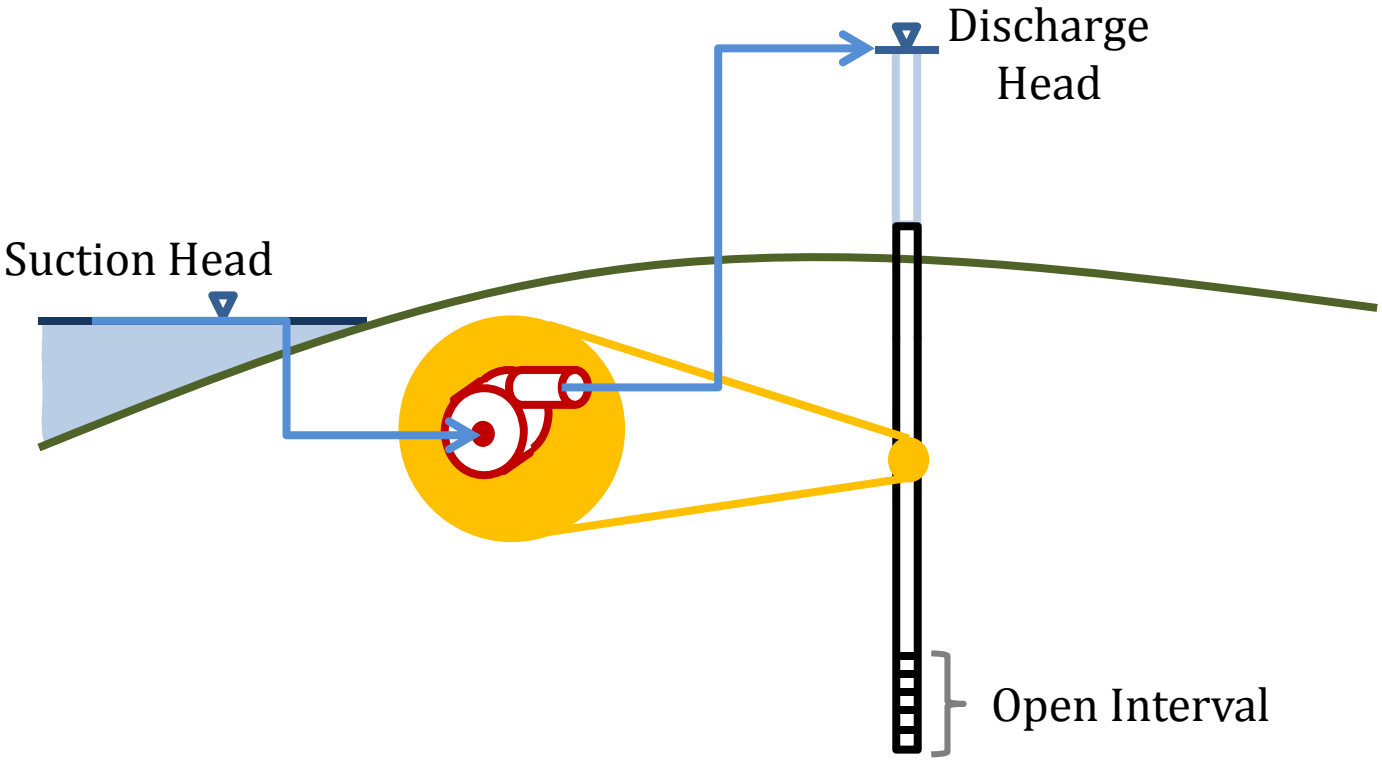
- Ambient pre-fracture water pressure estimated as pressure from steady state February 2004 calibration model
- Specific weight of water: 62.4 lb/ft^3
- Specific weight of all materials: 130 lb/ft^3
- Angle of internal friction: 28.9°

ROCK FRACTURE POTENTIAL
MAXIMUM TOTAL HEAD

REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE 3.1

JUNE 2013



Notes:

This figure shows a simplified schematic of an ASR well pump when it is injecting into an artesian aquifer from a surface water body.

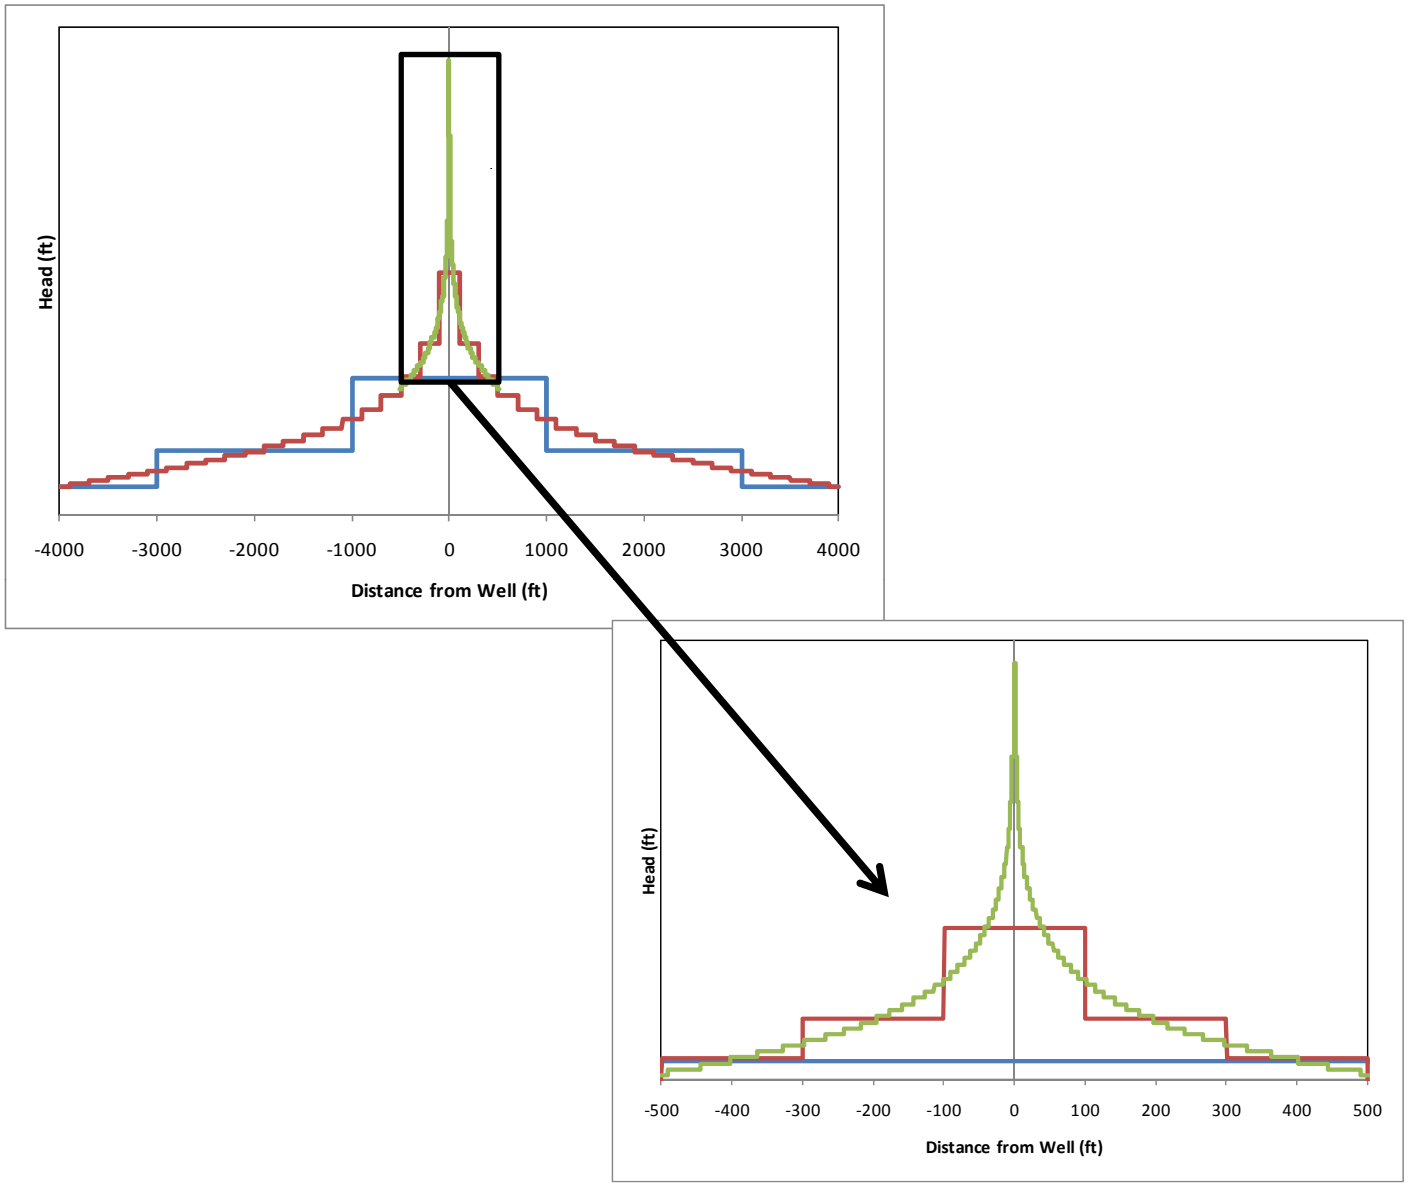
The head the pump must overcome is the difference between the discharge head and the suction head. The discharge head is the model-calculated head in the aquifer at the ASR site. The suction head is estimated to be the ground surface elevation at the ASR well. This assumes that the source water body is near the ASR well site and that there are no headlosses.

ASR Injection Well Schematic (Artesian Aquifer)

Figure 3.2

Regional Model Production Scenario Report

June 2013



Legend

- Uniform Grid; 2000-ft cells
- Uniform Grid; 20-ft Cells
- Variably Sized Grid Cells; 2-ft Cells at Well Location

Notes:

These plots show the effects of grid resolution on the model results near an injection well. Each line represents the results of the same model run on a different grid. Note that the grid with the smallest cells (green line) has a significantly higher head at the well location than either of the two coarser grids.

Since the RASRSM has 2000-ft cells at most of the ASR sites, the head computed at the ASR cells is quite a bit lower than what would be experienced by the pump.

Note that both plots show the same information, but the lower right plot is zoomed in.

5

Notes:

This figure shows the ground surface elevations for St. Lucie and Martin Counties and the surrounding areas. A ridge coming down through Okeechobee County through the corner of St. Lucie County and into Martin County is indicated with a dotted red oval.

Because of this ridge, the calibration model does not predict artesian conditions along the top of this ridge, and only slightly artesian conditions are indicated along the side slopes.

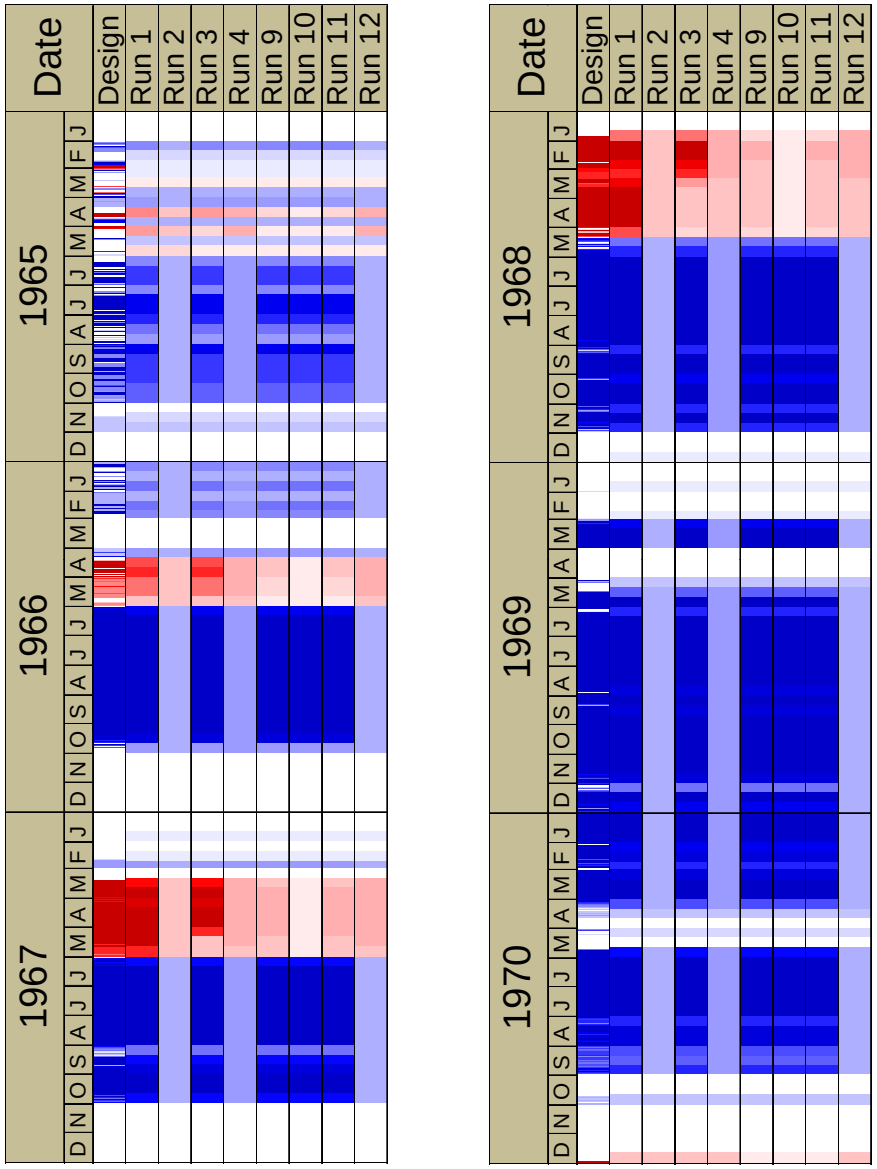
Readers should keep in mind that even small ASR pumping can greatly affect artesian conditions near this ridge.

GROUND SURFACE ELEVATIONS IN SAINT LUCIE AND MARTIN COUNTIES AND SURROUNDINGS

REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE 3.4

JUNE 2013



Notes:

These plots show the pump rates for the ASR wells in the SFWMM-D13R design and in each of the production scenarios for the RASRSM-D13R. Each day is designated with a small stripe, with the earliest part of the year (January) at the top of each box.

Note that the model scenarios were run with 10-day stress periods, requiring constant pumping during each 10-day time period. This accounts for the thicker stripes in the model run columns.

Darker colors indicate greater pumping rates. Blue indicates recharge(injection); red indicates recovery (extraction).

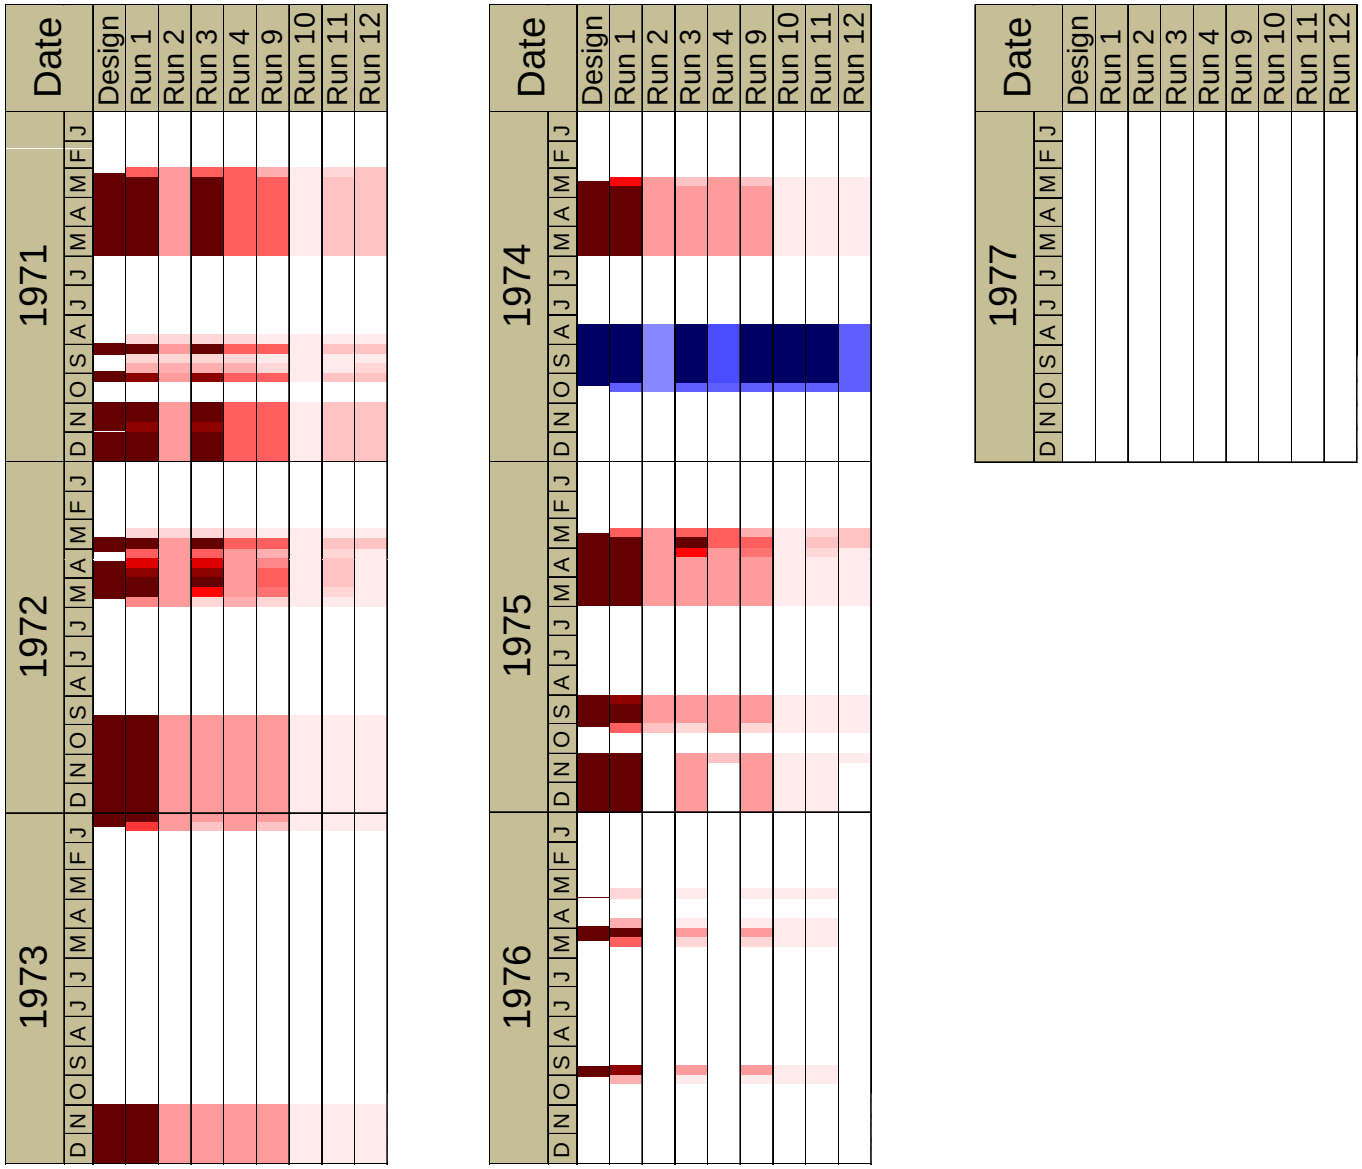
LAKE OKEECHOBEE BASIN ASR PUMPING COMPARED FOR D13R SCENARIOS (1965-1970)

REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE 4.3

JUNE 2013



Notes:

These plots show the pump rates for the ASR wells in the SFWMM-D13R design and in each of the production scenarios for the RASRSM-D13R. Each day is designated with a small stripe, with the earliest part of the year (January) at the top of each box.

Note that the model scenarios were run with 10-day stress periods, requiring constant pumping during each 10-day time period. This accounts for the thicker stripes in the model run columns.

Darker colors indicate greater pumping rates. Blue indicates recharge(injection); red indicates recovery (extraction).

Notes:

Scenario 1 includes all of the 333 ASR wells specified by the SFWMM-D13R design. All are fully penetrating in the UF Aquifer.

This plot shows the highest pressure at each site which the pump would need to overcome in order to inject storage water during the 13-year simulation.

The PDT determined that it would be important to keep this pressure below 100 psi (indicated by the heavy black line).

Note that maximum pressures are shown for all aquifers and all sites even if ASR pumps are not located there for the current scenario.

Notes:

Scenario 1 includes all of the 333 ASR wells specified by the SFWMM-D13R design. All are fully penetrating in the UF Aquifer.

A number of individual sites were chosen from the UF Aquifer at distances of 5, 15 and 25 miles from the proposed ASR well sites. This figure shows the drawdown and "drawup" at each output time step for 12 of these sites.

The plots were calculated by subtracting the heads calculated by the D13R model from those calculated by the no project run. This results in a positive value for "drawup" and a negative value for drawdown.

The colors of the points on the map correspond to the colors of the lines on the plots.

The symbols on the map (x, triangle and diamond) indicate the distance from the ASR sites.

Notes:

Scenario 3 keeps all the wells from Scenario 2 in the UF and adds the remainder of the design wells into the APPZ. This allows the model to match the injection flows. Extraction flows are lower because of the lower assumed recovery efficiency in the APPZ. All wells are fully penetrating in their respective aquifers.

Flow rates are divided evenly among the wells in each basin. Maximum flow rate for any one well is 5 mgd.

Legend

Notes:

Scenario 3 keeps all the wells from Scenario 2 in the UF and adds the remainder of the design wells into the APPZ. This allows the model to match the injection flows. Extraction flows are lower because of the lower assumed recovery efficiency in the APPZ. All wells are fully penetrating in their respective aquifers.

A number of individual sites were chosen from the UF Aquifer at distances of 5, 15 and 25 miles from the proposed ASR well sites. This figure shows the drawdown and "drawup" at each output time step for 3 of these sites.

The plots were calculated by subtracting the heads calculated by the D13R model from those calculated by the no project run. This results in a positive value for "drawup" and a negative value for drawdown.

The colors of the points on the map correspond to the colors of the lines on the plots.

The symbols on the map (x, triangle and diamond) indicate the distance from the ASR sites.

Notes:

Scenario 4 is a reduction of the wells from Scenario 3 which meets the requirements for pump pressure (100 psi). All wells are fully penetrating in their respective aquifers.

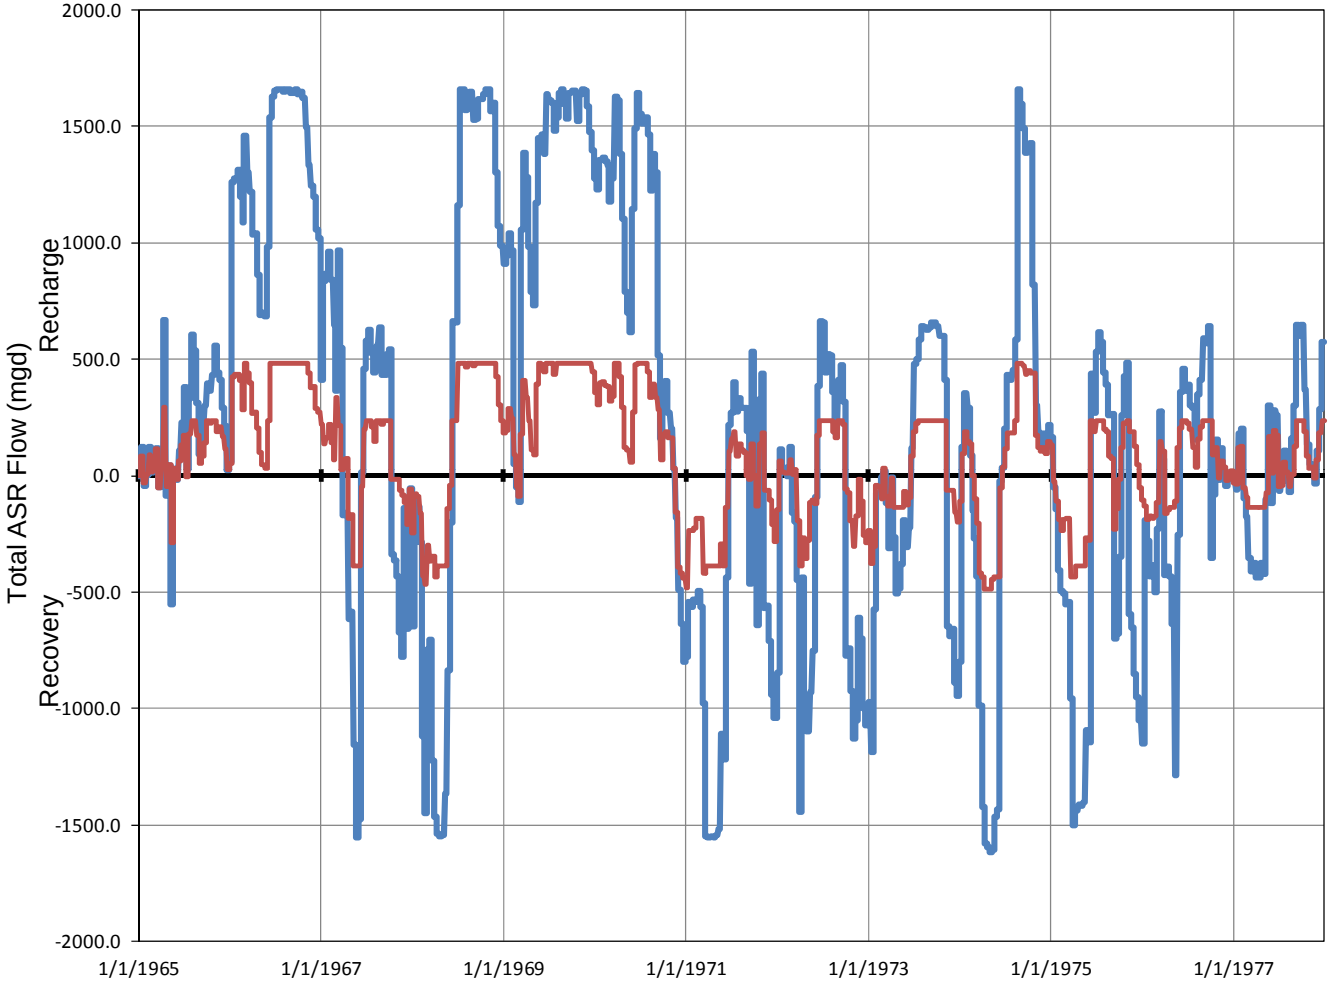
Flow rates are divided evenly among the wells in each basin. Maximum flow rate for any one well is 5 mgd.



Legend

- Scenario 1 – ASR Flux
- Scenario 4 – ASR Flux

Notes:

Scenario 4 is a reduction of the wells from Scenario 3 which meets the requirements for pump pressure (100 psi). All wells are fully penetrating in their respective aquifers.

This plot shows the extraction and injection rates for all wells at all sites for Scenario 1 and Scenario 4. Positive rates are recharge (injection), while negative rates are recovery (extraction).

Notes:

Scenario 4 is a reduction of the wells from Scenario 3 which meets the requirements for pump pressure (100 psi). All wells are fully penetrating in their respective aquifers.

This plot shows the highest pressure at each site which the pump would need to overcome in order to inject storage water during the 13-year simulation.

The PDT determined that it would be important to keep this pressure below 100 psi (indicated by the heavy black line).

Note that maximum pressures are shown for all aquifers and all sites even if ASR pumps are not located there for the current scenario.

SCENARIO 4 – MAXIMUM PUMP PRESSURE REQUIREMENTS

- Modeled Recovery (extraction)

Notes:

Scenario 4 is a reduction of the wells from Scenario 3 which meets the requirements for pump pressure (100 psi). All wells are fully penetrating in their respective aquifers.

These three plots show the comparison between the SFWMM-D13R designed annual injection and extraction volumes at the ASR wells and the actual assigned rates for the RASRSM-D13R for three of the basins.

The table presents the percentage of SFWMM-D13R annual flow rates that are included in this scenario of the RASRSM-D13R. These percentages are not recovery efficiencies.

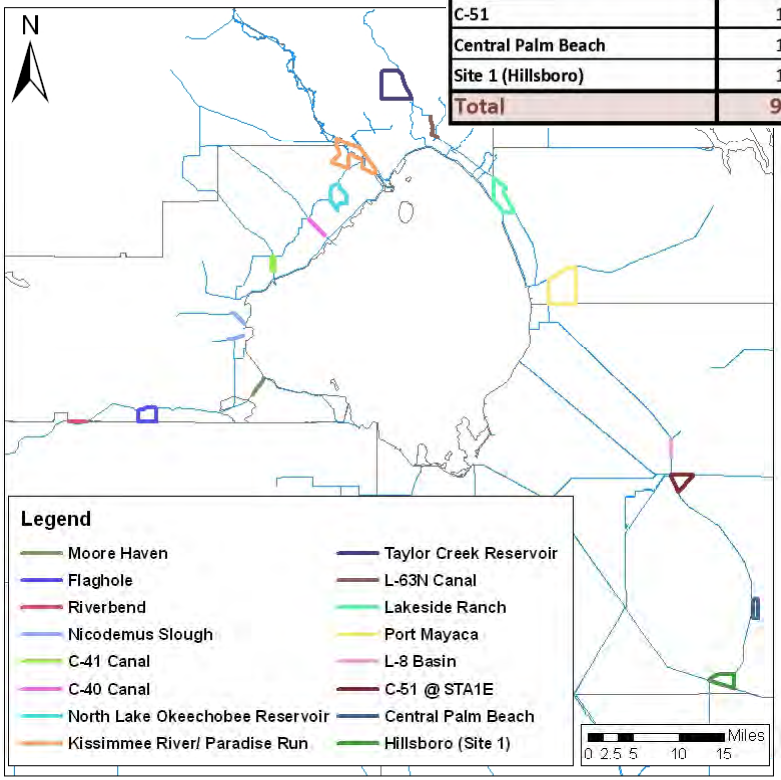
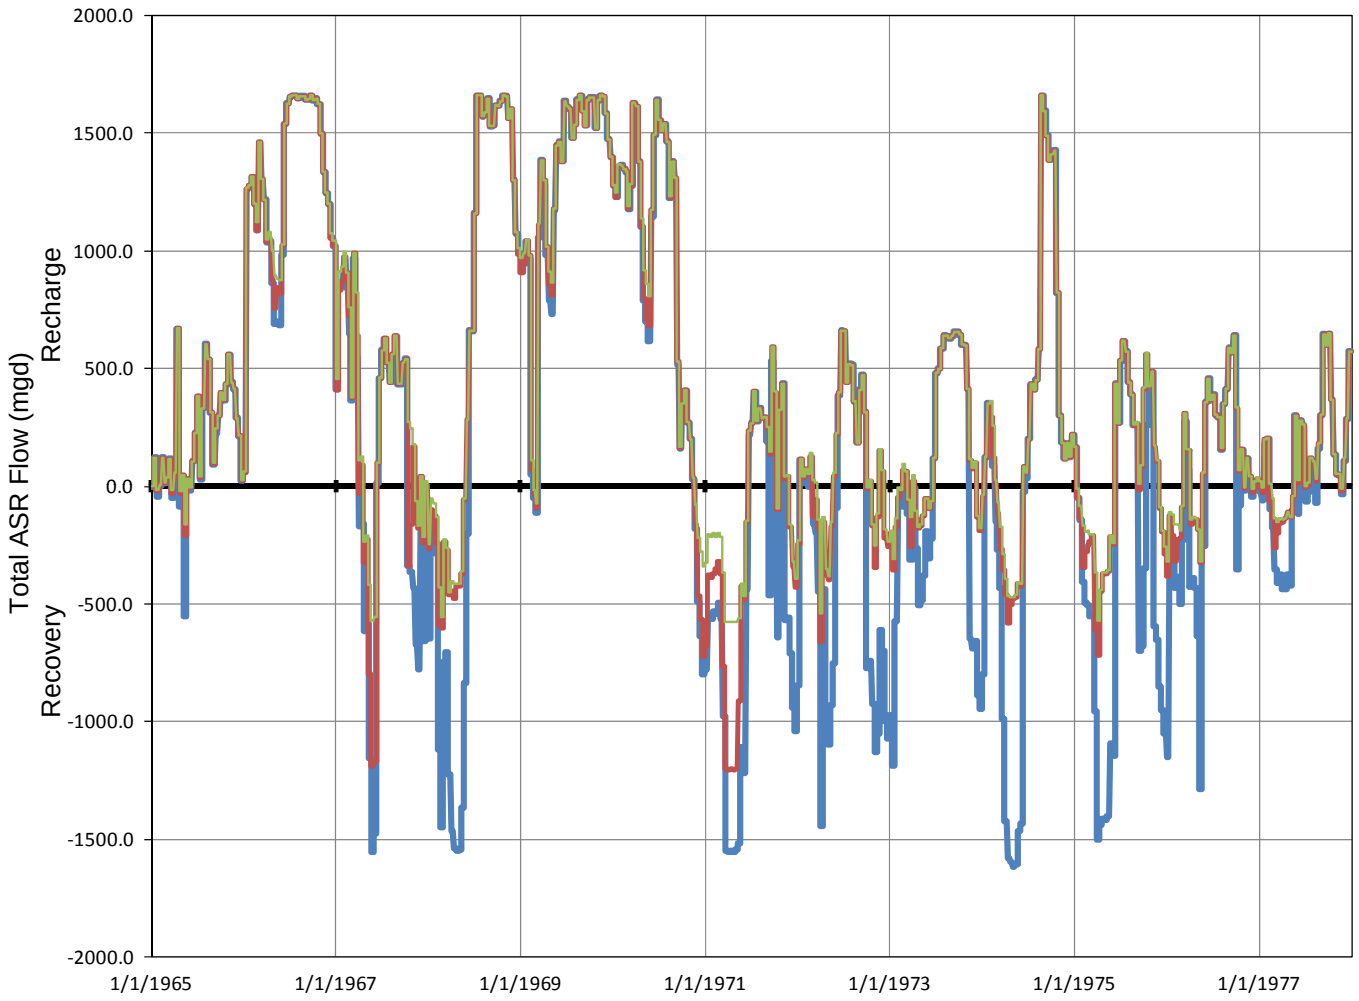
Total		94		37		101		232	333



Notes:

Scenario 9 is similar to Scenario 5 except the BZ wells have been given a recovery efficiency of 0% (no recovery) and have been made 10 mgd wells. Therefore, there are half as many BZ wells. In a few sites, the numbers of wells in the UF or APPZ was adjusted slightly to prevent half wells in the BZ.

Flow rates are divided evenly among the wells in each basin. Maximum flow rate for any one well is 5 mgd in the UF and APPZ and 10 mgd in the BZ.



Legend

- Scenario 1 – ASR Flux
- Scenario 5 – ASR Flux
- Scenario 9 – ASR Flux

Notes:

Scenario 9 is similar to Scenario 5 except the BZ wells have been given a recovery efficiency of 0% (no recovery) and have been made 10 gpm wells. Therefore, there are half as many BZ wells. In a few sites, the numbers of wells in the UF or APPZ was adjusted slightly to prevent half wells in the BZ.

This plot shows the extraction and injection rates for all wells at all sites for Scenario 1, Scenario 5 and Scenario 9. Positive rates are recharge (injection), while negative rates are recovery (extraction).

Scenario 9 – ASR Well Fluxes (Compared to Runs 1 & 5)

Notes:

Scenario 9 is similar to Scenario 5 except the BZ wells have been given a recovery efficiency of 0% (no recovery) and have been made 10 gpm wells. Therefore, there are half as many BZ wells. In a few sites, the numbers of wells in the UF or APPZ was adjusted slightly to prevent half wells in the BZ.

This plot shows the highest pressure at each site which the pump would need to overcome in order to inject storage water during the 13-year simulation.

The PDT determined that it would be important to keep this pressure below 100 psi (indicated by the heavy black line).

Note that maximum pressures are shown for all aquifers and all sites even if ASR pumps are not located there for the current scenario.

Notes:

Scenario 9 is similar to Scenario 5 except the BZ wells have been given a recovery efficiency of 0% (no recovery) and have been made 10 gpm wells. Therefore, there are half as many BZ wells. In a few sites, the numbers of wells in the UF or APPZ was adjusted slightly to prevent half wells in the BZ.

These plots show the maximum reduction in artesian flow at each model cell as a percentage when compared to the flow expected without the ASR project.

Permit rules require that the reduction in Saint Lucie and Martin Counties be less than 10%.

Note the gray area in the northwest corner of the figures, which coincides with a ridge and does not normally have artesian conditions.

Scenario 9 – Maximum Reduction in Artesian Flow Capacity

In a few sites, the numbers of wells in the UF or APPZ was adjusted slightly to prevent half wells in the BZ.

A number of individual sites were chosen from the UF Aquifer at distances of 5, 15 and 25 miles from the proposed ASR well sites. This figure shows the drawdown and "drawup" at each output time step for 12 of these sites.

The plots were calculated by subtracting the heads calculated by the D13R model from those calculated by the no project run. This results in a positive value for "drawup" and a negative value for drawdown.

The colors of the points on the map correspond to the colors of the lines on the plots.

The symbols on the map (x, triangle and diamond) indicate the distance from the ASR sites.

Notes:

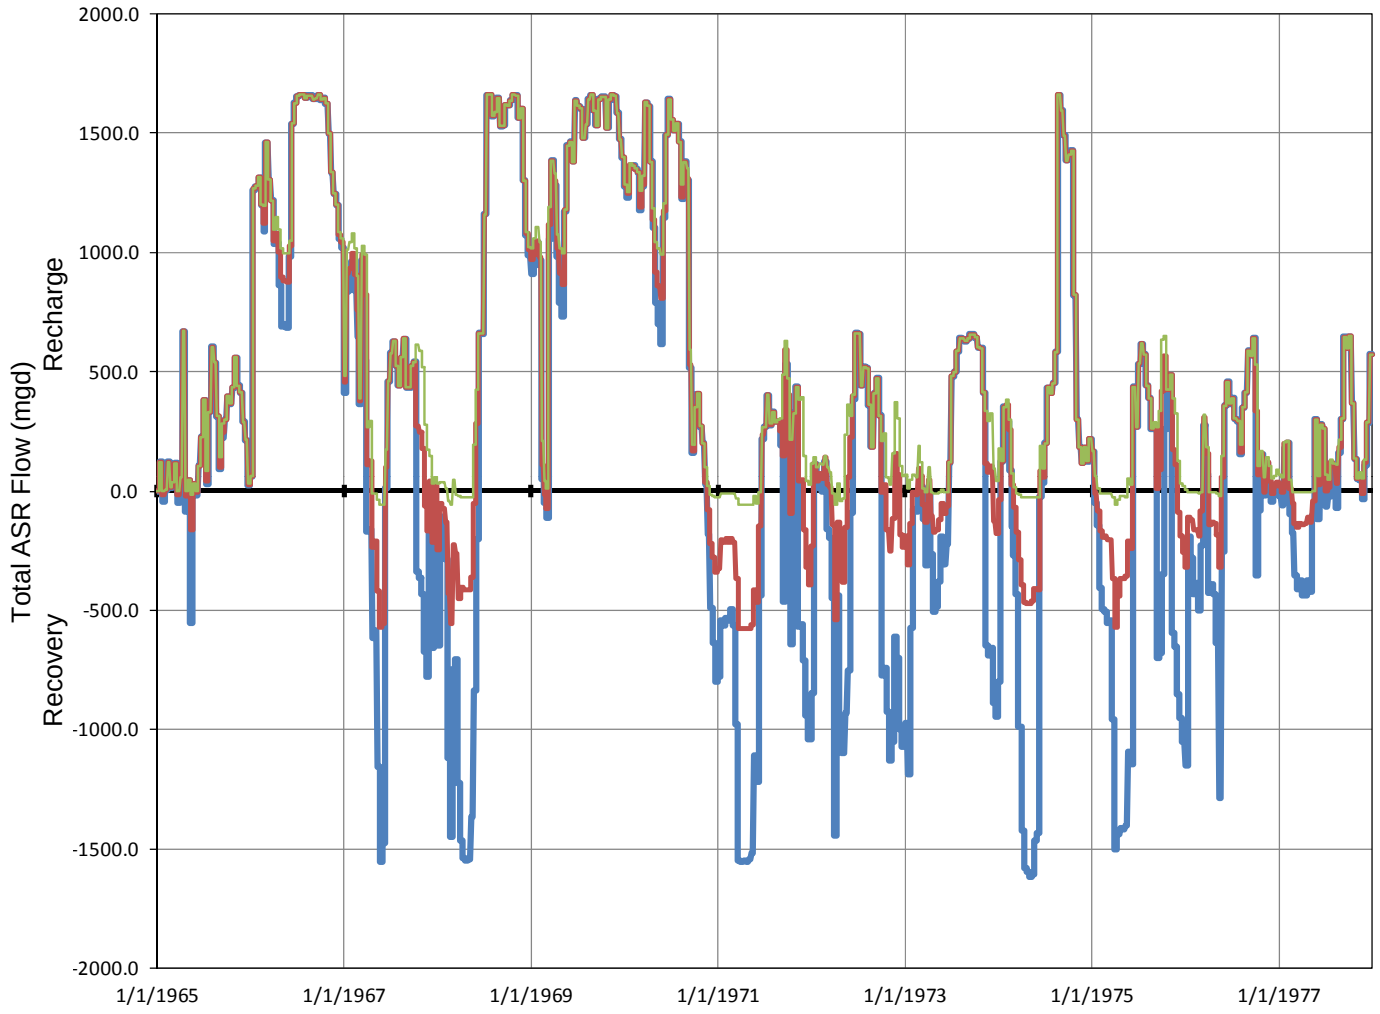
Scenario 10 is a variation on Scenario 9. The numbers of wells and injection volumes are identical, but the extraction volumes have been cut back to reduce drawdown.

Reductions have been applied as a percentage of the Scenario 9 rates as shown in the lower table.

The extraction percentage is the percentage applied to the extraction rates to reduce drawdown effects. This is not the recovery efficiency.

Flow rates are divided evenly among the wells in each basin. Maximum flow rate for any one well is 5 mgd in the UF and APPZ and 10 mgd in the BZ.



Legend

- 15-Mile Distance Locations
- 25-Mile Distance Locations

Notes:

Scenario 11 is a variation on Scenario 9. The numbers of wells and injection volumes are identical, but the extraction volumes have been reduced to meet APPA performance measures.

A number of individual sites were chosen from the UF Aquifer at distances of 5, 15 and 25 miles from the proposed ASR well sites. This figure shows the drawdown and "drawup" at each output time step for 9 of these sites.

The plots were calculated by subtracting the heads calculated by the D13R model from those calculated by the no project run. This results in a positive value for "drawup" and a negative value for drawdown.

The colors of the points on the map correspond to the colors of the lines on the plots.

The symbols on the map (x, triangle and diamond) indicate the distance from the ASR sites.

Notes:

Scenario 12 is the same as Scenario 11 but the BZ wells have been removed.

Reductions have been applied as a percentage of the Scenario 9 rates as shown in the lower table.

The extraction percentage is the percentage applied to the extraction rates to reduce drawdown effects. This is not the recovery efficiency.

Flow rates are divided evenly among the wells in each basin. Maximum flow rate for any one well is 5 mgd in the UF and APPZ and 10 mgd in the BZ.

Legend

- Scenario 1 – ASR Flux
- Scenario 11 – ASR Flux
- Scenario12– ASR Flux

Notes:

Scenario 12 is the same as Scenario 11 but the BZ wells have been removed.

This plot shows the extraction and injection rates for all wells at all sites for Scenario 1, Scenario 9 and Scenario 11. Positive rates are recharge (injection), while negative rates are recovery (extraction).

Scenario 12 – ASR Well Fluxes (Compared to Scenarios 1 & 11)

Notes:

Scenario 12 is the same as Scenario 11 but the BZ wells have been removed.

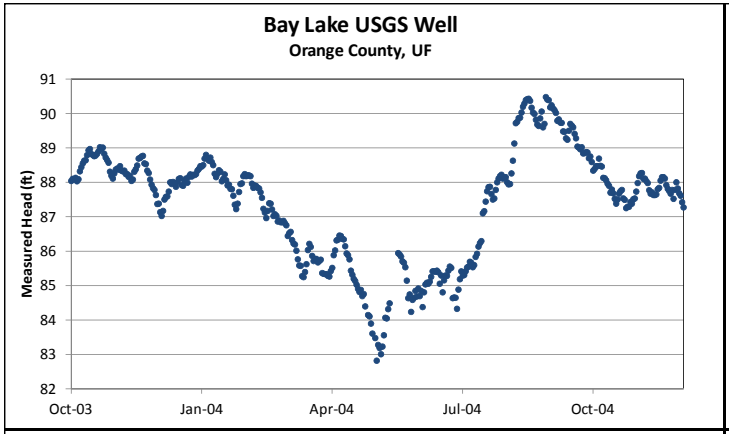
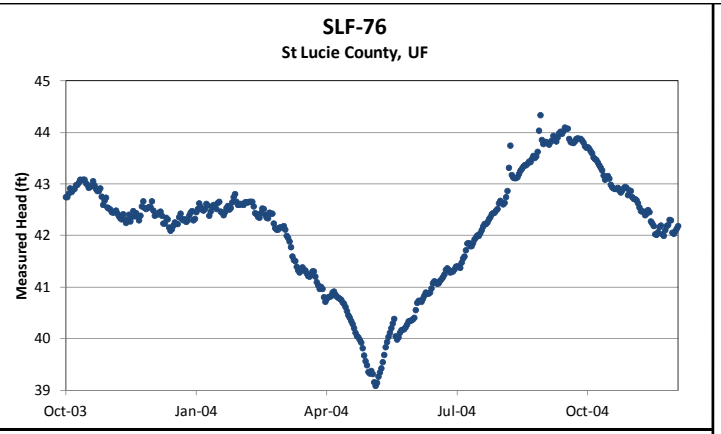
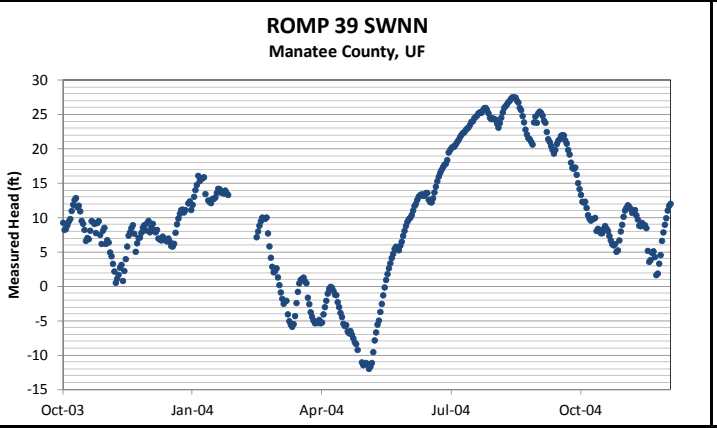
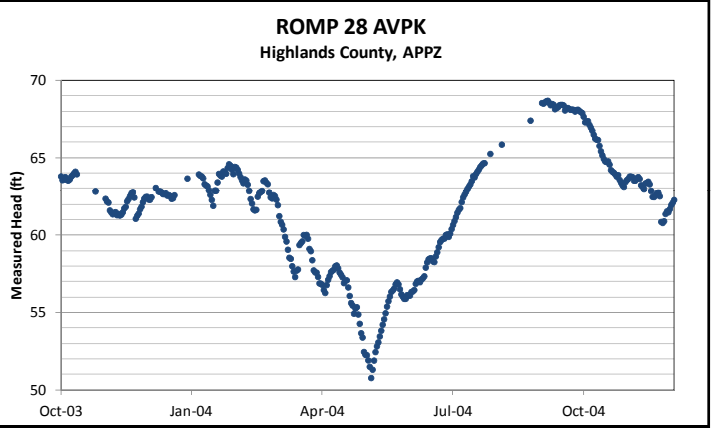
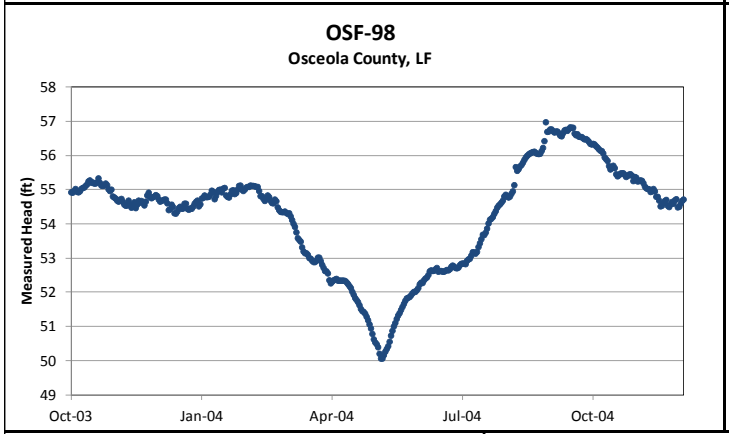
This plot shows the comparison between the SFWMM-D13R designed annual injection and extraction volumes at the ASR wells and the actual assigned rates for the RASRSM-D13R for all basins. The table presents the percentage of SFWMM-D13R annual flow rates that are included in the RASRSM-D13R.

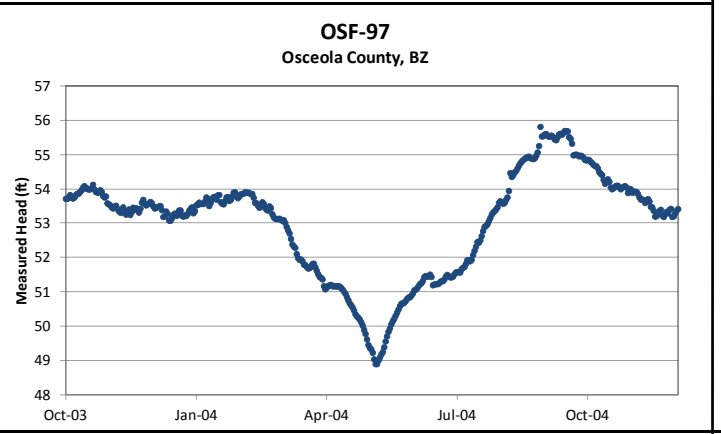










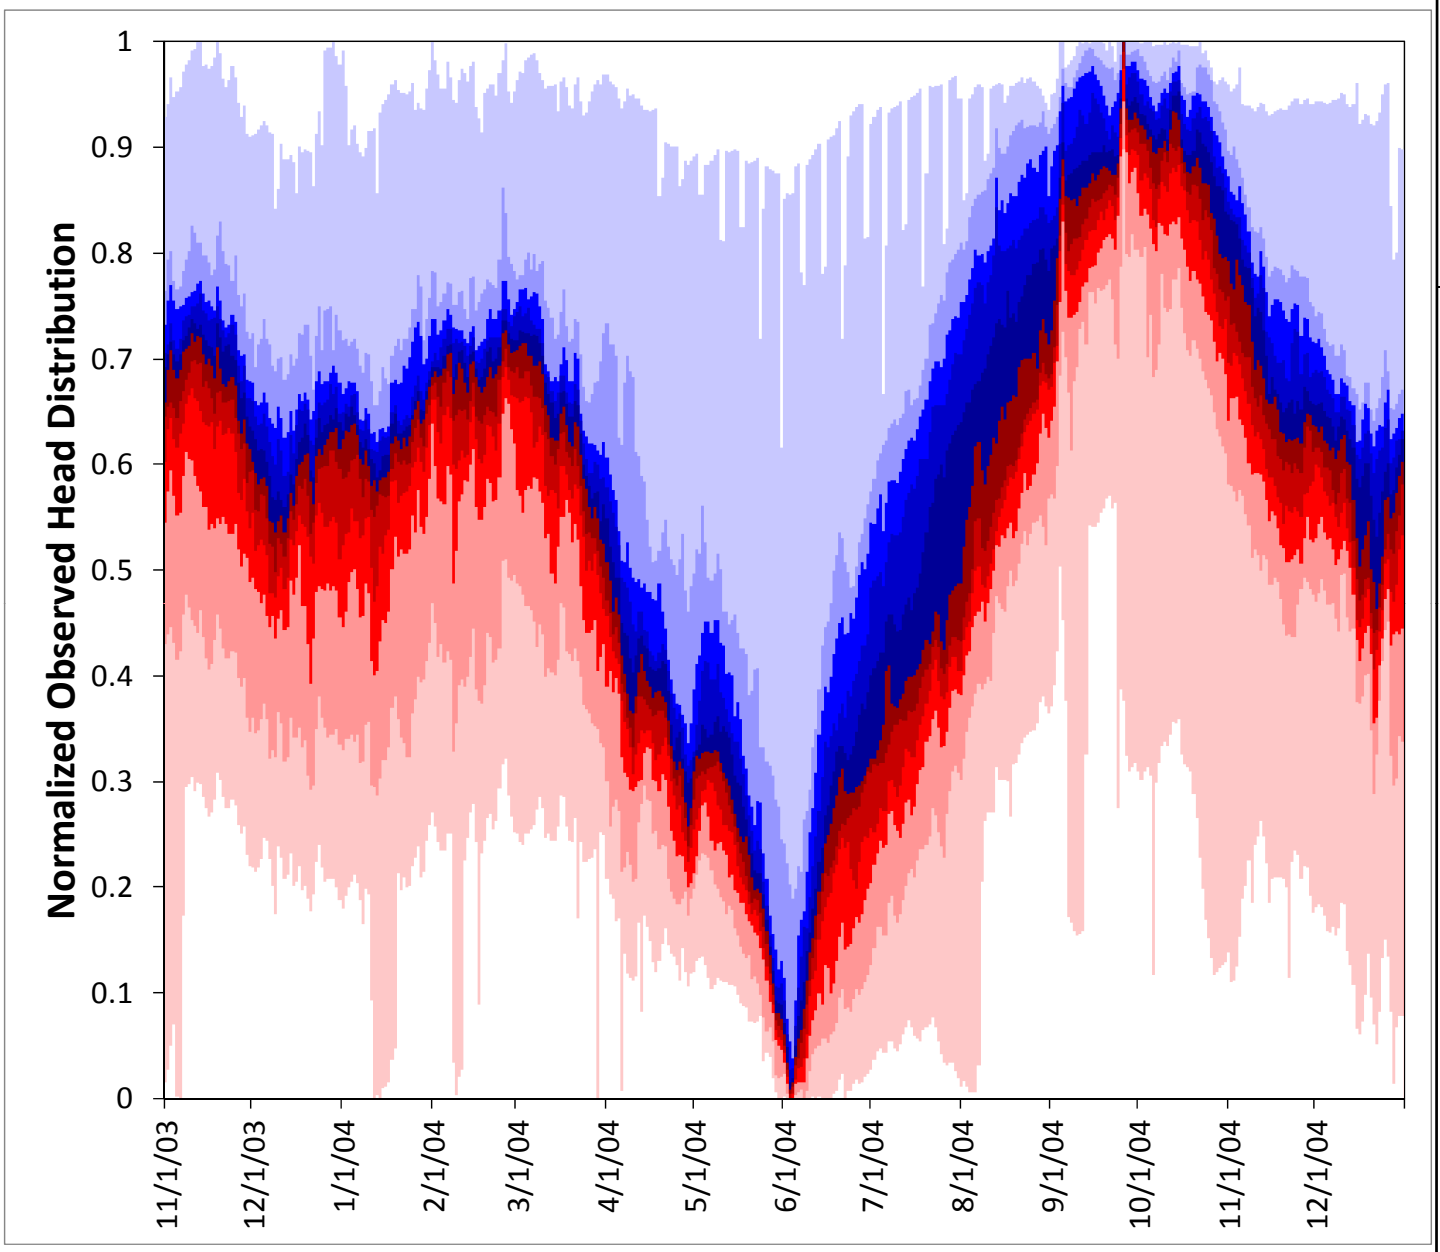


Notes:

These plots show the measured heads at six monitoring wells scattered across the regional domain in all four aquifers for the calibration period.

Notice that despite distances and confining units, all six wells have a steep decline down to a low head occurring between June 2 and June 4. Similarly, all six wells show a more gentle rise to a peak during the end of September 2004 and beginning of October 2004.

Each well has a different magnitude and range of heads and some have more damped responses to regional stresses, but all six have very similar head signatures during this time period.



Normalized Observed Head

Maximum

Median

Minimum

10% of the values fall into each colored box.

Notes:

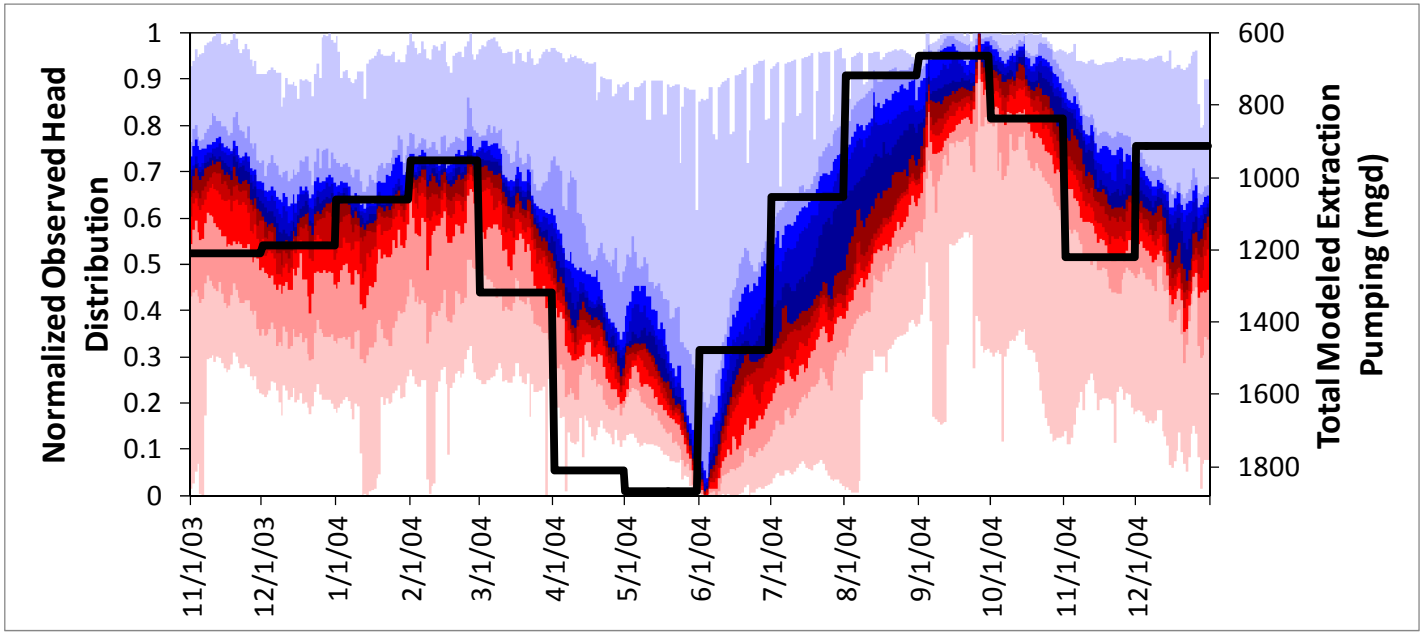
This plot was created by gathering the observed head plots for 74 observation points (see Figures 4.41 through 4.94 in the Calibration Report, NAP, 2011). Points were eliminated from the distribution only if there were fewer than 400 observations made between 10/31/2003 and 12/31/2004.

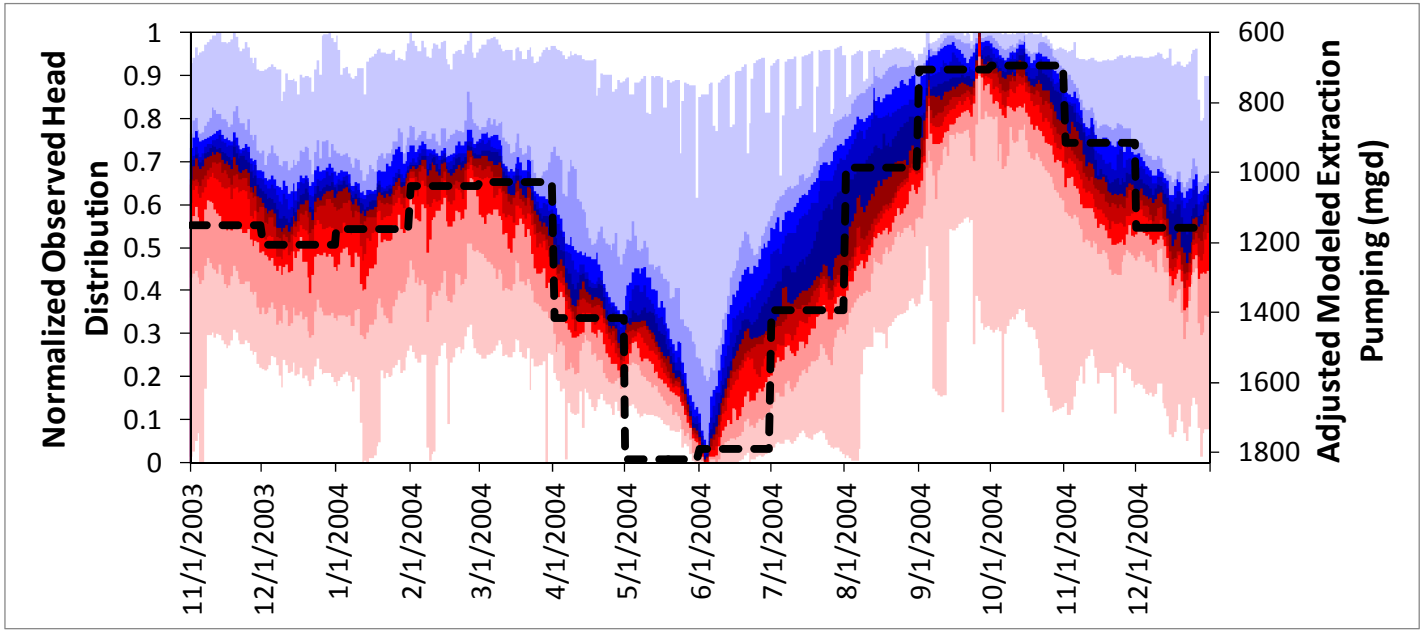
Heads at each point were normalized using the following formula:

$$H_N = \frac{H - H_{\min}}{H_{\max} - H_{\min}}$$

Here, H is the head and subscripts indicate normalized (N), minimum (min), and maximum (max). Minimums and maximums were computed over the 14 month period only. The normalized heads for each day of the period were then separated into bins of 10% and plotted as shown. Note the very narrow range of normalized heads for the middle 80% of the wells.

The head figures in the Calibration Report (NAP, 2011) show that some head plots have outliers, sudden shifts in head, and unusual local phenomena. These largely unexplained errata were not removed in the making of this plot and are the main explanation for the large, outer bands.





Normalized Observed Head

Maximum

Median

Minimum

10% of the values fall into each colored box.

Modeled Extraction Pumping

Adjusted Modeled Extraction Pumping

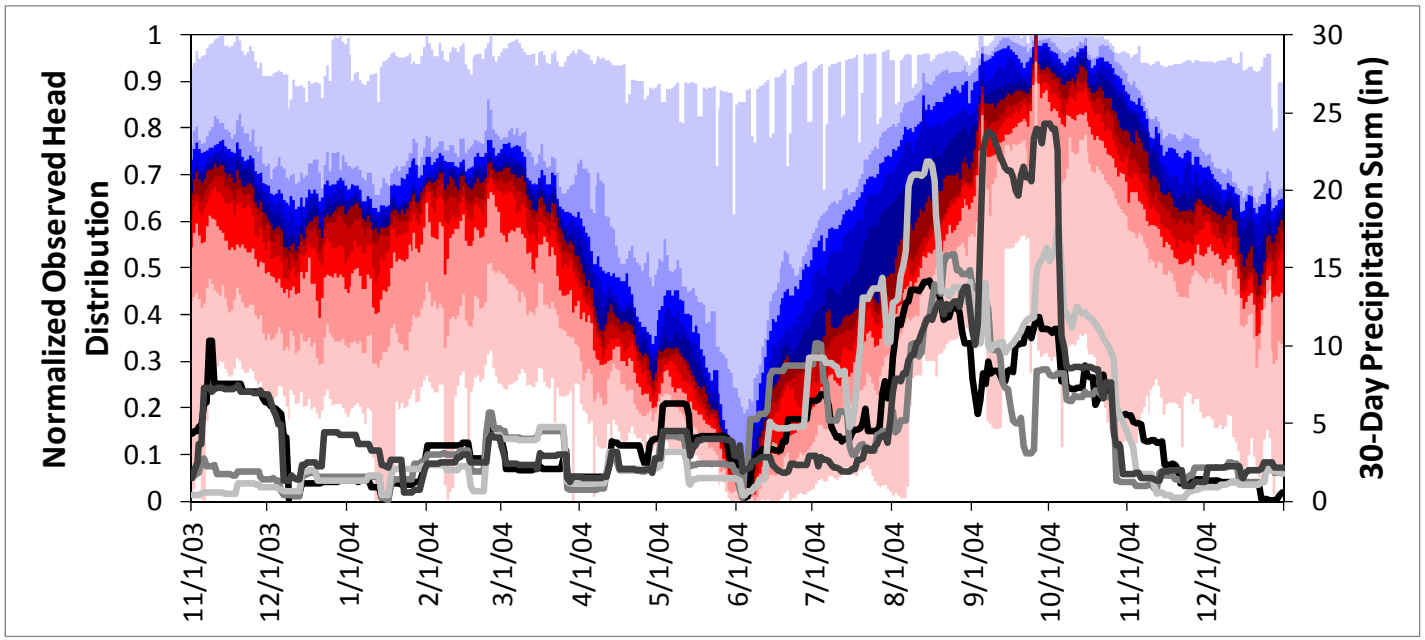
Notes:

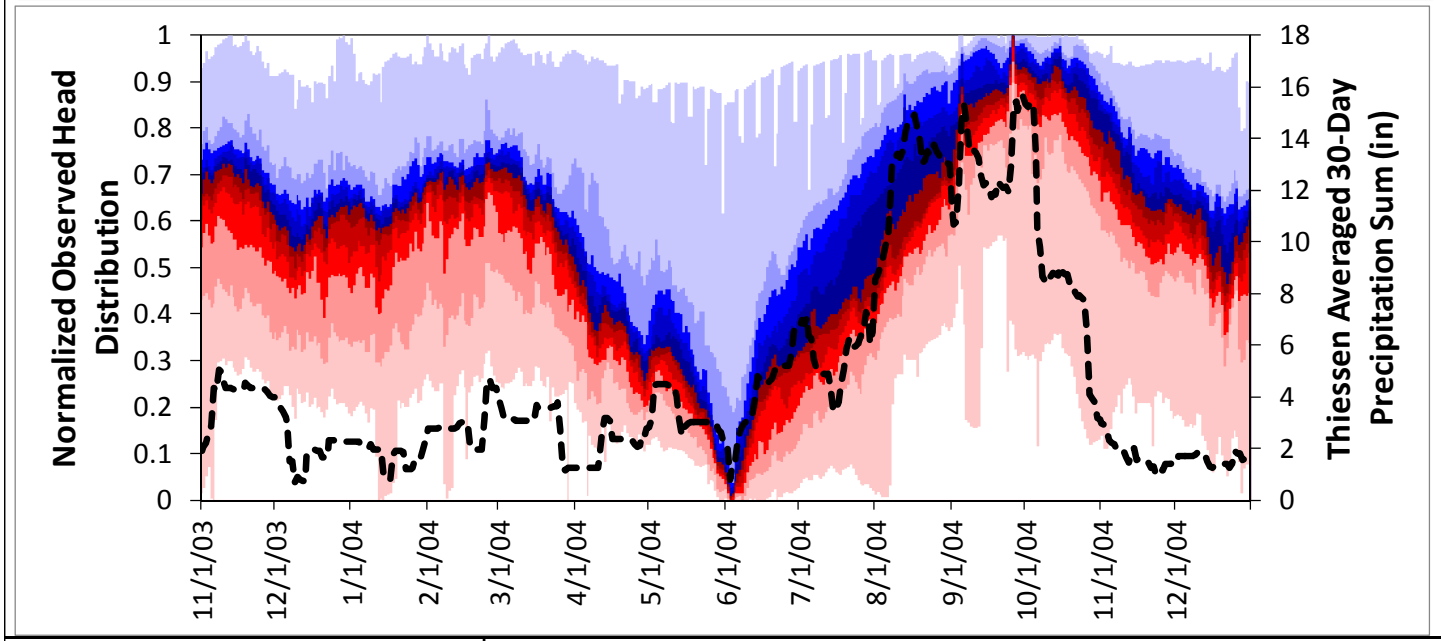
The colored bars on these plots represent the distribution of normalized observed heads for 74 observation points. The development of these bars is described on Figure 4.166.

Each distribution is compared to the modeled extraction pumping. The solid black line (upper plot) represents the monthly averaged extraction pumping for all aquifers and all areas of the domain. Note the correlation to the median of the normalized observed heads is close, but slightly lagged.

The dotted black line (lower plot) is an adjustment of the monthly averaged plot. In this case, 80% of the previous month's pumping is added to 20% of the current month's pumping. Note the very close correlation between the heads measured in the field and the regional extraction pumping.

Note that the extraction rates are labeled on the right axis and the values are arranged in reverse order (high pumping at the bottom of the scale).





Normalized Observed Head

Maximum

Median

Minimum

10% of the values fall into each colored box.

30-day Precipitation Sums:

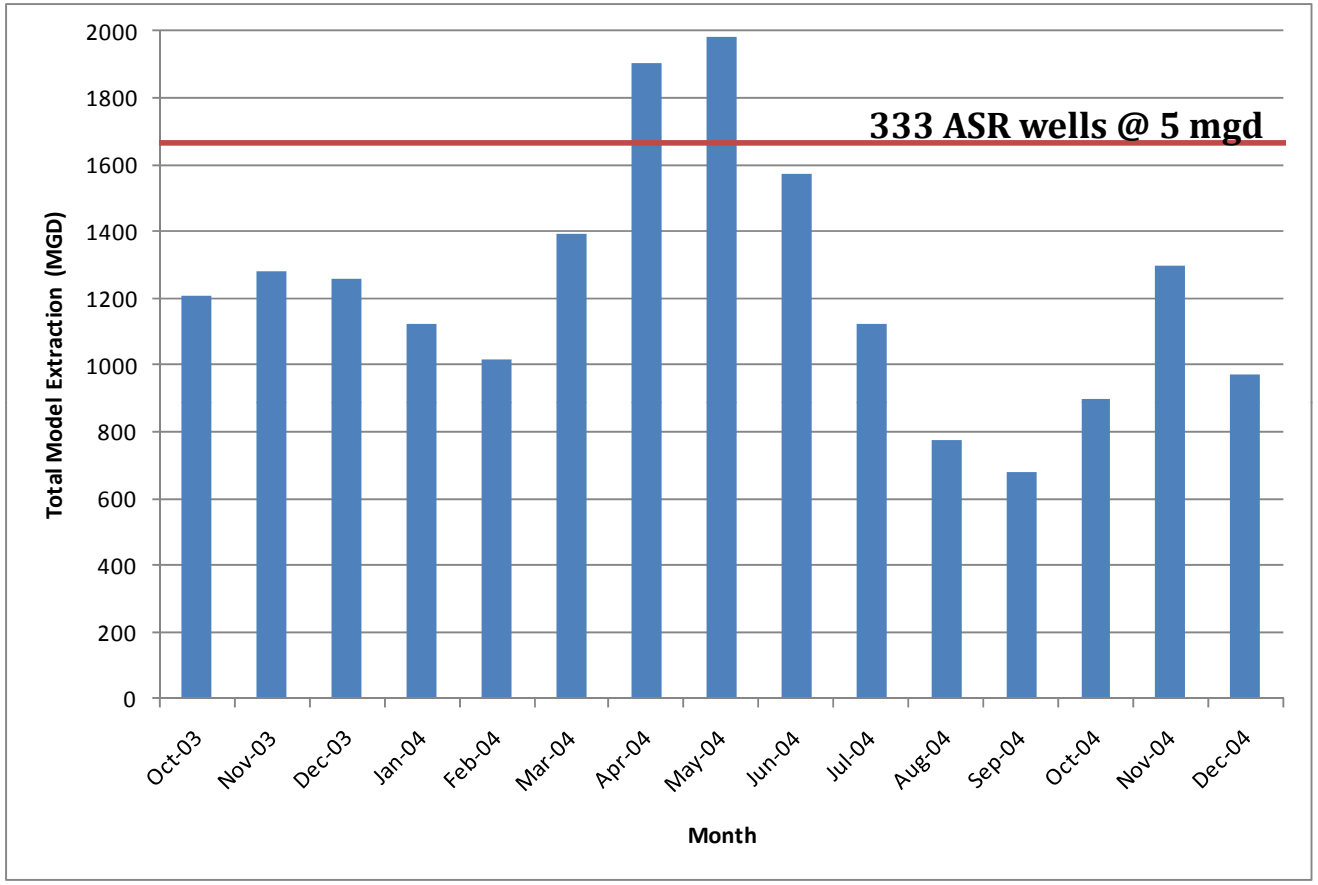
- Miami
- West Palm Beach
- Orlando
- Tampa
- Thiessen Average

Notes:

The colored bars on these plots represent the distribution of normalized observed heads for 74 observation points. The development of these bars is described on Figure 4.166.

Each distribution is compared to the precipitation. Daily precipitation data was available for four airports from National Climatic Data Center, 2012). Precipitation data has been smoothed by summing the previous 30 days of precipitation. The Thiessen average precipitation (lower plot) was calculated by comparing the Thiessen polygon areas (clipped to the model domain) to the total area of the model domain.

Note the poor correlation between head and precipitation during the winter and spring of 2004 and the fall of 2004. Good correlation is found during the summer of 2004. Precipitation is probably a major factor in the sudden rise in head seen at nearly all observation wells beginning in early June 2004.



Notes:

This plot shows the total extraction volume from all regional pumping wells (agricultural, public water supply, industrial, etc.) for each month of the calibration period (October 2003 – December 2004) compared to the total extraction volume which would be realized if all 333 proposed ASR wells were to extract at full capacity together.

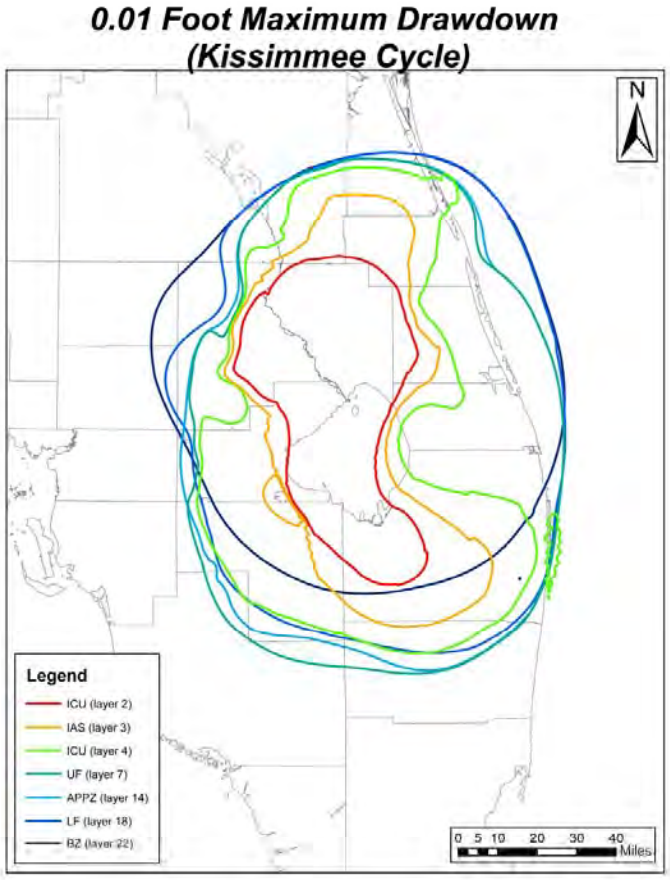
Note that the ASR system as proposed represents an enormous amount of water when compared to current water use in the Floridan aquifers.

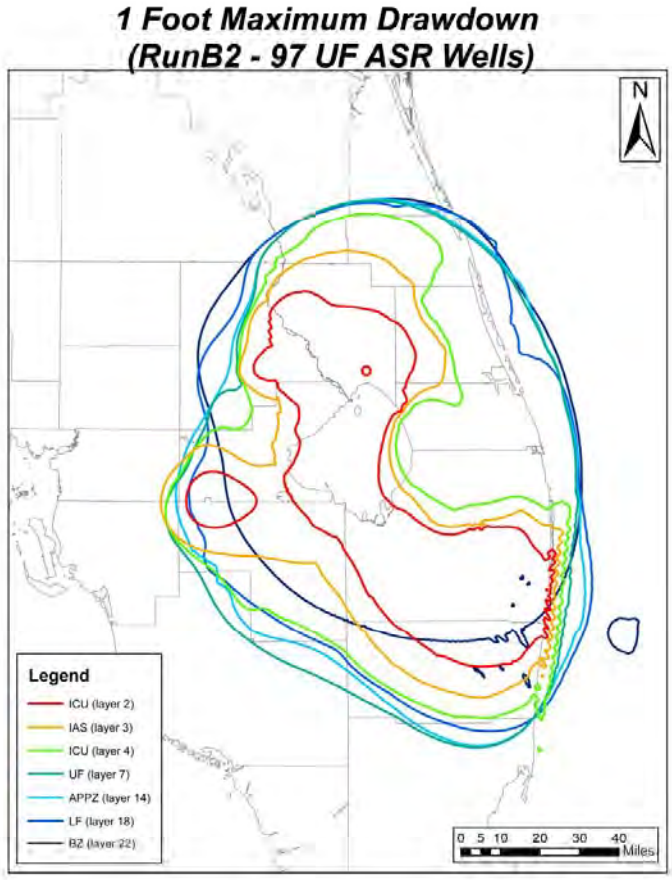
COMPARISON OF PROPOSED ASR SYSTEM TO EXISTING REGIONAL GROUNDWATER USE

REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE 4.169

JUNE 2013





Notes:

These figures show the maximum drawdown for two runs on the RASRSM. On the left, the Kissimmee River pilot ASR was run with the pilot test pumping at 5 mgd. The contours show the location of the 0.01 foot maximum drawdown for each aquifer.

The figure on the right shows an early RASRSM-D13R simulation with 97 wells in the UF, divided among the proposed ASR sites. The maximum pump rate for each well is 5 mgd. In this figure, the lines are for the 1 foot maximum drawdown.

The RASRSM-D13R scenario (right) has nearly 100 times as many ASR wells as the cycle test model (left) and the maximum drawdown contours in the RASRSM-D13R figure (right) are 100 times the maximum drawdown contours on the cycle test figure (left). The areas impacted by the ASR wells as shown by the contour lines are similar. That is, the drawdown caused by 100 ASR wells is approximately 100 times the drawdown caused by 1 ASR well.

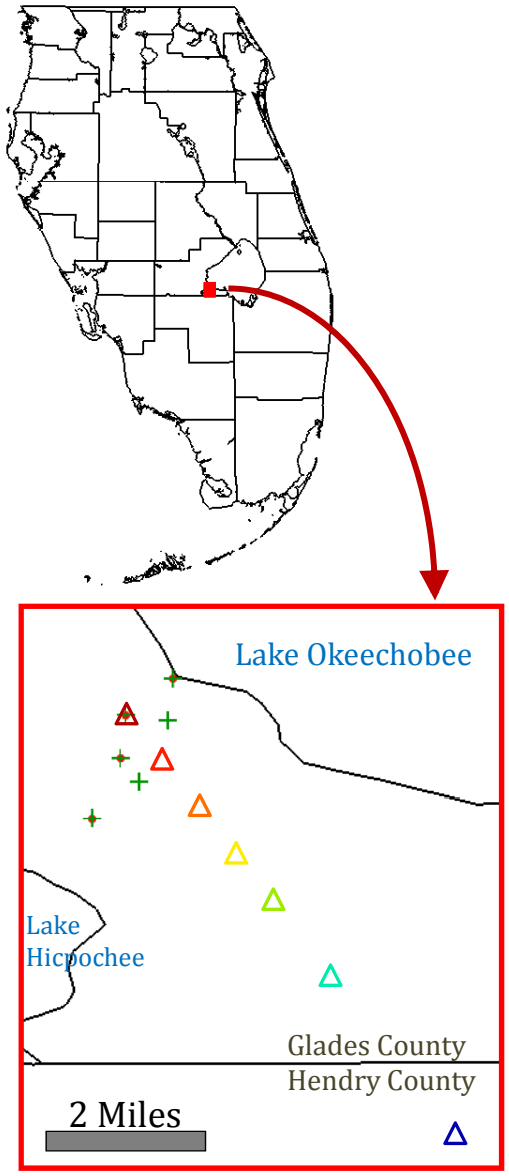
Differences in shape are caused primarily by the different distributions of wells in the two models.

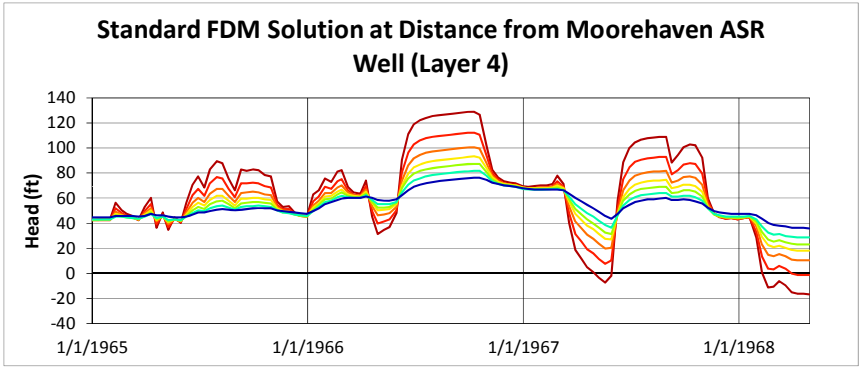
COMPARISON OF DRAWDOWN AT KISSIMMEE PILOT SITE TO REGIONAL DRAWDOWN FOR D13R SCENARIO

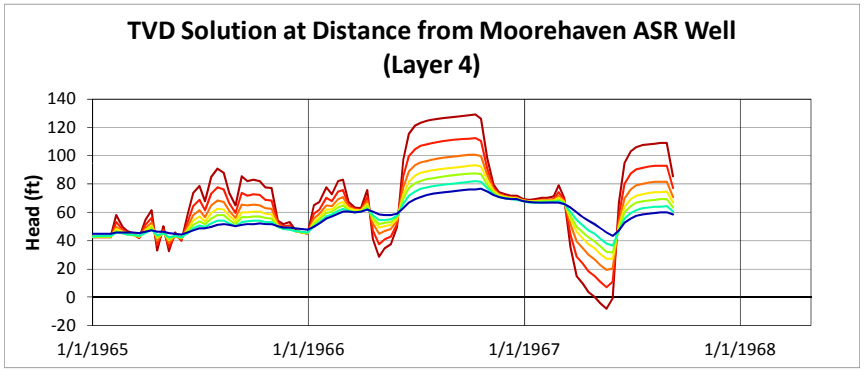
REGIONAL MODEL PRODUCTION SCENARIO REPORT

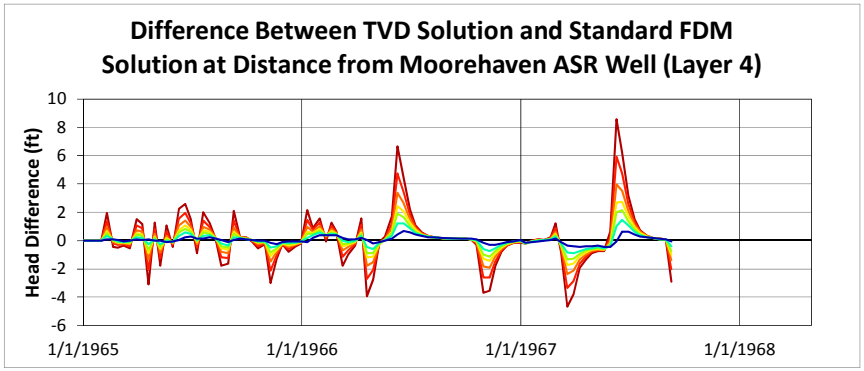
FIGURE 4.170

JUNE 2013









Legend

- ASR wells (UF)
- ASR wells (APPZ)
- ASR wells (BZ)
- Comparison points (color matches plot lines)

Notes:

These plots compare the heads calculated by the Standard FDM method (using upstream weighting) to those calculated by the TVD method (Courant Number = 0.2).

The map at left shows the comparison points and the relative positions of the Moorehaven site ASR wells, which are found in both the UF and BZ layers for Scenario 11.

These comparison points are placed in the ICU (layer 4 of the model). They are placed at varying distances with the nearest point (dark red) in the same cell as the ASR well and the furthest point (blue) nearly 7 miles southeast of the site.

Although there are no ASR wells in this layer of the model, the greatest difference between the two solution techniques is found in this layer at this site.

Note that as the impact of the ASR well is reduced with distance, so, the difference between the two solution methods is also reduced. Also, although the impact of the ASR wells continues throughout the pumping period, the differences between the methods drop off within a few weeks or months of the initial pumping change.

Notes:

These plots compare the heads calculated by the Standard FDM method (using upstream weighting) to those calculated by the TVD method (Courant Number = 0.2).

The map at left shows the comparison points and the relative positions of the Hillsboro site ASR wells, which are found in both the UF and BZ layers for Scenario 11.

These comparison points are placed in the APPZ (layer 14 of the model). They are placed at varying distances with the nearest point (dark red) in the same cell as the ASR well and the furthest point (blue) more than 14 miles southeast of the site.

Note that as the impact of the ASR well is reduced with distance, so, the difference between the two solution methods is also reduced. Also, although the impact of the ASR wells continues throughout the pumping period, the differences between the methods drop off within a few weeks or months of the initial pumping change.

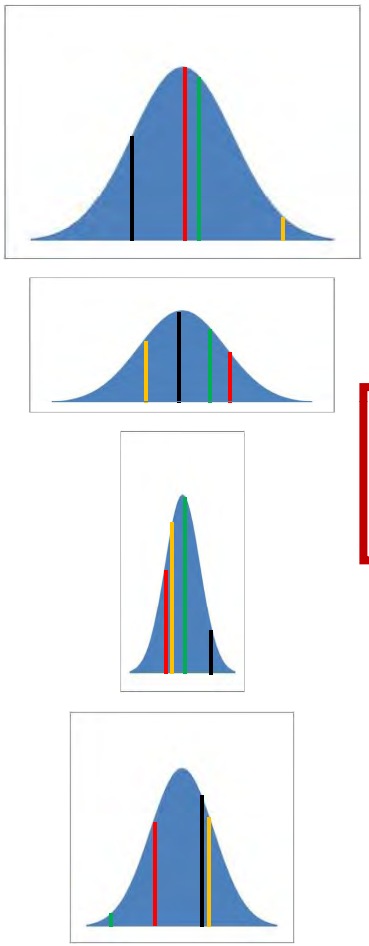
Comparison of Standard FDM to TVD Solution Hillsboro Site, APPZ (Layer 14)

Regional Model Production Scenario Report

Figure 5.3

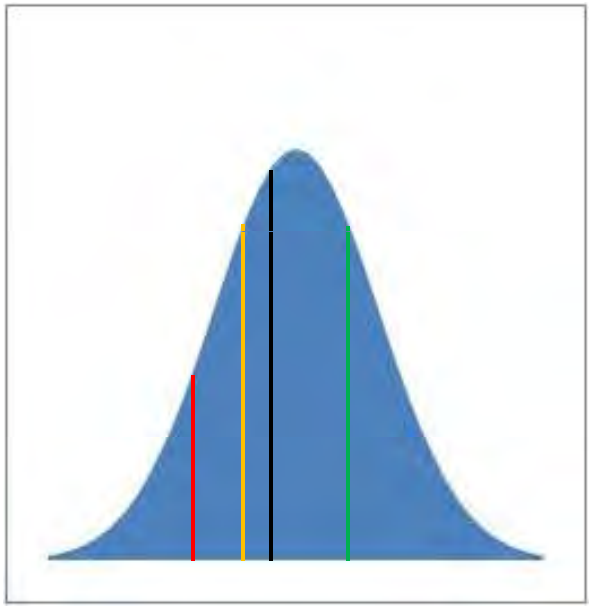
June 2013

Input Parameters



Numerous Model Runs

Model Output



Notes:

In a Monte Carlo analysis, probability distributions are assigned to each input parameter. The computer randomly selects a value for each parameter based on the assigned distribution and then runs the model, resulting in a number of "equally probable" model results. With enough model runs, the probability distribution of the model output can be discerned. This allows the modeler to report a range or distribution of model output instead of a single "correct" result.

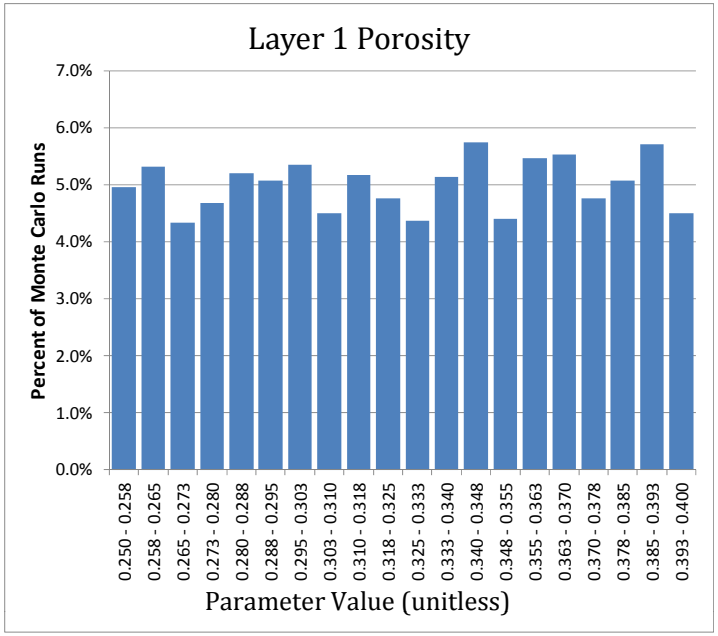
For example, in this cartoon, the blue bell curves are the distributions and the colored lines represent individual randomized model runs. Just four randomized runs have been pictured as colored lines, but when the model is run hundreds or thousands of times, the model output can also be presented as a probability distribution.

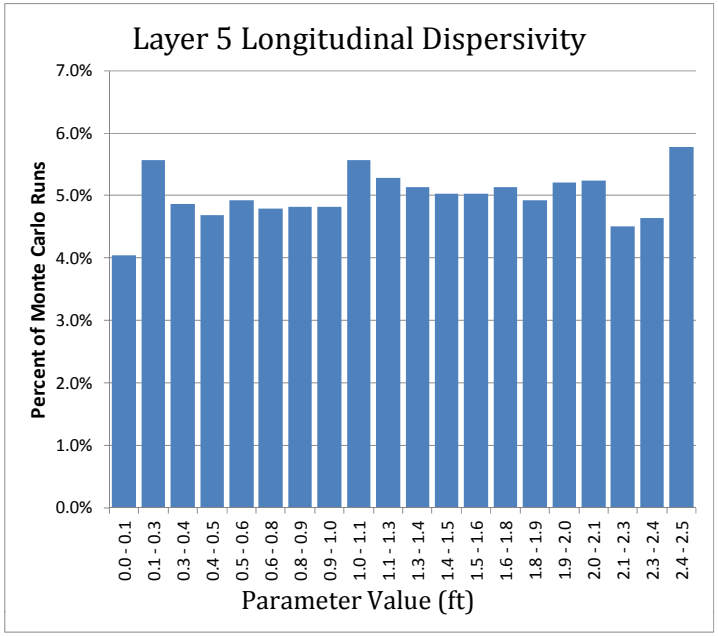
SCHEMATIC OF MONTE CARLO ANALYSIS

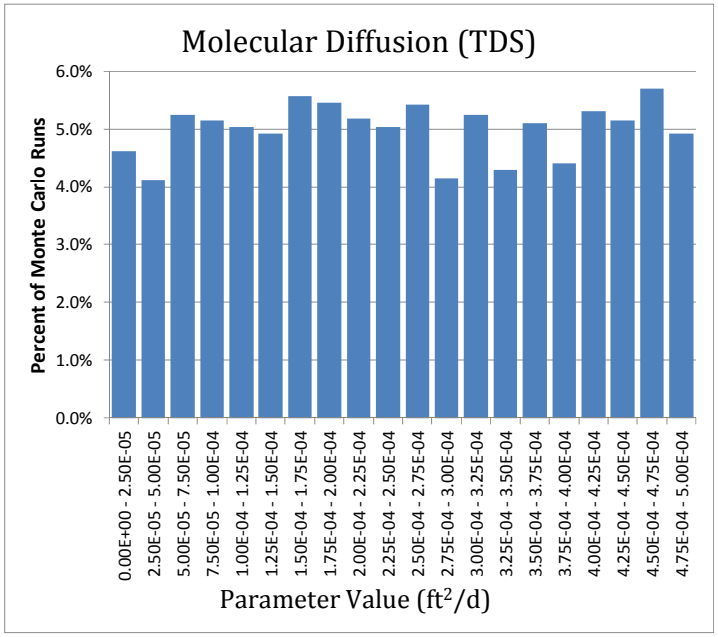
REGIONAL MODEL PRODUCTION SCENARIO REPORT

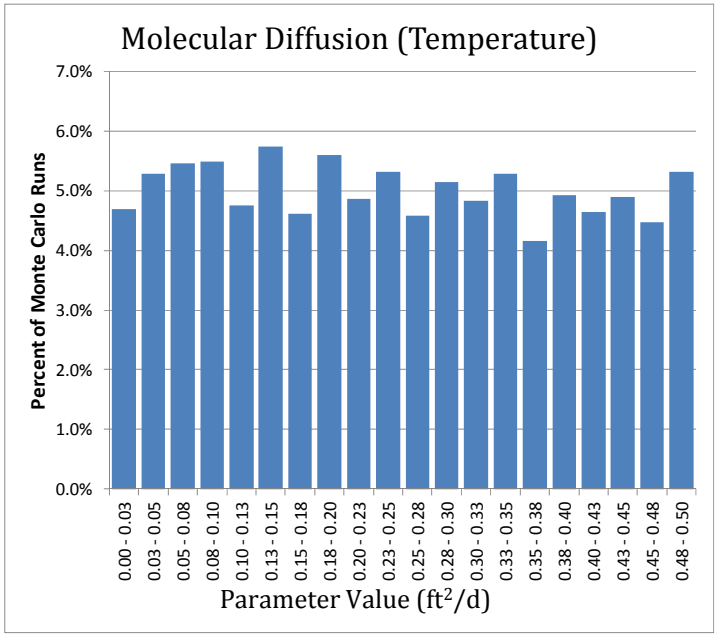
FIGURE 6.1

JUNE 2013









Notes:

Porosity, longitudinal dispersivity and molecular diffusion were given uniform distributions over a range of reasonable values in the Monte Carlo scenarios. The computer selected random values within the ranges for each of the 2892 Monte Carlo selections. These plots show examples of the resulting distributions and indicate a generally uniform distribution as expected.

Note that the plots are designed with 20 bins, so each bar would be at 5% if there were an infinite number of randomizations. As there are only 2892 randomizations, we can be content with the fact that each bar is between 4% and 6%.

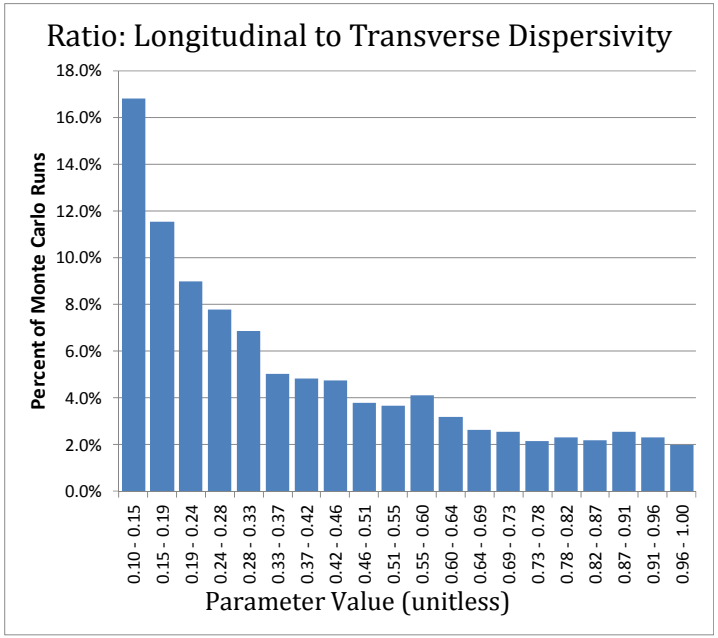
Similar plots could be provided for porosity and longitudinal dispersivity in the other layers of the model; however, they are omitted for simplicity since they are quite similar to those presented.

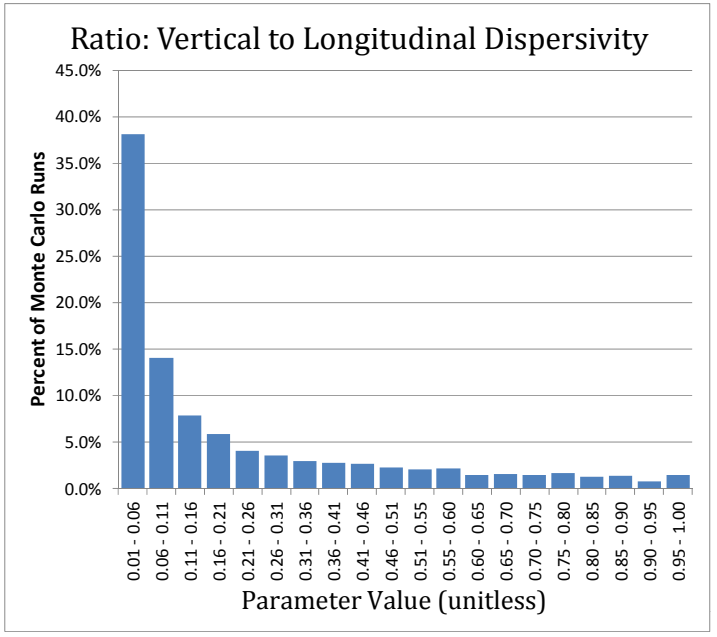
EXAMPLES OF UNIFORM DISTRIBUTION PARAMETERS FOR MONTE CARLO ANALYSIS

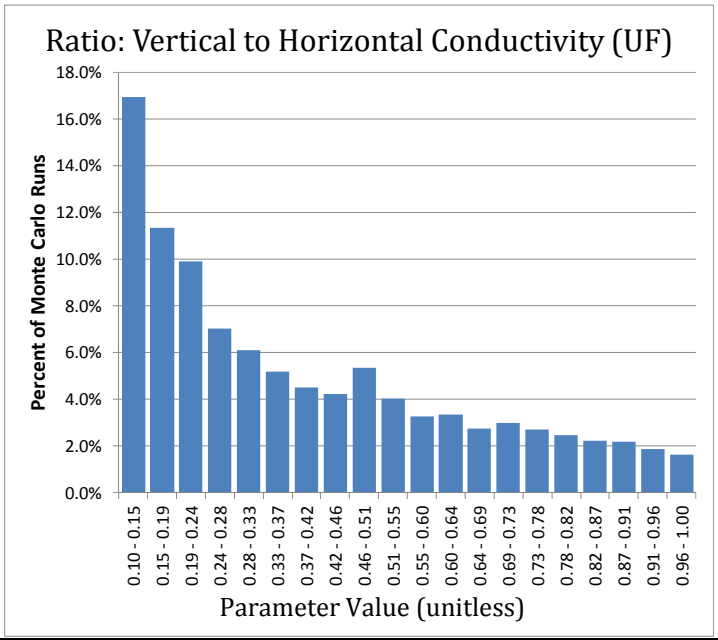
REGIONAL MODEL PRODUCTION SCENARIO REPORT

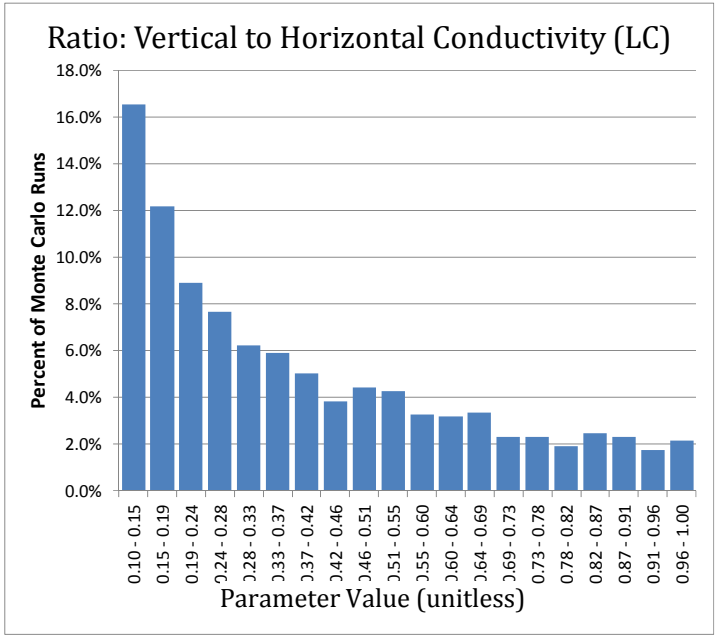
FIGURE 6.2

JUNE 2013









Notes:

Directional ratios for dispersivity and hydraulic conductivity were given log distributions over a range of reasonable values in the Monte Carlo scenarios. The computer selected random values within the ranges for each of the 2892 Monte Carlo selections. These plots show examples of the resulting distributions and indicate a clear log distribution as expected. The Monte Carlo simulation assumed that it was more likely that the values be on the lower end of these ranges and selected random values accordingly.

Similar plots could be provided for conductivity ratios for the other geologic units in the model; however, they are omitted for simplicity since they are quite similar to those presented.

EXAMPLES OF LOG DISTRIBUTION PARAMETERS FOR MONTE CARLO ANALYSIS

REGIONAL MODEL PRODUCTION SCENARIO REPORT

- 120-140
- 140-160
- 160-180
- 180-200
- 200-500

Notes:

The map at upper left shows the pilot points used in the calibration model to set the horizontal hydraulic conductivity for the UF. Points are colored according to the calibrated hydraulic conductivity value.

During the Monte Carlo analysis, each pilot point was allowed to vary uniformly from half the calibrated value to twice the calibrated value. During each scenario, the computer randomly selected a value within the acceptable range for each point and then performed the krigging interpolation as shown on the following figure (6.5).

Plots like these could be presented for each pilot point in this layer and for those points in all other layers.

MONTE CARLO RANDOMIZATION OF HYDRAULIC CONDUCTIVITY - A

REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE 6.4

- 120-140
- 140-160
- 160-180
- 180-200
- 200-500

Notes:

Once the randomized values had been assigned to each pilot point (see the previous figure, 6.4), the kriging was performed to yield a conductivity field for each Monte Carlo iteration.

The horizontal hydraulic conductivity distribution used in the calibrated model is shown here (top left) with three of the randomized distributions used in the Monte Carlo simulation.

Notice that general trends are unchanged and available data has been honored, but that each randomized distribution is slightly different.

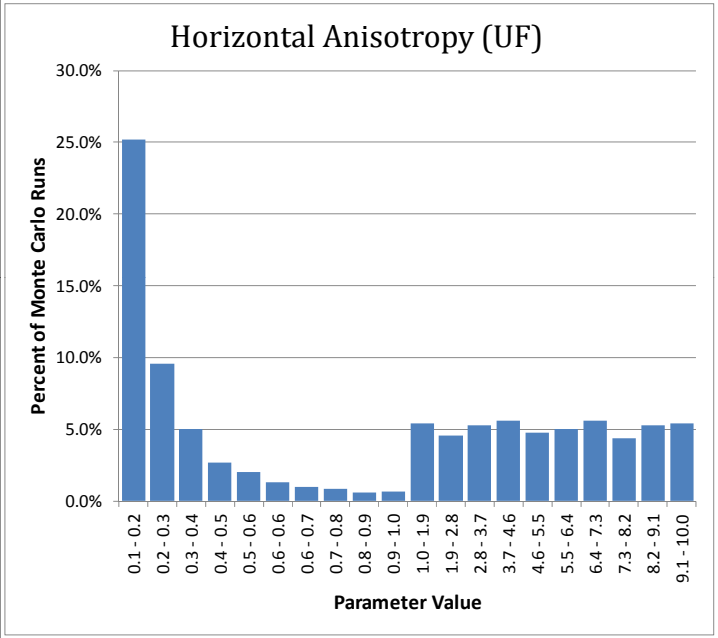
Similar plots could be provided for other layers of the model or for other randomizations, but they are omitted for simplicity.

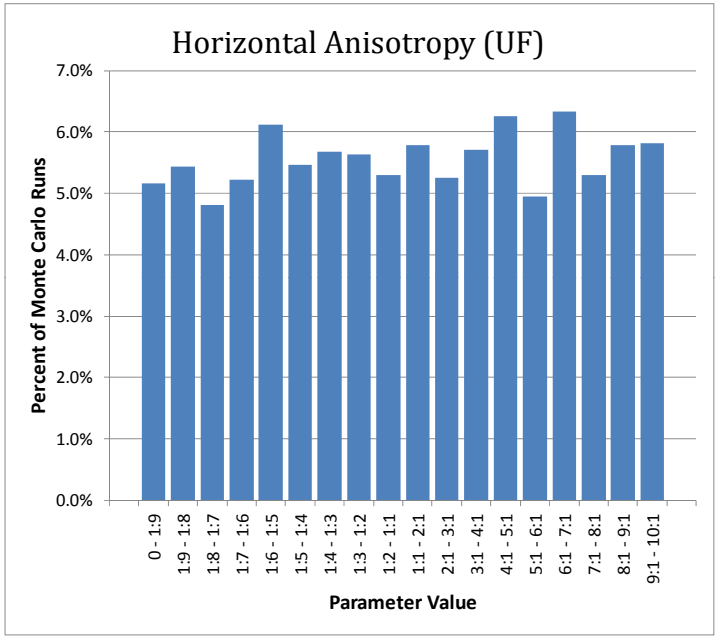
Monte Carlo Randomization of Hydraulic Conductivity - B

Regional Model Production Scenario Report

Figure 6.5

June 2013





Notes:

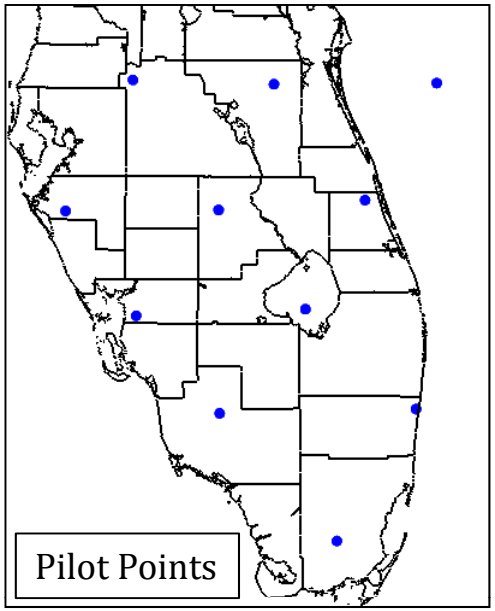
These plots illustrate the results of an "inverted" uniform distribution used in the Monte Carlo analysis setup.

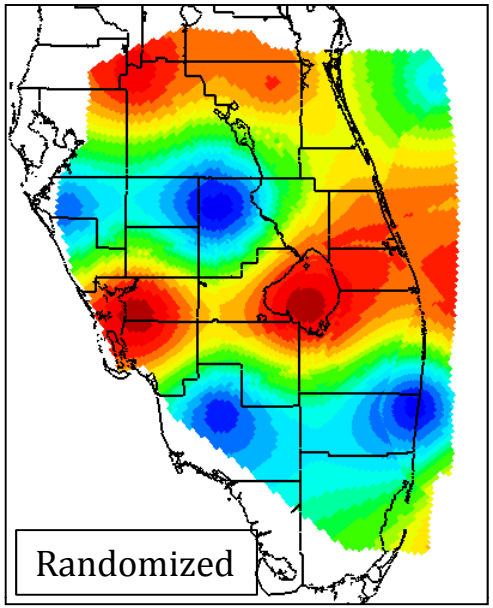
The details of the distribution development are given in Section 6.1.4.

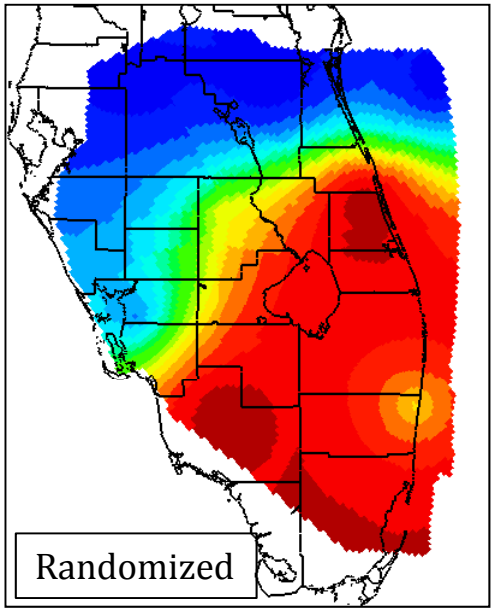
These plots show the input distribution for the anisotropy of the UF aquifer. In SEAWAT, anisotropy is input as a decimal ratio of the hydraulic conductivity along the grid columns to that along the grid rows.

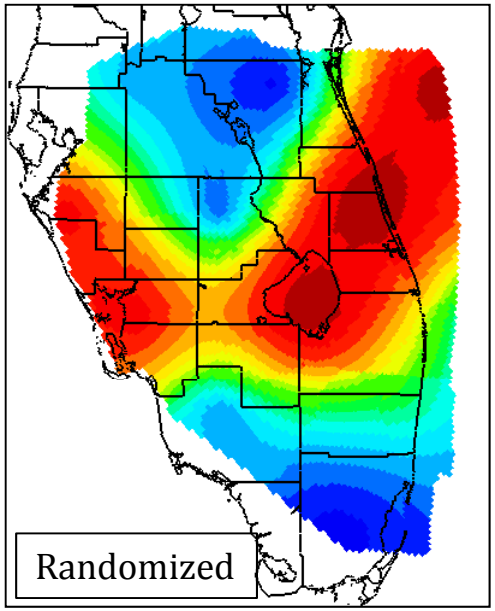
In the plot at left, the first 10 bins have sizes of 0.1, while the last 10 bins have sizes of 0.9. The left half of the plot seems to indicate a log distribution on anisotropy values which favor flow along the grid rows. The right half of the plot seems to indicate a uniform distribution on anisotropy values which favor flow along the grid columns.

When the bins are resized as ratios to unity, the entire range is uniformly distributed. It is just as likely, then, that the anisotropy will favor flow along the rows with a ratio of 1:5 as that it will favor flow along the columns with a ratio of 5:1.









Horizontal Anisotropy

- 0.925 – 0.95
- 0.95 – 0.975
- 0.975 – 1.0
- 1.0 – 1.025
- 1.025 – 1.05
- 1.05 – 1.075
- 1.075 – 1.1
- 1.1 – 1.125
- 1.125 – 1.15
- 1.15 – 1.175
- 1.175 – 1.2

Notes:

Starting conditions for TDS and temperature were set in a two-step process. A multiplier between 0.8 and 1.2 with a uniform distribution was assigned to each of a set of pilot points (shown at upper left).

The multipliers were interpolated to the cells of the grid using kriging. Three examples of the multiplier field are shown here.

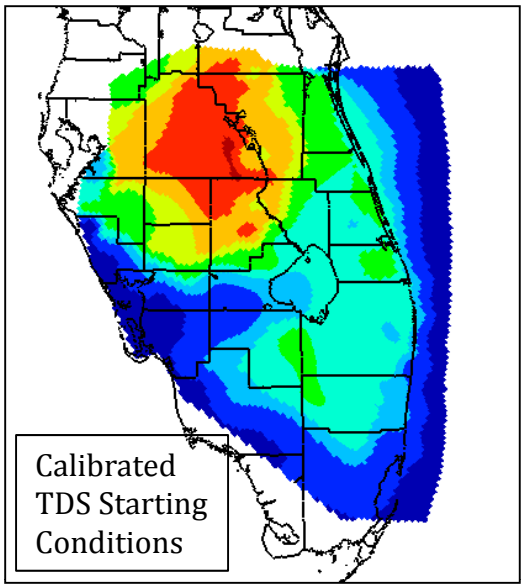
The following figure (6.9) shows the resulting starting TDS fields for the APPZ.

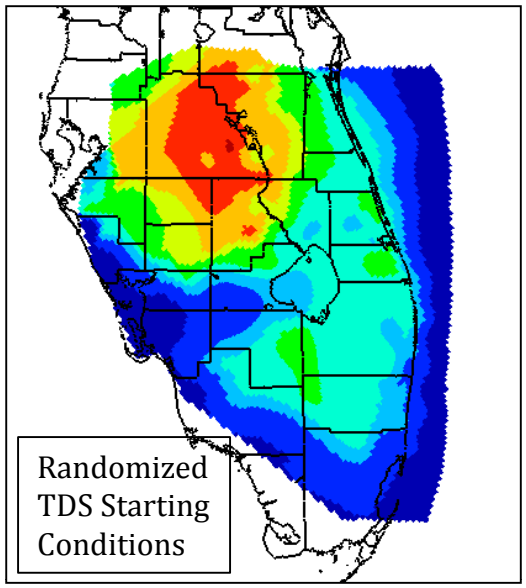
MONTE CARLO RANDOMIZATIONS OF TDS STARTING CONDITION (STEP 1)

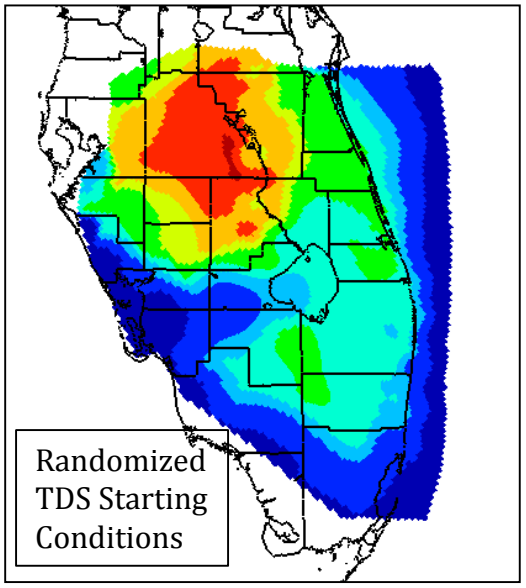
REGIONAL MODEL PRODUCTION SCENARIO REPORT

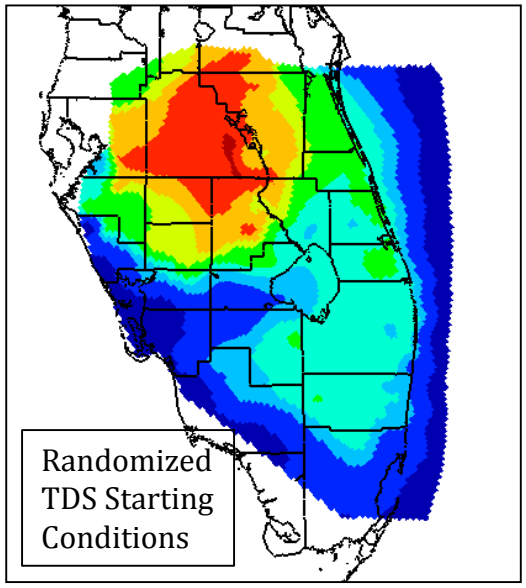
FIGURE 6.8

JUNE 2013









TDS (mg/L)

- <100
- 100 – 250
- 250 – 500
- 500 – 1000
- 1000 – 2500
- 2500 – 5000
- 5000 – 10000
- 10000 – 25000
- 25000 - 50000

Notes:

The starting conditions for TDS and temperature for the Monte Carlo analysis were set using a two-step method.

In the first step, shown on the previous figure (6.8), each cell in the model was assigned a multiplier between 0.8 and 1.2.

In the second step, shown here, the multiplier was applied to the calibrated TDS starting conditions to slightly change the condition.

Here, three randomizations of the starting conditions are compared to the calibrated condition (top left) for the APPZ.

A similar process was followed for the temperature starting conditions.

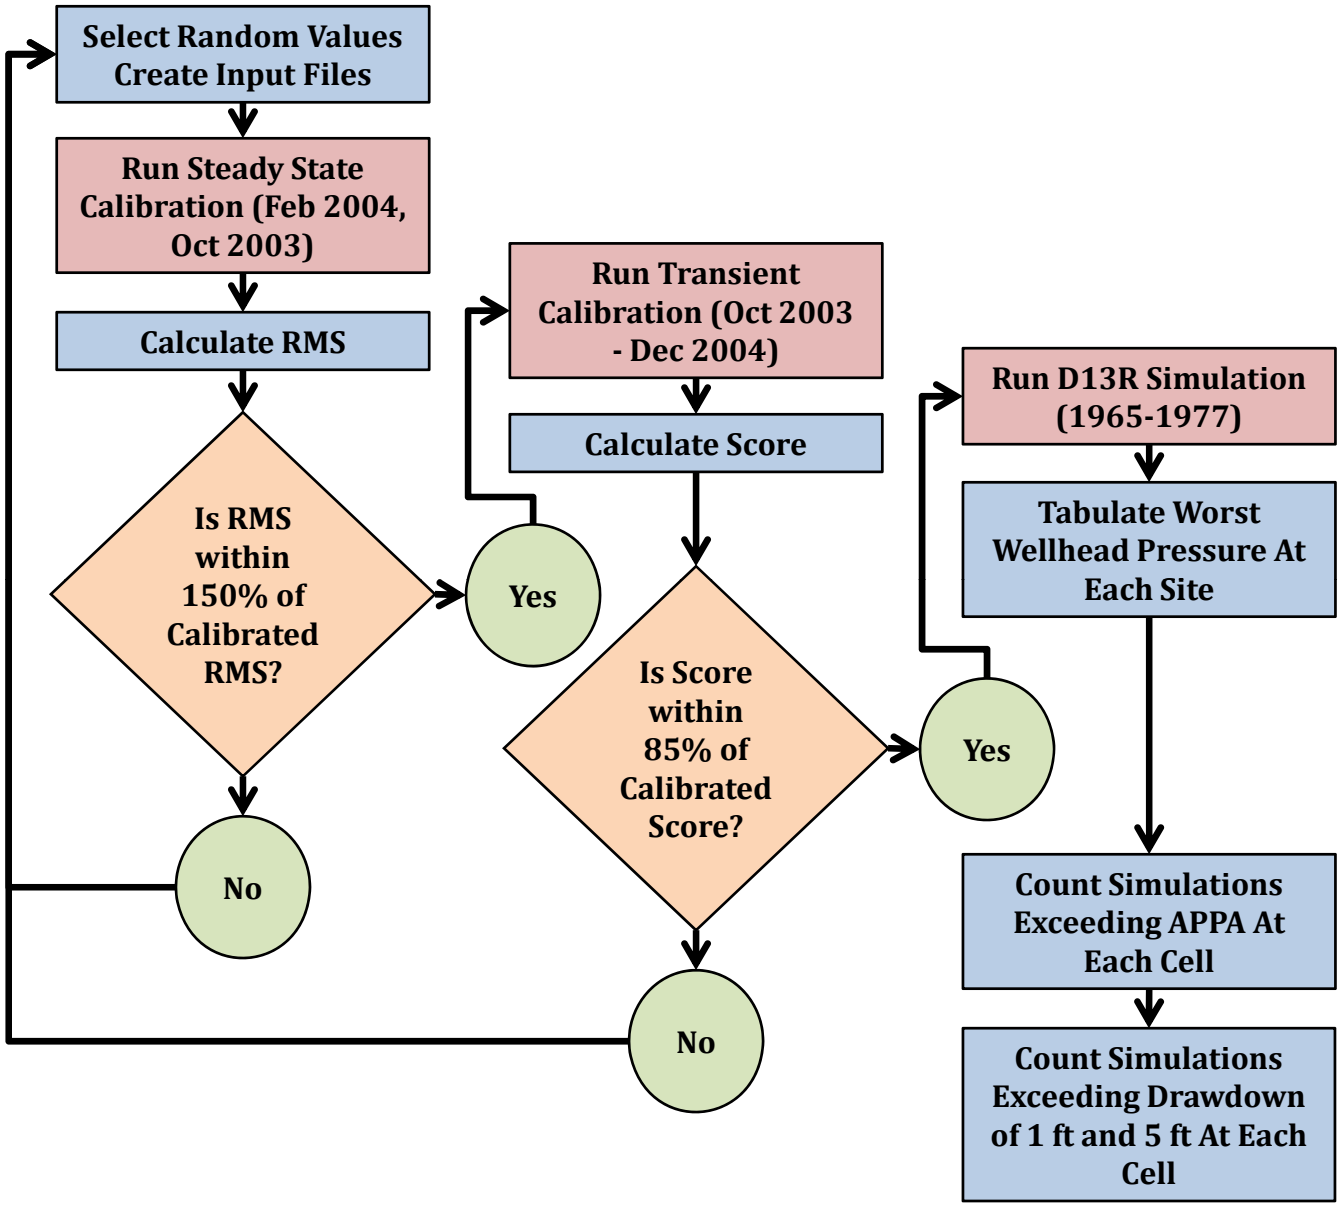
Note that only subtle changes have been introduced, allowing each Monte Carlo randomization to honor the available data.

MONTE CARLO RANDOMIZATION OF TDS STARTING CONDITIONS (STEP 2)

REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE 6.9

JUNE 2013



Notes:

This flow chart shows the process that was followed for each of the Monte Carlo simulations.

2836 sets of randomized parameters were developed and run through the steady state calibration models.

Of those, 1553 sets of randomized parameters met the steady state calibration standard and were run through the transient calibration model.

Of those, 825 met the transient calibration standard and were run through the RASRSM-D13R simulation.

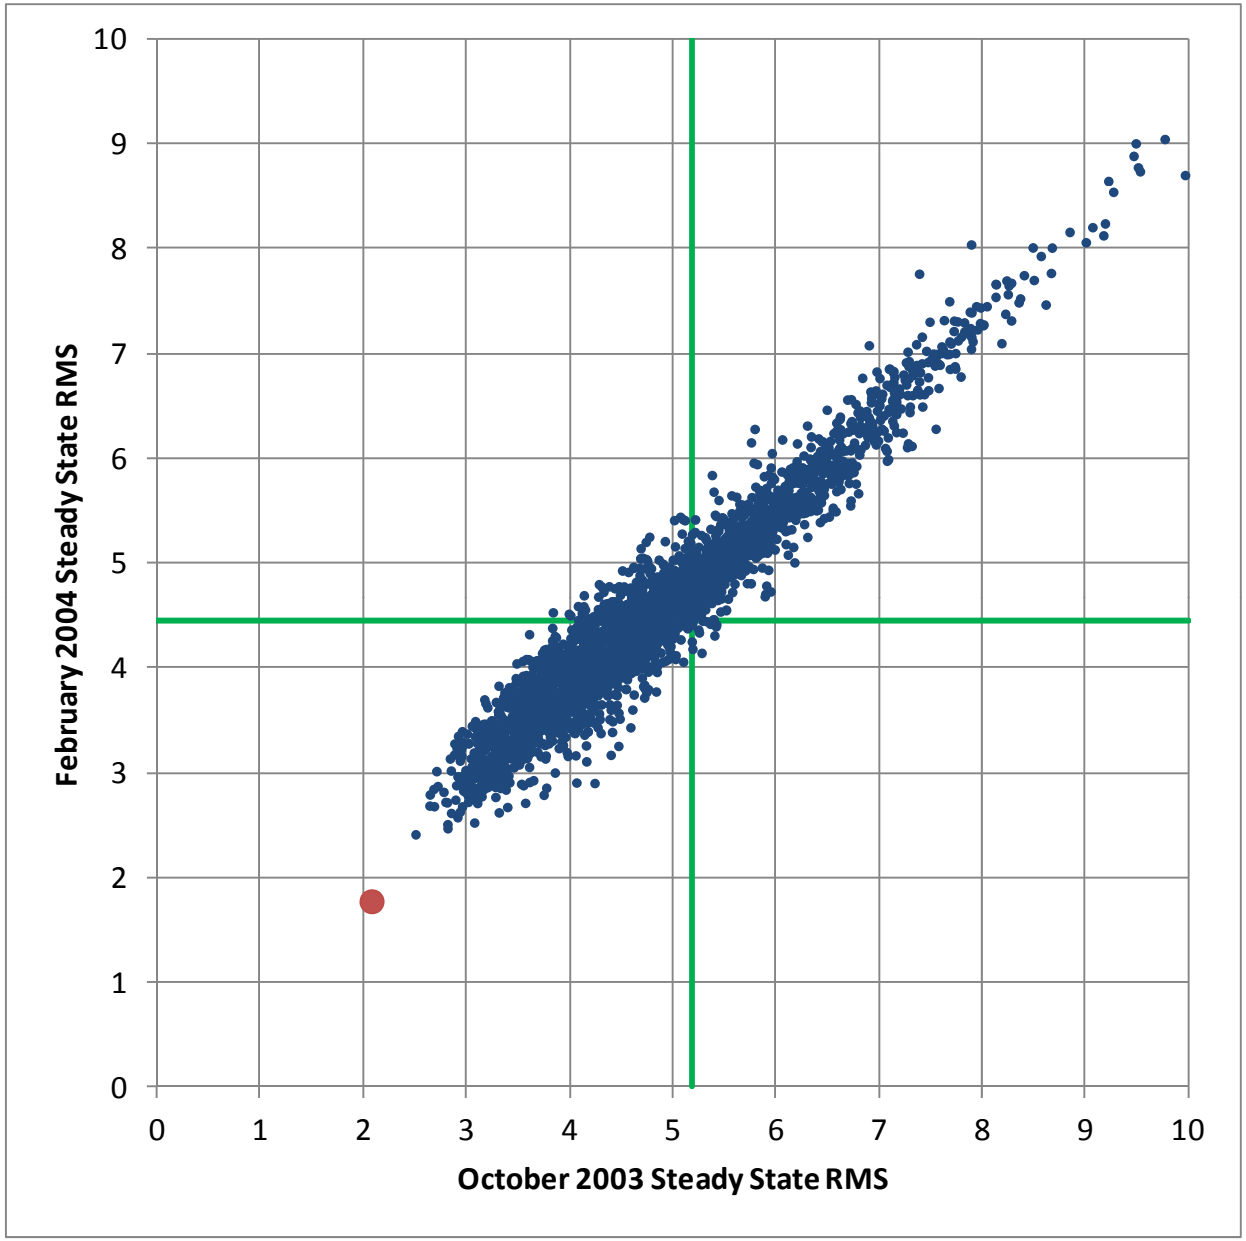
The results of the performance measure analyses on the D13R results were tabulated to analyze the uncertainty in the results.

MONTE CARLO ANALYSIS FLOW CHART

FIGURE 6.10

REGIONAL MODEL PRODUCTION SCENARIO REPORT

JUNE 2013



Legend

- Monte Carlo Randomized Scenario Results
- Calibrated Model Result
- RMS Requirements for Monte Carlo Simulation

Notes:

Each blue dot on this plot represents one randomized scenario tested for steady state calibration. In order to be selected for the next step, the dot must fall in the lower left quadrant, beyond the limits shown by the green lines.

The green lines represent a 150% change from the calibrated RMS values (indicated with the red dot).

STEADY STATE CALIBRATION TEST STATISTICS FOR MONTE CARLO ANALYSIS

- Comparison of October Steady State RMS to Transient Calibration Score
- Calibrated Model February Steady State RMS and Transient Calibration Score
- Calibrated Model October Steady State RMS and Transient Calibration Score

Notes:

This plot compares the steady state calibration RMS (for both October 2003 and February 2004) to the transient calibration score for all Monte Carlo randomizations that passed the steady state requirement (see Figure 6.11).

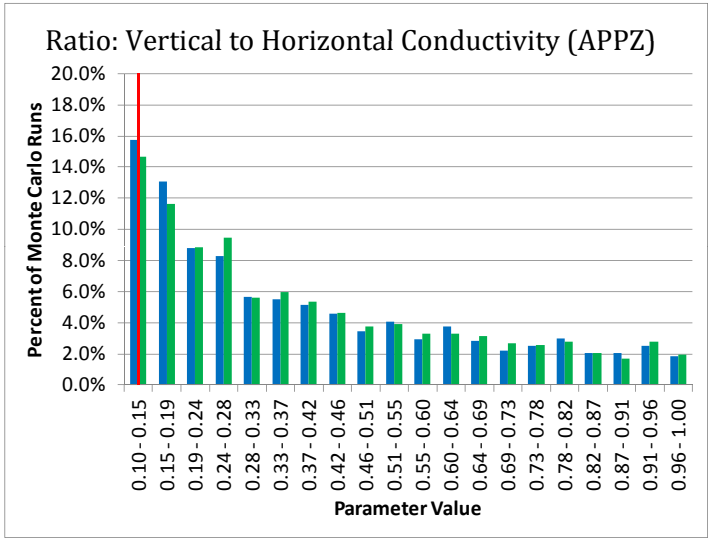
The green line indicates the transient calibration requirement. To be selected and continue to the D13R portion of the process, the transient calibration score must be above 153.

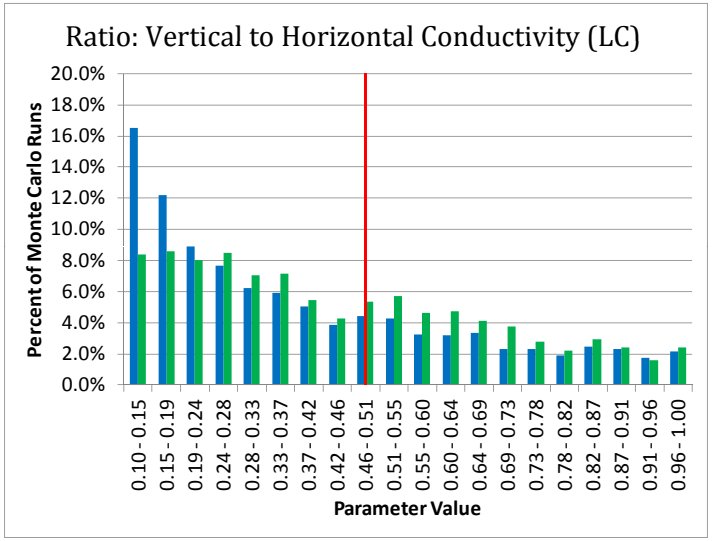
TRANSIENT CALIBRATION STATISTICS FOR MONTE CARLO ANALYSIS

REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE 6.12

JUNE 2013





Legend

- Randomized Scenarios
- Acceptable Scenarios
- Calibrated Value

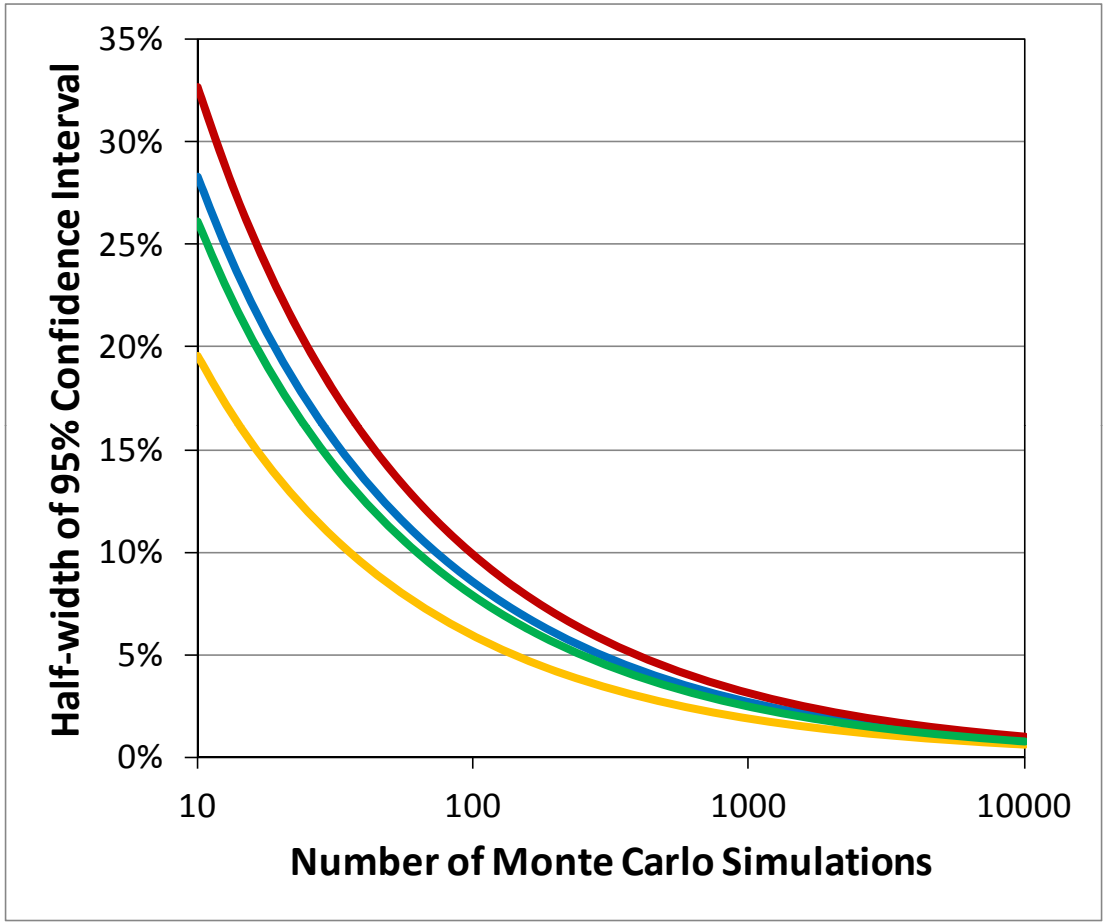
Notes:

Here the distributions of randomized values are compared to the distribution of parameter values in selected simulations, i.e., those that passed the steady state and transient calibration tests.

Also shown on each plot is the value used in the original calibration runs.

In the plot at left, the distribution of each set of parameters is very similar, with the most likely values falling near the calibration value.

In the plot at right, the calibration tests have eliminated some of the low parameter values which did not allow a good calibration. Since the input distribution was an error and did not match the calibrated value, this helped to improve the input parameter distributions



Legend

- 10% Pass Rate
- 25% Pass Rate
- 50% Pass Rate
- 80% Pass Rate

Notes:

Since the results of this Monte Carlo simulation are binary (either pass or fail), the half-width of the 95% confidence interval depends only on the percentage of Monte Carlo runs passing the requirement and the total number of simulations.

There were 825 simulations, so the largest 95% confidence interval half-width was 3.4%.

Note that the largest half-width occurs with 50% passing and the interval is smaller for both larger and smaller pass rates.

RELATIONSHIP BETWEEN NUMBER OF MONTE CARLO SIMULATIONS AND THE HALF-WIDTH OF THE 95% CONFIDENCE INTERVAL

- Upper/Lower Bound 95% Confidence Interval

Notes:

This plot shows the change in percentage passing the pump pressure requirement with the 95% confidence interval at the Lakeside Ranch UF site as the Monte Carlo scenarios progressed.

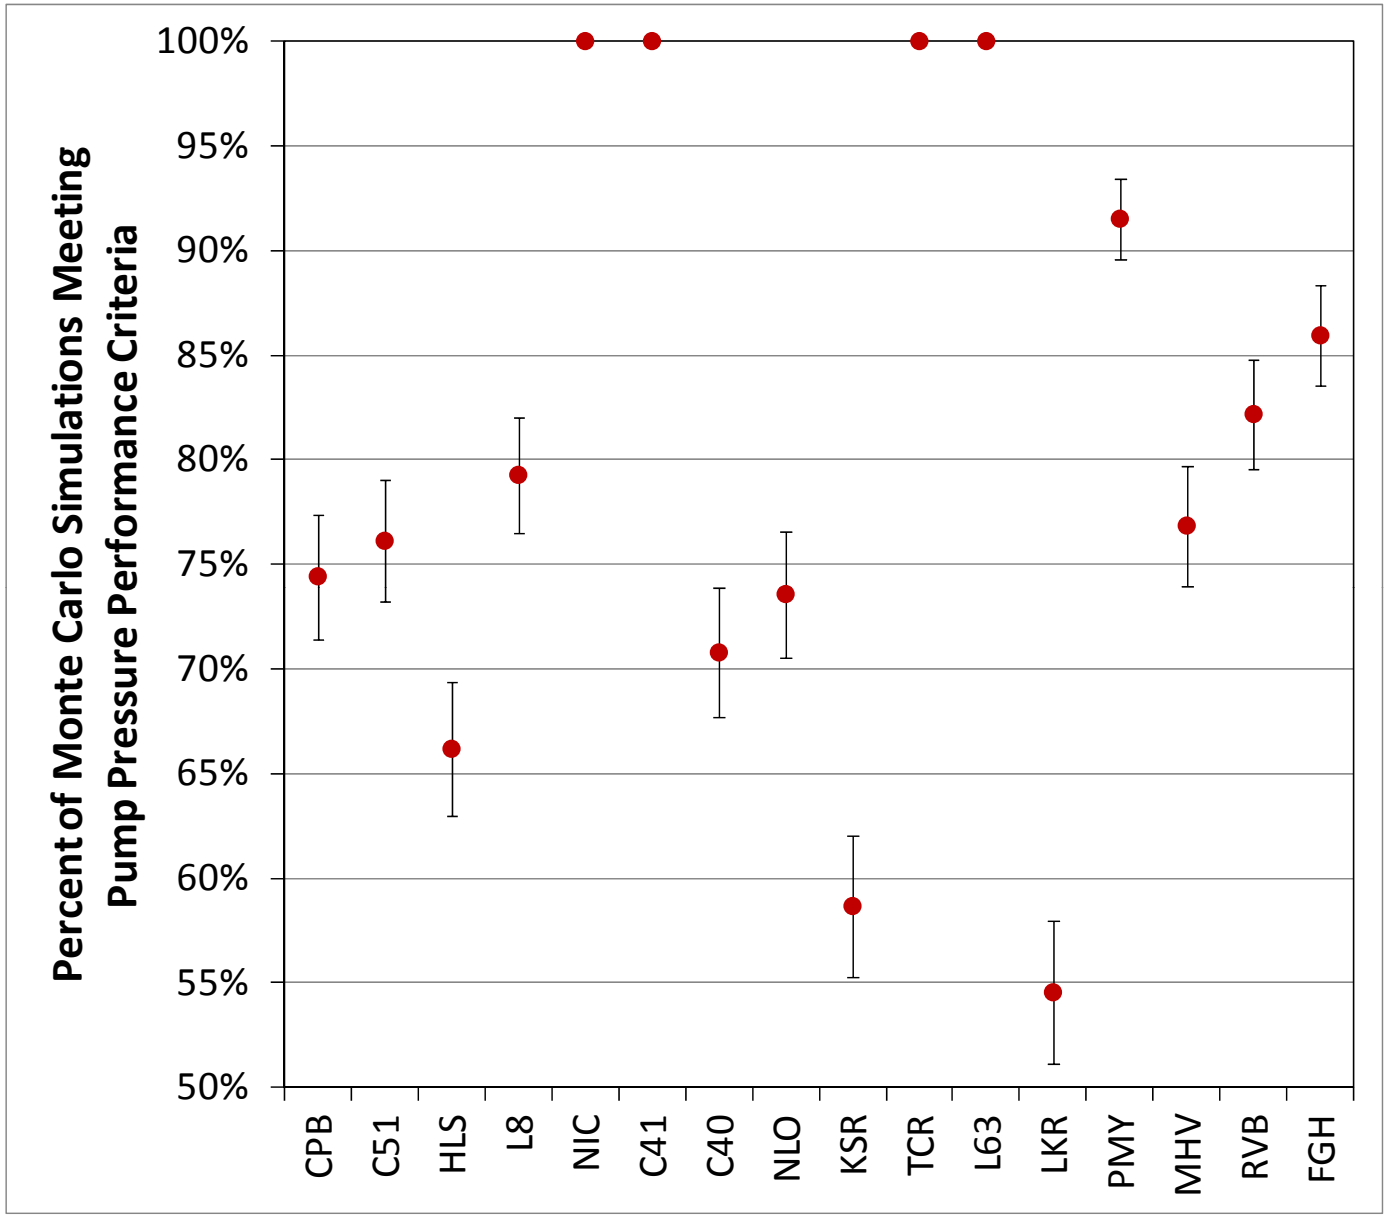
As the number of Monte Carlo simulations increases, the stability of the red line improves and the confidence interval (between the gray lines) shrinks.

EXAMPLE: CHANGE IN PERCENTAGE PASSING AS NUMBER OF MONTE CARLO SIMULATIONS INCREASES (LAKESIDE RANCH, UF)

REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE 6.27

JUNE 2013



Percent of Monte Carlo Runs Meeting Performance Measure with 95% Confidence Interval

Notes:

This plot shows the percentage of 825 Monte Carlo scenarios which met the performance criteria for pump pressure in the UF. Each solution was analyzed to determine the maximum pressure at each site. If the maximum pressure was over 100 psi, it was considered to have failed the performance measure for that site.

The error bars indicate the 95% confidence interval on each point, which is dependent on the number of Monte Carlo runs and the pass rate.

Similar plots are not shown for the APPZ or BZ sites since all Monte Carlo runs met the criteria.

Key	Site

A. Analysis of Specified Head Boundary Condition Impacts to D13R Regional Model plus Figures

B. Interagency Modeling Center Comments to Draft Report with Responses and Figures

APPENDIX A

ANALYSIS OF SPECIFIED HEAD BOUNDARY CONDITION IMPACTS TO D13R REGIONAL MODEL

1 INTRODUCTION

As described in Section 3.3 and Appendix C of the Regional Groundwater Model Calibration Report (NAP, 2011), specified head boundary conditions were used to assign heads to the surface and the sides of all aquifers in the model. (See Figure A.1) This type of boundary condition assumes there is an infinite source or sink of water available at each boundary and allows the model to add or remove any volume of water necessary to match the user-specified heads at the boundary. This assumption is valid at the eastern boundary of the RASRSM, where the aquifer layers outcrop in the Atlantic Ocean since no reasonable amount of pumping in the model domain would result in a change to the ocean level.

Similarly, specified heads were set in all cells across the top surface of the model. The alternative would have been to gather precipitation, evapotranspiration and seepage data and apply a flux to the surface. This would have required additional vertical discretization of the upper hydrogeologic layers. Because of the likely sparse nature of both sets of data, the incoming flux at the surface of the model would have been used as additional calibration parameters, increasing the uncertainty in the calibration and the non-uniqueness of the solution. Further, the surface waters in southern Florida are highly engineered with a vast, complicated system of canals, reservoirs and stormwater treatment areas (STA). The inclusion of these features would have added unwarranted complexity to the surface system. Instead, the measured heads at the base of the Hawthorn unit were interpolated and applied to the surficial grid layer and the model was allowed to add or remove water as necessary to honor those measured heads. In effect, the model calculates the infiltration or exfiltration necessary to match the field measured heads in the SAS. This simplification was made to reduce data collection efforts and to save the majority of the computational energy for the areas near the ASR wells in the FAS. Since the source of ASR recharge water is the surface water system, increases in heads in the SAS caused by ASR pumping will only replaced water that has already been removed. Similarly, recovered ASR water is to be returned to the surface water system, replacing any loss of water caused by the ASR system. Because the SAS is so highly engineered, it can be assumed to act as an infinite source/sink of water.

There is, however, no infinite water source at the south, west or north boundaries of the model. Instead, the boundary heads were based on measured groundwater heads and the boundaries were set far from the proposed ASR sites to prevent ASR impacts to the boundaries. Other pumping closer to the boundaries may exist, but those impacts would be included in the measured groundwater heads. This simplification was made for several reasons:

- Extension of the northern boundary to a more suitable boundary location (likely at some distance) would have greatly increased the level of effort in data collection.
- Extension of the southern and western boundaries to ocean outcrops would have greatly increased the uncertainty in the model since the outcrop in the Gulf of Mexico is nearly 150 miles from the shore and there is little or no groundwater data available in that large area. All parameters would have had to be estimated or extrapolated from measurements in the peninsula.

- Extension of the boundaries in either location would have significantly increased the size of the model and the computational time required to solve the governing equations. Since the existing model already taxes the capabilities of available computers, the resolution of the model would have had to be reduced to include the additional area.
- Pumping at the proposed ASR locations was not expected to impact the boundaries since they were so far away.

The specified heads at the edges of the aquifers were set based on the assumption that the boundaries were far enough from the proposed ASR sites that the effects of the pumping would not impact the boundaries. However, the area of influence of the ASR wells could not be known until after the calibration was finished and the production runs were completed. At this point, it is generally too late to go back and extend the boundaries further. Plus, for the reasons listed above, it was not feasible to include the additional areas in the model, even if necessary.

With the completion of the RASRSM-D13R runs described in the main report, an analysis of the maximum drawdown and "drawup" was completed as part of the investigation of the performance of each scenario. As shown in Figures 4.20, 4.39, 4.58, 4.77, 4.96, 4.115, 4.134, and 4.153 of the main report, significant levels of head change extend to the western, southern and northern boundaries of most of the aquifers for all scenarios. This indicates that the assumptions implicit in the use of specified head boundary conditions at these locations may have been violated.

This appendix describes the analysis which was used to determine the degree of impact to the model results from these faulty boundary condition assumptions.

2 TEST MODEL

It is difficult to quantify the effects of the boundary conditions on the RASRSM since we don't know how the model would have behaved had the boundaries been extended to more suitable locations. Instead, a set of smaller test models were built to analyze the impacts. Although the test model cannot be directly used to determine the influence of the near boundary conditions, it can be used to assess trends and can lead to a better understanding of the conditions.

2.1 BASE MODEL SETUP

A set of five MODFLOW models of varying sizes were built. Each was a single-layered, square model centered at the same location and built of square cells 10 ft on a side. The layer thickness was 100 feet and the layer was assumed to be unconfined. No density dependence was included. All boundaries were set using a specified head condition. Figure A.2 shows the boundaries of each model. Individual data on each model is listed in the following table.

Table A.1: Test model sizes

Model Name	Size (ft x ft [acres])	Number of cells on each side	Total Number of Cells
Largest	2990 x 2990 [205]	299	89401
Larger	1990 x 1990 [91]	199	39601
Large	990 x 990 [23.5]	99	9801
Small	390 x 390 [3.5]	39	1521
Smallest	110 x 110 [0.3]	11	121

The boundaries of the "Largest" grid were assumed to coincide with an infinite water source, making the boundary condition valid. The model was imagined as an island in a large lake or ocean so that all heads around the island coast were equal (50 feet). This model is assumed to represent "truth" for the purposes of this test. The other four models were designed with boundaries set inland of the shore. These were intended to test the impacts of assigning specified head boundary conditions based on site measured conditions instead of true infinite water sources. The boundary conditions on these four models were set based on the steady state results of the "Largest" model. This process reproduces the methodology used in the regional ASR model to set the boundary condition heads based on measured data.

An ASR well was placed in the center of the models and it was assigned a short pumping cycle. The sizes of the models and the pump rates of the ASR well were developed so that the boundaries of the "Small" and "Smallest" models were clearly impacted by the ASR well, while the boundary of the "Larger" model was not.

Finally, a small area of constant recharge was added to the center of each model, around the ASR well. The purpose of this recharge was to add a small rise in the water table at the center of the model. In this way, the natural flow of water would be outward, towards the boundaries before the ASR well impacted the system. This was meant to match the general trend of water flow from the north of the regional ASR model towards the south, east and west boundaries.

The flow parameters were simple, with the hydraulic conductivity set to 10 ft/d everywhere and the specific yield set to 0.1.

The first stress period of each model was a steady state condition with the recharge but no ASR pumping. A recharge rate of 5 ft/d was applied to each of 24 grid cells in the center of the model. Since each grid cell had an area of 100 ft^2, this resulted in the addition of 12,000 ft^3/d of water to the model. The results of this first stress period are shown in Figure A.3. Since the boundary conditions for the four smaller models were set based on the solution from the "Largest" model, all heads are identical. This is to reproduce the conditions that would exist if the heads of the smaller models were set from field measurements.

Following the first stress period, the models were subjected to a 50-day pumping schedule for the center ASR well. The schedule consisted of 10 days of injection at a rate of 20,000 ft^3/d (about 0.15

mgd) followed by 10 days of rest, then 10 days of extraction at a rate of 10,000 ft^3/d (about 0.075 mgd), 10 days of rest and 10 days of injection at 20,000 ft^3/d.

2.2 Base Model Results

The head profiles from base model (described above) are shown in Figure A.4 for each of the grids at the end of the injection and extraction periods. Both the "Large" and "Larger" models closely match the head results from the "Largest" model, which represents reality and from which the boundary conditions were taken. The "Small" model is pretty accurate at the end of the extraction period, with a head error of less than 1 foot, but at the end of the injection period, error is somewhat higher, up to nearly 4 feet at the edge of the model. The errors on the "Smallest" model are even larger: about 4 feet at the end of extraction and over 8 feet at the end of injection.

Figures A.5 through A.8 show the results of this base model at different locations. The top half of each figure shows the heads as they change with time for each of the models. Note that head values are labeled on the left axis. Generally, the smaller models quickly reach a steady state condition, indicated by a flat (zero) slope on the head plots. The bottom half of each figure shows the boundary fluxes caused by the ASR well pumping. These are the boundary fluxes calculated by the model with the flux from recharge (12,000 ft^3/d) subtracted. The values, listed on the right axis, are positive for flow into the model and negative for flow out of the model. The steady state condition is recognized in these plots when the boundary fluxes equal to the ASR pump rates (10,000 ft^3/d for injection; -20,000 ft^3/d for extraction).

For this base model, the "Smallest" model reaches a steady state condition almost immediately after the pumping changes. The "Small" model also reaches a steady state condition, but it takes several days to reach this condition. None of the other three models reach this steady state condition. Heads for the "Large", "Larger", and "Largest" models are nearly indistinguishable, except for some minor differences in the "Large" model. Fluxes for the "Larger" and "Largest" model move only slightly. There is an impact to the boundary fluxes on the "Large" model, but it never reaches the level of the ASR pump rates and it is damped and delayed. Head impacts at other points in the model follow similar patterns, but the magnitudes of the head changes are smaller for locations further from the ASR well.

Generally, heads are underpredicted by the smaller models during the injection periods. Note that this is non-conservative. When allowed to run to steady state, heads are overpredicted by smaller models during extraction periods, but depending on previous conditions and the length of time for extraction, the heads can be slightly underpredicted, as well. The worst head differences generally occur at the end of pumping periods and the beginning of rest periods.

This test indicates that the changes in flux caused by the ASR wells can be used as a proxy for the head impacts of the boundary condition effects. When the flux signature changes immediately to the ASR pump rate, there is a significant impact on the model heads caused by the boundary conditions being too close to the ASR wells. When the flux signature is damped and delayed from the ASR pumping schedule, there is only a minor impact to model heads caused by the boundary condition problems.

2.3 Model Variations

After analyzing the results of the base test model, a few variations were run to investigate the effects of the model parameters on the head and flux variations caused by boundary effects.

2.3.1 Variation 1 – Reduce Hydraulic Conductivity

In the first variation, the horizontal hydraulic conductivity was reduced from 10 ft/d to 1 ft/d. The results are shown in Figures A.9 through A.12. The smaller conductivity value increases the effect of the recharge and the ASR well pumping. Thus, heads are much higher in this variation than in the base model. The boundary fluxes caused by the ASR well quickly reach steady state for the "Small" and "Smallest" models. There is no discernible impact to boundary flux for either the "Larger" or "Largest" models. The heads for the three largest models are indistinguishable on the plots.

The important conclusion from this variation is that when the conductivity is lower, the head errors caused by the nearer specified head conditions are greater but the boundary fluxes caused by ASR pumping decrease.

2.3.2 Variation 2 – Increase Aquifer Thickness

For the second variation, the thickness of the aquifer was increased by dropping the bottom elevation of the grid from 0 ft to -50 ft. These results are shown in Figures A.13 through A.16. The head impacts of the ASR pumping are smaller for these models because of the greater thickness of the aquifer. The impact of the ASR wells on boundary flux is slightly greater for the thicker aquifer runs but the head differences are slightly smaller.

2.3.3 Variation 3 – Increase Storage

For the last variation, the storage was increased by changing the specific yield from 0.1 to 0.5. Higher storage causes an increase in the time required for the model to reach a steady state condition. As concluded by the base model, significant head differences caused by boundary effects are found when the models reach steady state conditions.

2.4 Conclusions from Test Model

The purpose of this test model was to understand better the boundary effects from specified head boundaries on an ASR model. The models were also built to understand the relationship between head errors in the interior of the model due to boundary effects and the fluxes through the model boundary caused by the ASR wells. Conclusions from this exercise include:

- Head errors are greatest at the end of pumping periods and the beginning of rest periods.
- Heads are under-predicted by too-small models during injection.
- Heads are over-predicted by too-small models during extraction when the systems near steady state; head differences earlier in the pumping period are affected by previous conditions.
- Significant head errors in the interior of the model occur for models which reach steady state.
- Steady state conditions can be recognized both by a flattening of the heads and the arrival of boundary fluxes at the rate of ASR pumping.

- Generally, if the fluxes stay well below ASR pumping rates, the heads errors caused by the boundary effects are minor.
- When aquifer thickness is increased, boundary fluxes increase, but they are not matched by a similar increase in head errors in the interior of the model.
- When the conductivity is increased, boundary fluxes increase, but they are not matched by a similar increase in head errors in the interior of the model.
- When the storage term is decreased, steady state conditions are reached sooner, with the associated head impacts.

3 Regional Model Analysis

All of the performance measures used to assess the acceptability of the RASRSM-D13R scenarios were based on the head results of the model. Therefore, it is the impact of boundary effects on interior heads that are of greatest importance.

Because we cannot rerun the RASRSM-D13R with larger boundaries, we cannot directly determine the impact of the specified head boundary conditions on the head results of the model. However, by comparing the fluxes leaving the model through the boundaries with and without the ASR wells pumping, and using the lessons learned from the test models described in Section 2, we can draw some conclusions about the possible impact to the performance measure results.

For each specified head cell of the model, the impact of the ASR wells was quantified by comparing the flux to or from the model without the ASR wells to the flux with the ASR wells. The sign convention specifies that flux into the model be positive, while flux leaving the model is negative. The flux with ASR wells was subtracted from the flux without the ASR wells. A positive flux difference, then, indicates that flux out of the model has been increased by the ASR wells, flux into the model has been decreased or, an area which previously had flux into the model has now switched to flux leaving the model. Similarly, a negative flux difference indicates that flux out of the model has been decreased, flux into the model has been increased or an area which previously had flux out of the model has now switched to flux entering the model.

These flux differences were then summed up across “questionable” boundaries, which are defined as any non-ocean boundary where a specified head was assigned without the existence of a suitable infinite source/sink of water. These are the north, west and south boundaries of each of the aquifer units.

On Figures A.21 through A.25, the flux differences (changes to boundary fluxes caused by ASR pumping) at questionable boundaries are compared to the total ASR pumping throughout the 13-year period of the model. The total ASR pumping all ASR sites. Note that some sites may be injecting while others are extracting and the two rates have been summed with extraction rates being set to negative.

In Figure A.21, the questionable boundary flux differences in the IAS/ICU are depicted next to the total ASR pumping. Note that the total boundary flux differences never exceed 0.6 mgd, which is much less

than the pumping for a single ASR well (5 mgd). It is clear from the plot that there is a significant delay in the increase of the boundary flux and the flux is far from steady state. The low flux impact and the lack of steady state conditions indicate that the impacts to the model results are minimal in this unit.

Figure A.22 shows the questionable boundary flux differences in the UF along with the same plot of the total ASR pumping as in the previous figure. Again, the flux differences are small compared to the ASR pumping rates, with the maximum rate at approximately 13 mgd, less than three ASR wells. During most of the model period, the flux differences are below 5 mgd. As before, the plot shows no sign of steady state conditions, so the head impacts are likely minimal in the interior of the model.

The questionable boundary flux differences in the APPZ are shown in Figure A.23. Here, the maximum flux differences are nearly 11 mgd, slightly more than the capacity of two ASR wells. During most of the modeled period, the flux differences are below 3 mgd. There is no sign of steady state conditions, indicating minimal head impacts caused by the boundary conditions.

Figure A.24 shows the questionable boundary flux differences in the LF unit. In this unit, the boundary fluxes become more significant. The maximum difference between fluxes with and without the ASR wells is over 36 mgd, more than the capacity of seven ASR wells. Although the flux difference plot is still well below the total ASR pump rate and has not reached a steady state condition, there is clearly less damping in this unit. The head impacts are still expected to be minimal, but are probably more pronounced than in the upper aquifer units.

Finally, Figure A.25 shows the questionable boundary flux differences in the BZ. This unit shows the greatest flux difference caused by the ASR pumping with the maximum rate at nearly 435 mgd, the equivalent of almost 87 ASR wells. Although this seems like a significant flux difference, the plot still shows no evidence of arrival at steady state conditions. And the flow rate is still far below the maximum ASR pumping rate of over 1600 mgd. There is, however, a significant drop in the damping effects of the flux difference plot. Changes in flux occur quite rapidly after a change to the ASR pumping. The head impacts are expected to be minimal, but may be more pronounced than in the upper units.

Figure A.26 compares the boundary flux distributions across the 13-year period for each of the four aquifer units (UF, APPZ, LF, BZ). This plot reiterates the information from the previous plots.

It seems clear that there is no significant impact to heads in the IAS/ICU due to boundary condition effects. The confining unit in layer 4 of the model appears to cut off the ASR pumping from the western boundary of the IAS. This minimal impact is also apparent in the drawdown plots in Figure 4.134 of the main report. Significant head differences from the ASR system barely reach the western boundary of the model in a few places. No specified head boundary conditions are set on the north or south boundaries in these layers.

The impact to heads in the UF and APPZ is also likely insignificant. There is severe damping in the boundary flux difference plots and the flux differences are quite small compared to the ASR pumping. Impacts to heads are assumed to be within the error tolerance of the model.

The impacts to heads in the interior of the LF and BZ units could be larger. The damping observed in the upper units is less pronounced in these units. The magnitudes of the flux differences are also larger. However, neither unit reaches a steady state condition. Based on the test models described in Section 2, head impacts are not significant when the boundary flux differences are well below the ASR pumping rate and when they do not reach a steady state condition.

Further analysis of the model parameters in each of the layers can lend additional credence to the idea that head impacts are insignificant. Figure A.27 compares the aquifer thicknesses for each of the four aquifer units (UF, APPZ, LF, BZ). Note that the distributions are based on total area, not on total number of cells. One quarter of the model domain area fits into each section of the blue bar, with an additional quarter fitting into the black lined error bars above and below the blue bars. In Figure A.27, we see that the BZ thickness is 500 ft across the entire domain. The majority of each of the other aquifers is much thinner than 500 ft. One of the conclusions of the test model presented in Section 2 of this appendix was that an increased thickness can cause an increase in boundary flux differences without an associated increase in head errors. Thus, some of the large boundary flux differences experienced by the BZ may be the result of a thicker unit, not the result of additional error caused by the boundary condition selection.

Figure A.28 compares the horizontal hydraulic conductivities of each of the four units. Although there is a wide distribution of hydraulic conductivities in all units, the majority of the BZ has been assigned a hydraulic conductivity value that is at least one full order of magnitude higher than the majority of the values in the other units. The conductivity values in the LF are slightly higher than those in the APPZ and about an order of magnitude higher than those in the UF. One of the conclusions of the test model presented in Section 2 of this appendix was that higher conductivity values can have an impact on the boundary flux changes without having a parallel impact on interior head results. Some of the flux differences observed in the LF and BZ (shown in Figures A.24 and A.25) could be due to greater hydraulic conductivity, and not due to faulty boundary condition assignments.

Figure A.29 compares the specific storage values assigned to each of the four units. Note that the LF and the BZ have generally lower specific storage than the upper aquifer units. As described in Section 2 of this appendix, the smaller storage values result in a faster arrival at steady state conditions. This is seen in the regional model as a slight reduction in the damping effect of the boundary flux differences. However, since neither aquifer reaches any condition that appears to be steady state, there is little reason to suppose that head impacts in the interior of the model are significant.

4 CONCLUSIONS

A test model was built to investigate the relationship between flux differences at questionable boundaries due to ASR pumping and interior head differences caused by the specified head boundary conditions which did not correspond to infinite source/sinks of water. The table below lists the observations on the test model, the corresponding observations on the RASRSM and the conclusions that can be drawn.

Test Model Observations	RASRSM-D13R Observations	Conclusions
Head errors are greatest at the end of pumping periods and the beginning of rest periods.	The limiting factors on the performance measures generally occur at the end of the pumping periods when the head impacts from the ASR wells are greatest.	This is non-conservative for the RASRSM.
Heads are under-predicted by too-small models during injection.	N/A	This is non-conservative for the RASRSM.
Heads are over-predicted by too-small models during extraction when the systems near steady state; head differences earlier in the pumping period are affected by previous conditions.	N/A	This is non-conservative for the RASRSM.
Significant head errors in the interior of the model occur for models which reach steady state. Steady state conditions can be recognized both by a flattening of the heads and the arrival of boundary fluxes at the rate of ASR pumping.	The flux differences at the boundaries never reach steady state during the RASRSM run.	Head errors caused by the poorly defined boundary conditions are unlikely to be significant in the RASRSM.
Generally, if the fluxes remain below ASR pumping rates, the head errors caused by the boundary effects are minor.	The flux differences are far short of the ASR pumping rates in each aquifer unit of the model.	Head errors caused by the boundary effects are expected to be minor in all layers.
When aquifer thickness is increased, boundary fluxes increase, but they are not matched by a similar increase in head errors in the interior of the model.	The BZ, where the greatest flux differences were observed, is thicker than most areas of other units in the model.	Some of the boundary flux differences observed in the BZ are likely due to the increased unit thickness and do not indicate a significant head impact in the interior of the model.
When the conductivity is increased, boundary fluxes increase, but they are not matched by a similar increase in head errors in the interior of the model.	Hydraulic conductivities are generally greater in the LF and BZ layers of the model, where the greatest flux differences are observed.	Some of the boundary flux differences observed in the LF and BZ are likely due to greater hydraulic conductivity and do not indicate a significant head impact in the interior of the model.

Test Model Observations	RASRSM-D13R Observations	Conclusions
When the storage term is decreased, steady state conditions are reached sooner, with the associated head impacts.	The specific storage in the LF and BZ layers is generally smaller than in the UF and APPZ layers.	The smaller storage term in the LF and BZ account for the loss of some of the damping in the flux difference plots. However, a steady state condition is never reached in any of the layers.

The analysis and observations described in this appendix have led to the conclusion that the selection of specified head boundary conditions at areas interior of the ocean outcrop have not adversely affected the analysis of performance measures in the interior of the regional model. Any differences will be minor and within the error tolerance of the model.

- Aquifer Layers
- Confining Units
- Specified Head Cells

Notes:

Specified head boundary conditions were applied to the top surface of the model, the Atlantic Ocean outcrop for all layers and the inland north, west, and south boundaries for aquifer layers.

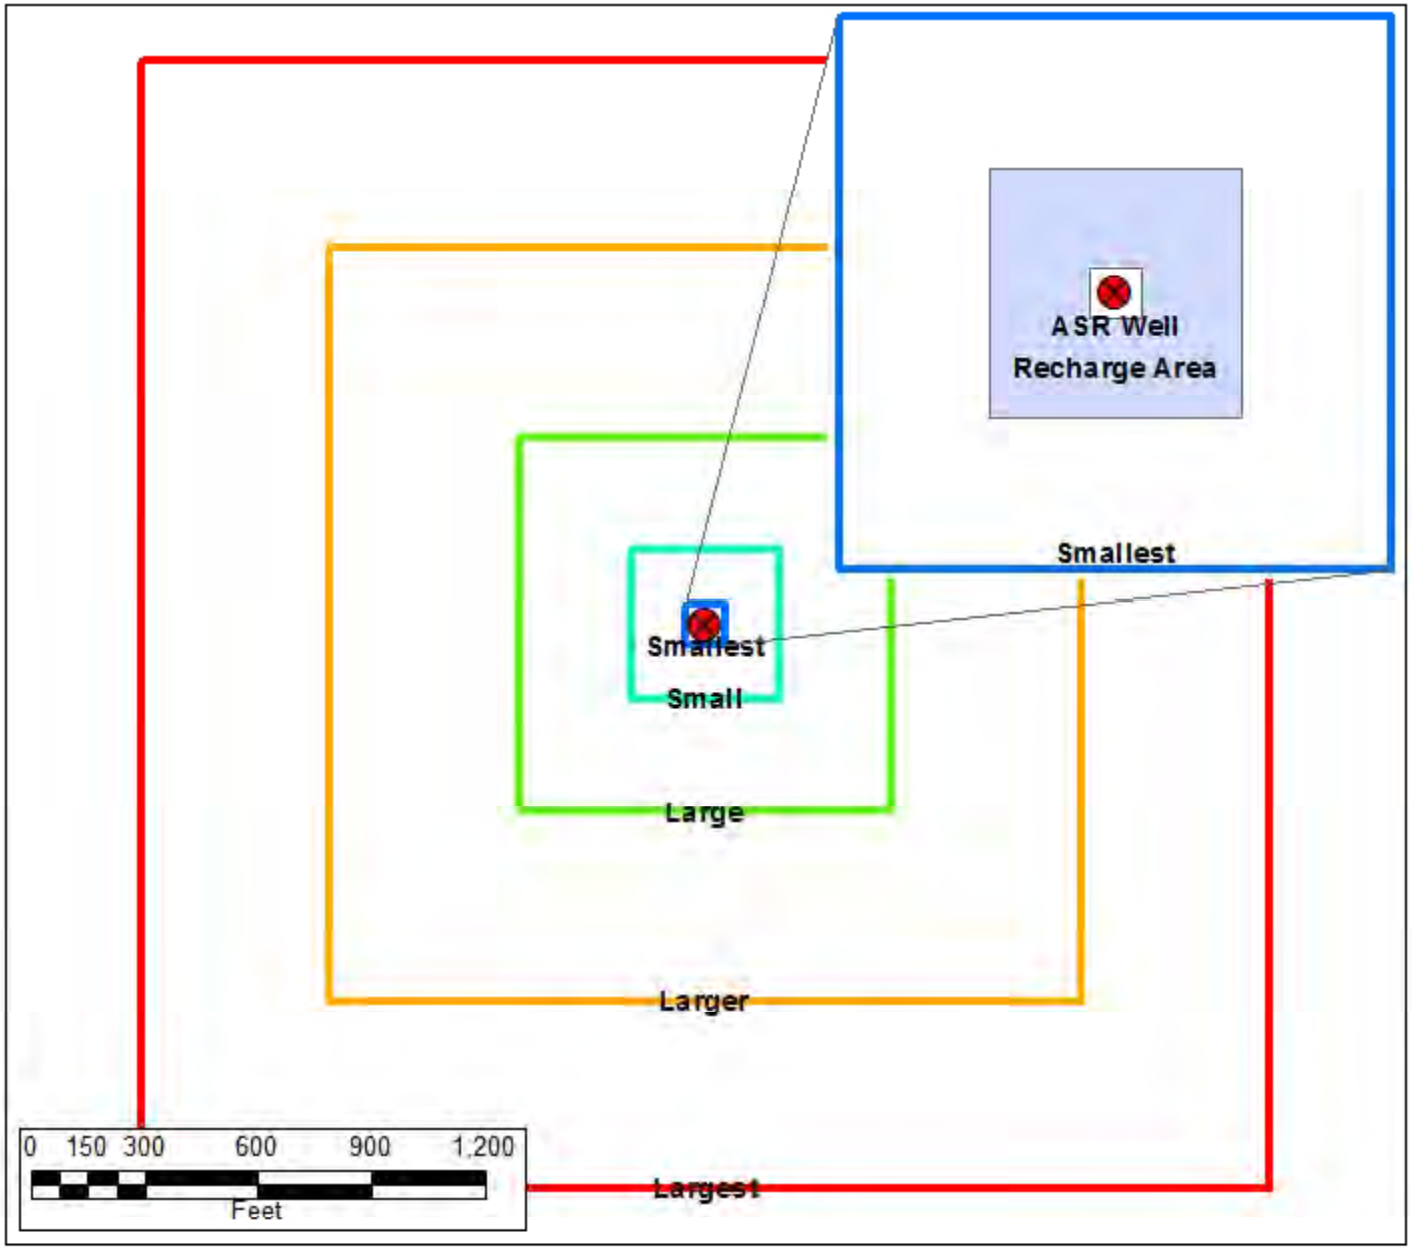
Vertical exaggeration is 50.

SPECIFIED HEAD BOUNDARY CONDITIONS

DRAFT REGIONAL MODEL PRODUCTION SCENARIO REPORT

FIGURE A.1

JUNE 2013



Notes:

The five test models were designed to be of varying sizes centered around the ASR well. A small area of recharge was set in the middle to produce a slightly raised water table with flow going out to all boundaries.

Each model consisted of 10 ft x 10 ft square cells and the thickness of the single layer was 100 ft.

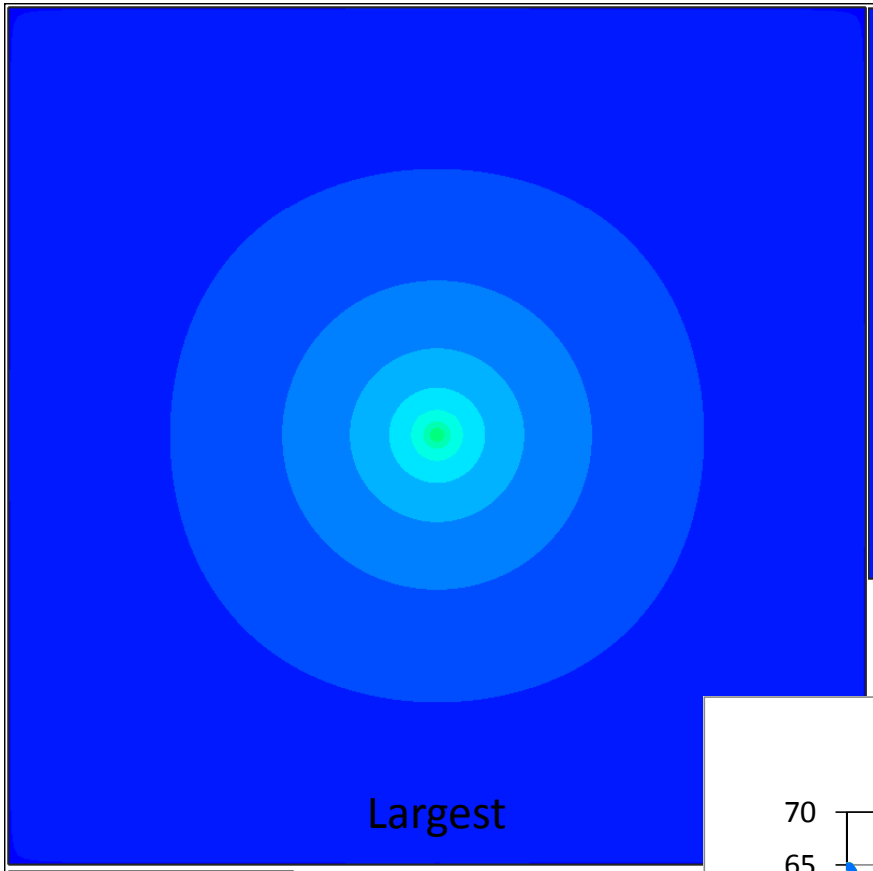
The specified head boundary condition of 50 ft was set at the boundary of the "Largest" model. The steady state results of that model were then used to set the boundary conditions of all other models.

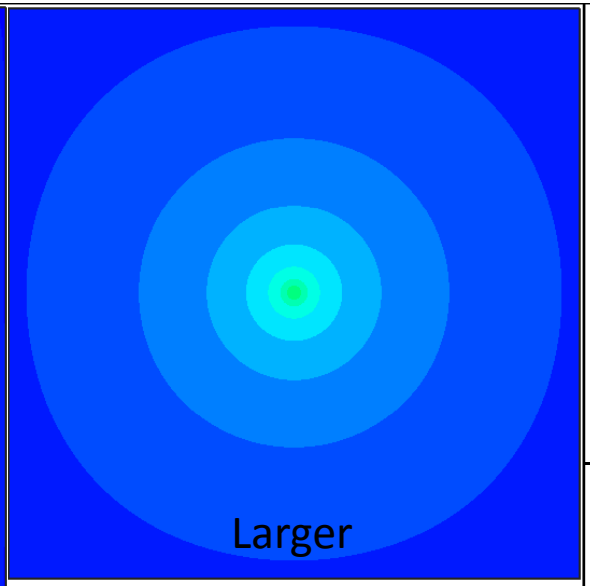
TEST MODEL BOUNDARIES

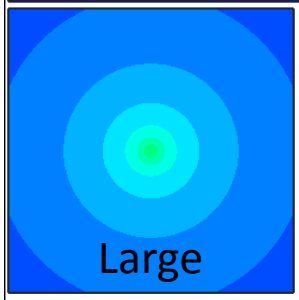
FIGURE A.2

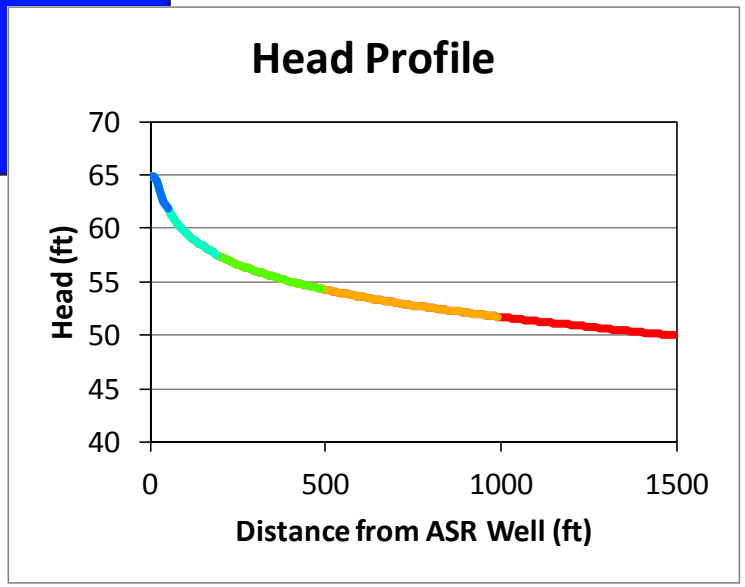
DRAFT REGIONAL MODEL PRODUCTION SCENARIO REPORT

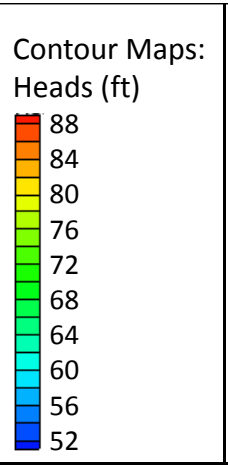
JUNE 2013











Notes:

These figures show the steady state condition used as a starting condition for the ASR test model. The "Largest" model has specified heads of 50 ft along the entire outside boundary and a small area of recharge near the center. The boundary conditions on the outside boundaries of the smaller four models are set from the "Largest" model and all have the same area of recharge near the center. The five images and the head profile plot show that the initial condition for each of the five models were identical.

APPENDIX B

IMC COMMENTS TO DRAFT REPORT WITH USACE RESPONSES

This appendix presents the comments from the IMC review of the Draft Production Scenario Report. The comments have been copied verbatim into the left column of this appendix. Comments have been divided into table rows for convenience. The right column of this appendix presents USACE responses to the comments, an indication of updates to the report and explanations where necessary.

IMC MSR 324 Task 4c -- Review of "Draft Regional Model Production Scenario Report Aquifer Storage and Recovery Regional Modeling Study"

Interagency Modeling Center (IMC)

IMC Comments	USACE Responses
Purpose The purpose of this document is to provide comments based upon the review of the report submitted in support of the Aquifer Storage and Recovery (ASR) modeling study based on the use of a calibrated regional model to analyze the effects of the proposed Comprehensive Everglades Restoration Plan (CERP) ASR system consisting of 333 ASR wells with the potential to inject or extract 5 mgd each. <u>Documents Reviewed</u> The document shown below was submitted for IMC review: • "Draft Regional Model Production Scenario Report, Aquifer Storage and Recovery Regional Modeling Study." US Army Corps of Engineers, September, 2012. Individual reviewers in some cases reviewed additional documents when certain parts of the report above needed further clarification. The technical comments made by the IMC review team on this document follow. **Technical Comments** The review was limited to the document above, and therefore does not extend to the model code, model input or model output files. The comments are listed following the review objectives agreed upon by the USACE and the IMC.	No response necessary.

IMC Comments	USACE Responses
1. Are the text and figures clear and understandable?	
In general, the text and figures are clear and understandable.	No comment necessary
The box and whisker plots in Figure 2.7 through Figure 2.9 do not seem appropriate to be within Section 2.2 (Choice of Time Period). A more appropriate section or subsection heading should be selected to suit precipitation analysis described in these figures.	The purpose of these box-and-whisker plots and the associated analysis was to support the decision to shorten the modeled time period from 30 years (like the SFWMM-D13R model) to just 13 years. As such, we feel this is the right place to include this analysis and the associated figures. Additional text and explanations have been added to Section 2.2 to clarify this purpose.
It would be helpful if the proposed ASR sites are shown in Figure 3.1(as was done in Figure 1.1) to understand better the rock fracture potential maximum total head in relation to the ASR well sites.	Figure has been updated.
In Figure 4.20 (Scenario 1 – Maximum Drawdown and "Drawup" by Aquifer) and subsequent figures for the other scenarios, it would be helpful to add the boundary locations of the model to these figures as these boundaries are relevant to the discussions in the appendix.	Figures have been updated.
In Figures 4.33, 4.52, and similar figures describing ASR well fluxes for the various scenarios, the legend uses Run1, Run 2, etc. Shouldn't these be Scenario 1, Scenario 2 etc?	Figures have been updated.
A correction should be made on the note section of Figure 4.108 from 10 gpm wells to 10 mgd wells.	Figure has been updated.
In Figure A.5 to Figure A.8, show the 0 (zero) line on the flux scale as this is a critical location in understanding the data.	Figures have been redesigned to show zero flux line.

IMC Comments	USACE Responses
Overall, the report is well organized. However, the report would be considered more complete if the model setup section had included setup and discussions of initial TDS/temperature and head conditions, how TDS/temperature was accounted for in the methodology on page 7 for boundary conditions, and detailed discussions of recovery efficiency uncertainty in Section 7.	Section 2.7 has been added to the document to describe the setup of the initial conditions (head, TDS and temperature). There was no need to account for TDS and temperature when developing the boundary conditions because SEAWAT allows the user to enter observed heads for the boundary conditions. During calculations, the model determines the effective freshwater head using the water quality and the observed head. SEAWAT does not have the capability to automatically stop extraction when the water quality reaches a certain threshold. In addition, this is a regional model and cannot be expected to accurately calculate near-field impacts of the wells – including water quality of extracted water. Recovery efficiency was an assumption and an input to the model. Assumed recovery efficiencies were based on hydraulic conductivity, existing water quality and experience at the two pilot sites as described in Section 2.6.1. The initial conditions set for the model did not impact decisions regarding assumed recovery efficiency.
2. Is the methodology used to convert the calibration model to the 1965-1977 time –period adequate to meet the goals of the projects?	
The modelers should state the reasons why it was necessary to develop the regional model production scenarios using the RASRSM-D13R model instead of using the SFWMM-D13R. The reasons should include the limitations of addressing the performance measures using SFWMM-D13R and the difference in the characteristics of the aquifer systems modeled using SFWMM-D13R and RASRSM-D13R.	Several new paragraphs have been added to Section 2 to describe the shortcomings of the SFWMM and the need for the RASRSM-D13R model.

IMC Comments	USACE Responses
Please explain in more detail why the RASRSM would not be able to cover the 30-year period. It was stated in the document that file-size limitation and run time made it difficult to run the RASRSM for the 30 year period. Was investment on additional computer resources considered?	Several new computers were acquired during this project and additional computers were borrowed from other projects during the Monte Carlo analysis. During the course of every model, the desired extent, resolution and detail must be balanced with the available time and computer resources. Because the first 13 years of the 30-year D13R period was considered to be representative, the purchase of even more computer resources was not considered to be likely to provide significantly better results. Additional text has been added to section 2.2 to better explain the constraints of the model.
To reduce run-time and file-size a possibility could have been shutting-off the density-dependent and transport part of SEAWAT and run it as a MODFLOW model to assume freshwater conditions since the injected water in the ASR is freshwater and the salinity in the UF might not have an effect on the performance measure analyses to determine the number of wells to be installed in the UF.	As explained in more detail below, the density dependence was very important to the model. Although the UF is not very deep or salty, the BZ is quite deep and salty and exerts a great force on the upper layers of the model. Without the density dependence, the model would not have yielded accurate results.
In the event that reducing the time period to 13 years was the most appropriate way to proceed with the analyses of the performance measures, the methodology used by the modelers to convert the calibrated RASRSM model to RASRM-D13R while considering ASR requirements used in the SFWMM-D13R model is reasonable. However, it is requested that the modelers clarify or explain the following modeling issues:	No comment necessary.

IMC Comments	USACE Responses
a) Please explain the methodology to convert the calibrated RASRSM to an earlier time period for the conversion of all the important parameters. This conversion is to some extent a validation process, since stresses and boundaries are redefined and applied to a calibrated model with calibrated parameters such as geological (i.e., aquifer tops and bottoms), hydrogeological (i.e., hydraulic conductivity, storativity) and transport (i.e., dispersivity) parameters. The modelers discussed and justified recharge and pumping stresses and head boundary conditions; however, initial conditions of heads and TDS concentrations were not mentioned and discussed in the report. As the modelers know, in a transient flow and transport model, initial conditions, especially TDS concentrations, are crucial. Transport process is not reversible, and initial TDS concentrations should be reasonably defined and discussed before running a model. Please discuss how initial conditions of head and TDS concentrations were converted to the back time period of 1965-1977.	A new section (2.7) has been added to describe the selection of initial conditions.

IMC Comments	USACE Responses
b) The modelers justified the conversion of model period to 1965-1977. The justifications look reasonable for the flow aspects but more information is needed for the contaminant transport aspects of the model. The modelers justified reducing the time period to a short 13-yr period due to file size limitations and computational run-time, choosing 1965 as the start time to minimize impact by previous injection periods, choosing 1977 as end time to include periods covered by SAJ Lake Okeechobee models and to incorporate the entire first cycle of Lake Okeechobee basin wells. Precipitations, annual extracted/injected volumes, boundary conditions, and regional pumping are also redefined and discussed for the shorter model time period 1965-1977. Model time steps and stress periods were adjusted to reduce computer run-time as well. Though all this looks reasonable, the reviewers were concerned that when you take into consideration the whole period 1965-1995, 1965-1977 was probably a period for which data is least accurate or insufficient. 1977 in Figure 2.2 showed a return to zero storage volume. With this observation, a later time period for example, 1983-1995 could produce more reliable data for ASR design since later times in the model period seem to have better data quality especially for pumping data. Please explain in the report why a later period, for example 1983-1995, was not used. Could the results have been significantly different for the performance measures if the period 1983-1995 have been used considering that the aquifer storage volumes shape in Figure 2.2 for 1965-1977 and 1983-1995 are quite different? Why or why not?	Figure 2.2 shows the storage volume only for the Lake Okeechobee ASR basin. Although this represents the largest volume in the CERP ASR system, there are 4 other basins with significant ASR flows which do not return to zero storage in 1977. Only the Lake Okeechobee and Central Palm Beach basins have zero storage at any period other than 1965. Further, running the RASRSM-D13R model from 1983-1995 would not have covered the time period used in the SAJ Lake Okeechobee models. The use of the period 1983-1995 might have had minor impacts on the performance measure results. The pump pressure limit is affected by the largest injection rate at the ASR wells. The maximum injection rates (5 mgd/well) is achieved in all basins during the 1965-1977 period. Some minor impacts might be caused by longer periods of injection or greater volumes injected over long periods of time. The maximum annual injection volume in the Lake Okeechobee basin during the 1965-1977 period is approximately 98% of the maximum annual injection volume for the period 1965-1995. The maximum annual injection volume in the Caloosahatchee basin during the 1965-1977 period is also about 98% of the 30-year maximum. For the Lower East Coast basins, the comparisons range from 81% to 87%. Possibly a small increase in these pump pressures might have been noted, but the difference would be within the error of the model because the maximum rate (5 mgd) was met on numerous occasions in all basins. The APPA performance measure results are affected by the extraction rates in a few sites on the east and northeast shore of Lake Okeechobee, mainly Lakeside Ranch, Port Mayaca, L-63N, Taylor Creek, North Lake Okeechobee and Kissimmee River/Paradise Run. As noted above, all of these sites achieve full extraction rates (5 mgd) during the 1965-1977 period. Some additional minor impacts might be felt if the extraction rates continue for long periods of time or if large volumes are extracted. However the maximum annual extraction volume for this basin, over the 30-year period, occurred in 1975, a year included in the shortened 13-year period used in the RASRSM-D13R scenarios. For these reasons, we feel that no additional justification is needed for the use of the shortened time period for the RASRSM-D13R.

IMC Comments	USACE Responses
d) On Page 19, it was mentioned "after the calibrated RASRM had been adjusted to reflect the 1965-1977 period…" Please explain how the adjusted model reflects the 1965-1977 hydrological and transport conditions. Are there any comparisons and statistics that show that the results from the adjusted model are reasonable especially for the transport conditions?	A new section, 2.8, has been added along with a number of figures showing good correlations between modeled output and available head data. Regarding comparisons to transport conditions, the reader is directed to Section 2.7 which explains the fact that salinity conditions are not expected to change drastically in most areas of the model on a time scale of 40 years.
3. Is the methodology used to calculate the required pump pressure adequate to meet the goals of the project? Are the results reasonable?	

IMC Comments	USACE Responses
The methodology is reasonable. It is the Theim equation for confined aquifers under steady state conditions. However, in transient conditions as in this model, it could be assume that after a short period of time, release of water from storage is negligible in the vicinity of the well and the Theim equation will apply. The modelers conducted useful numerical experiments with smaller grid sizes, showing that the pressure is inversely proportional to the distance to the pumping well. Also, the lesser the distance to the pumping well, the higher the pressure, and pressure becomes more similar as the distance from the well increases. However, since grid size is about 2000 ft and it is unrealistic to run a numerical model with a 2 ft grid size, the modelers used the Theim equation to estimate pressure around a pumping well by reducing the grid size to a smaller one (2 ft). The equation also includes the transmissivity of the aquifer, thus high pressure is found in an aquifer with low transmissivity. The report mentioned that the PDT determined that it would be important to keep pressure head below 100 psi but the justification of this pressure was not given. Please site a reference to justify that this pump pressure requirement is realistic for ASR wells or how the pressure limit for an ASR well could be determined. This criterion proved to be very important and is used to optimize the ASR design in each of the scenario runs.	An additional sentence has been added to the first paragraph of Section 3.2 to explain that permitted wells in the FAS are normally tested to a level of 100 psi. This includes the pilot study ASR wells at Kissimmee River and Hillsboro.

IMC Comments	USACE Responses
On page 4 of the calibration model report, it states, "For the Phase II study, SEAWAT modeling was performed using the variable-density flow with solute transport mode." On page 13, the modelers state that the head difference is converted to pressure using the density of water which is a constant. But the water in the UF is brackish water and it was stated in Section 2.1 of the ASR calibration report that there are substantial density variations in the groundwater thus requiring the use of a density-dependent groundwater modeling code. If this is so, why was the variability in density not taken into account in the pump pressure calculations?	It may have been more correct to take this into account when calculating the pump pressures. However, the impact of the decision not to include TDS in this calculation is minor for a few reasons: Although the variation in TDS in the model is large, the variation in TDS at the proposed UF ASR sites is small. Figure 3.18 in the calibration report shows a range of about 500 – 5000 ug/L TDS at the proposed sites in the UF. This translates into a change in density of 0.02 – 0.23 lb/ft3. Temperature variations are smaller: about 24-29 degrees F (see Figure 3.29 in the calibration report). This equates to an increase in density up to 0.02 (for temperature below 25 degrees F) or a decrease in density up to 0.07 (for temperature above 25 degrees). Thus, if freshwater density is 62.25 lb/ft3, the maximum groundwater density that would be seen at any UF ASR site would be 62.5 lb/ft3. See equation 2.1 in the calibration report for details on the calculations. At 100 psi, the head difference for the freshwater density would be 231.3 ft. For a density of 62.5 lb/ft3, the head difference would be 230.4 ft. This difference of 1.1 feet is within the error of the model. Note that in the APPZ and BZ, the TDS levels are higher and so the densities are also higher. This means there may be a greater error caused by using the freshwater densities in these calculations. However, the APPZ and BZ pressures are well below the 100 psi limit in all scenarios and so any error introduced in this way will not impact the number of wells recommended at each site.

IMC Comments	USACE Responses
The results on the maximum pump pressure computed for each proposed ASR site revealed that all sites would need to be able to overcome pressures much greater than 100 psi. This was a very useful finding as this performance measure revealed to the modelers right away that the 333 ASR wells in the UF proposed in CERP would exceed 100psi and the number of ASR wells in the UF would need to be reduced/.	No response necessary.
4. Is the methodology used to calculate the reduction in artesian pressure adequate to meet the goals of the project? Are the results reasonable?	
The methodology used to evaluate artesian pressure reduction in the UF and the APPZ aquifers in Saint Lucie and Martin counties is reasonable. It basically used the Jacob and Lohman flow equation. The flow equation given in the report has an error in one of its coefficients. It should be 2.25 and not 2.5. The reviewers hope that this is a typo. Please revisit the calculations as an error of this nature might have a significant impact on the artesian pressure calculations.	This value of 2.25 was a typo and has been corrected in equation 3.8 and 3.9. However, because the calculation is a comparison between flows with and without ASR, this coefficient and many of the other parameters are canceled out during the subsequent derivation. Note that Equation 3.14, which was used in the analysis does not include the 2.25 coefficient and is not dependent on it. No error was introduced by this typo.

IMC Comments	USACE Responses
The flow reduction is calculated from simulated head pressure before and after the ASR project. The modelers used a similar procedure by Merritt (1997) using the Jacob and Lohman equation to calculate flow from an artesian well in the UF over time. The equation includes aquifer transmissivity, well radius, storage coefficient and difference between aquifer head and ground surface elevation. The flow reduction is presented in two ways by the modelers: 1) maps of the UF and APPZ layer with the cells colored by maximum percent flow reduction across the time period and 2) maps of cells colored by the number of days within 13 years that the 10% rule is exceeded. The methods measured magnitudes and frequencies of flow reduction within most of the two counties. An exception is that a ridge coming from the northwest increases the ground surface elevations, making the Merritt equation invalid when evaluating artesian wells. The performance measure is used to evaluate the effect of ASR wells on the flow reduction of artesian wells in Saint Lucie and Martin counties.	No response necessary.
The results obtained from applying the methodology are reasonable if the coefficient of 2.25 was used and show that the effect on the artesian conditions in St. Lucie and Martin Counties are significant and that most areas loose over 10% of artesian flow for more than 40% of the model time period when all 333 ASR wells are used in the UF.	No response necessary.
5. Are the descriptions of the eight D13R scenarios clear and are their purposes explained well?	

IMC Comments	USACE Responses
The descriptions of the eight scenarios are clear and their purposes are also explained though the reviewers didn't see the significance of some of the scenarios. Please explain how the 333 ASR wells were determined by the SFWMM-D13R model. Note that the SFWMM models the unconfined surficial aquifer system (SAS) that is the topmost layer in the aquifer system. A link-node approach was used to simulate the ASR wells assuming an efficiency ratio. ASR wells for CERP purposes are supposed to be placed in the UF which is a confined aquifer below the SAS separated by a complete separation between the SAS and the UF.	Additional text has been added to Section 2 to explain the determination of the need for 333 ASR wells and to explain the differences in the groundwater calculations made in the SWFMM-D13R and the RASRSM-D13R models
In the RASRSM calibration report Figure 2.2 shows that the model includes five confined aquifers and five unconfined units (see p.7 of calibration report). It is also stated on page 7 of the calibration report "The SEAWAT grid also includes the SAS although no calculations are made there." The reason is because of the assumed complete separation between the SAS and the UF. Please explain how the 333 ASR wells were determined using the SFWMM (an SAS unconfined system). Please confirm if the original CERP assumption that 333 ASR wells could be used in the UF aquifer and aquifers below is valid.	Additional text has been added to Section 2 to explain the determination of the SFWMM-D13R of the need for 333 ASR wells. This determination was made solely on the volume of excess water which needed to be stored and the volume of additional water that needed to be supplied during dry seasons. The purpose of this RASRSM-D13R model was to determine if these 333 wells could be used from a regional hydrogeologic perspective.
Nonetheless, the scenarios started from a full D13R design from SFWMM, and then scaled back to meet performance measures such as pump pressure requirement. During model runs, some ASR wells were moved among aquifers and pump rates and recovery efficiency were adjusted in order to meet performance measures.	No response necessary.
6. Do the results of the eight D13R scenarios make sense conceptually?	

IMC Comments	USACE Responses
Before discussing whether the eight RASRSM-D13R scenarios make sense conceptually, the reviewers are recommending that two quick possible preliminary scenarios (Scenario 0a and 0b) should be run using the 30-year period RASRSM calibrated model with all 333 ASR wells in the UF but with important changes in the run mode of SEAWAT to avoid the runtime problems encountered by the modelers. *Scenario 0a:* Solve the RASRSM model as constant density flow and no solute transport with the additional 333 ASR wells. ➢ This simulation would determine the sensitivity to variable-density and solute transport to UF heads when compared to Scenario 1. ➢ In SEAWAT, turn off the switch for no density-dependent flow and no solute transport so that the simulation is done using MODFLOW only. ➢ Make a note of the UF heads for each cell in the UF layers. *Scenario 0b:* Solve the RASRSM model as a constant density flow and solute transport with the additional 333 ASR wells. ➢ This simulation would determine the density-dependence on UF heads when compared to Scenario 1. ➢ In SEAWAT, turn off the switch for the variable density component and solve as coupled flow and transport model. ➢ Make a note of the UF heads for each cell in the UF layers. Once these two scenarios are run, compare the difference in heads between each of the two scenarios and Scenario 1 for the UF in a difference map. If the UF heads in Scenario 1 are not significantly different from that of Scenario 0a, then all the analysis and scenarios discussed in this work could be performed using the RASRSM model for scenario 0a as the base model for scenarios 1 through 8. To show the advantage of doing this preliminary scenario analysis, consider the following results obtained with the SFWMD lower east coast (LEC) SEAWAT model. It has similar layers as the RASRSM. Each row and column was 2400 ft by 2400 ft; the active cells per layer were approximately 51,040; the total active cells were 714,520 and the time step was 1 month. A simulation similar to Scenario 0a for the LEC model took 1hr and 10 minutes for a 6 year stress period on a 3 GHz EMG4T processor machine with 8 GB RAM. Scenario 0b took 7hr and 25 minutes and Scenario 1 took 8 hours and 30 minutes. These results show that if variable density and TDS concentration do not affect significantly the heads in the UF, then the performance measures analyses could have been done using SEAWAT using Scenario 0a as the base model. The run time could have been reduced by an order of magnitude of about 8 and possibly the modelers would have had no need to limit the modeling period to 1965-1977.	Removal of density dependence as suggested by this commenter will result in significant changes to groundwater heads and flows. Note that Scenario 0a and 0b will result in the same head results. The only difference between the two is that a TDS concentration will be calculated for Scenario 0b but not for 0a. As shown in Figures B.1 through B.4, the steady state calibration of the RASRSM is greatly different when density dependence is removed. Note that in Figure B.1, the UF heads in the southern 2/3 of the model are significantly lower when density dependence is removed. Similar effects are seen in all other layers of the model. Figure B.5 shows the comparison between model calculated heads and observed heads. Note that where the heads are high (near the Polk County recharge area) the inclusion of density dependence makes no difference. But in other areas of the model, the difference is stark and many error values are greater than 20 feet. A similar effect is shown in Figures B.6 and B.7 where a few comparison points are shown from the transient calibration run. As expected, when density dependence is removed, points far from the recharge area have much lower heads than the measured heads. The measured heads in the southern portion of the model domain are high because of the pressure exerted by the high TDS, low temperature (high density) water in the ocean, which enters the BZ and pushes upward on the water above it. This cyclical movement of water is not only supported by the results of this model, but also in a number of references (Kohout, 1965, Kohout, 1988, Bittner, et al., 2008). Figures B.8 through B.11 show the impact of removal of density dependence for Scenario 1 as suggested by the reviewer. Note that large sections of both the UF and APPZ have head differences greater than 50 feet between the two runs. When post-processing is used to compare the results against the performance measures, the results are shown in Figures B.12 through B.14. Pump pressures estimated for the ASR sites are slightly lower when density dependence is removed (compare Figure B.12 to Figure 4.17 in the main report). The results of the APPA analysis are significantly different since most of St. Lucie and Martin Counties are no longer artesian even without the ASR wells (compare Figure B.13 to Figure 4.18 in the main report). Drawdown and "drawup" caused by the ASR wells is only slightly different (compare Figure B.14 to Figure 4.20 in the main report). The removal of density dependence affects more than just the head results. It completely changes the flow regime. Figures B.15 through B.29 show the results of a few particle tracking exercises. Note that in many places, the direction of flow is opposite for the two runs. Flow directions are summarized in the next few figures. Figures B.30 through B.32 show the comparison of vertical flow through each of the confining units. The sign of the vertical component of flow is shown with red for downward flow and blue for upward flow. In the LC, MC2 and MC1, the majority of the flow is downward without density dependence and upward with density dependence. Figures B.33 through B.36 show the direction of the horizontal component of flow in the aquifers. There are significant differences in the direction of flow in the two runs, especially in the southern half of the model domain. This shows that the entire flow regime has changed with the removal of the density dependence. The time savings of a simple MODFLOW model without water quality transport equations would have been useful, but the results would not have been accurate. Full SEAWAT calculations were necessary in this case.

IMC Comments	USACE Responses
The following comments below pertain to the scenarios that are modeled and presented in this report. Some of the scenarios are reasonable as they follow a logical sequence after discovering that the 333 ASR wells proposed by CERP for the UF wouldn't meet the requirements of the performance measures. Therefore the task after this discovery was to determine whether wells that could not be placed in the UF could be distributed within the other aquifers. However, it leaves the reviewers with two very important questions shown below.	No response necessary.

IMC Comments	USACE Responses
With the decision made to distribute some of the wells among other aquifer units, please explain the rationale of placing wells in the Boulder Zone (BZ), instead of the Lower Floridan aquifer (LF). The LF aquifer is a permeable unit above the Boulder Zone which is separated from the BZ by the Lower Floridan Confining unit. Installing wells in the LF would be a much better alternative to installing wells in the BZ. The Boulder Zone is difficult to drill into, having the same rough, shaking, grabbing effect on the drill system and drilling rig as boulders would. Also, the TDS concentrations in the BZ (that of salt water) and the depth from ground level, makes this a challenging zone to work with.	The process of developing the D13R scenarios began with the UF aquifer only, as was envisioned by CERP. When it became clear that the UF could not handle all 333 wells, it was a natural step to begin placing some in the APPZ. However, it was soon obvious that even with the two aquifers, the full injection and extraction volumes could not be achieved. As the PDT discussed the next steps, consideration of the BZ was introduced as a way to dispose of excess water, protecting the estuarine habitats from excess fresh water and reducing flooding in Lake Okeechobee and the canals. The PDT was aware of the expense and difficulty in working with the BZ. These wells were not considered to be true ASR wells because of the low recovery efficiency, but were considered to be disposal wells for the removal of excess water. This run was meant to get as close as possible to the D13R volumes, even though it might eventually turn out to be difficult or expensive to build. Further discussions with the PDT in January 2013 (after the release of the Draft version of this report, but before receipt of IMC comments) resulted in the addition of Scenario 12 which removes the BZ wells from Scenario 11. A section on Scenario 12 (4.12) was added to this report. Unfortunately, scheduling constraints do not allow the repeat of the Monte Carlo analysis, however, because of the high conductivity in the BZ, the results would be very similar.

IMC Comments	USACE Responses
Scenario 1: The modeling run made for this scenario using the RASRSM-D13R followed the injection and extraction schedules used in the SFWMM-D13R model as closely as possible. All the 333 recommended ASR wells were in the UF. The simulated results and calculated performance measures showed maximum pump pressure requirements at all ASR sites are above 100psi, and even approach more than 400 psi at Taylor Creek and 800 psi at the L-63N site. The effects on the artesian conditions in Saint Lucie and Martin counties were significant; maximum drawdown is greater than five feet in most of the modeled area. The regional effects of the system are widespread and significant, because all 333 ASR wells were assigned in the UF. This scenario didn't satisfy the performance measures.	No response necessary.
Scenario 2: Based on simulated results in Scenarios 1, the modelers developed a strategy by removing wells until the pump pressure requirement of 100 psi was met at each site. It was mentioned that removing some ASR wells is somewhat arbitrary, but we would suggest removing those wells located at areas with relatively low hydraulic conductivity, which will thus significantly reduce maximum pump pressures below 100 psi. As a result, the scenario provided less storage and recovery volume and reduced the total number of ASR wells from 333 to 97.	The process of removing the ASR wells was termed arbitrary because it was not based on any specific algorithm. Wells were removed from sites where the pressure was above 100 psi. Removal continued until the pressure was within the limit. Naturally, this would mean removal of most wells from areas of low hydraulic conductivity or areas of high ASR well density. Text has been adjusted to clarify this.

IMC Comments	USACE Responses
Scenario 3: Scenario 3 was developed by having 97 ASR wells in the UF and 236 ASR wells in the APPZ aquifer which consists mainly of the Middle Floridan aquifer (MF). The results showed an increase in pump pressure requirements in the UF but most of the wells that were already in the UF didn't violate the 100 psi pump pressure criteria. The 100 psi criterion for the APPZ was violated in most of the 232 wells in the APPZ. Only 41 wells in the APPZ met the 100 psi requirement.	No response necessary.
Scenario 4: In this scenario, the modelers ended up removing 191 wells from the APPZ in order to satisfy the 100 psi performance measure criteria for both the UF and the APPZ. They were able to successfully leave 41 wells in the APPZ because these 41 wells were mainly in areas that didn't have the UF as an upper confining unit. The implication of this scenario is that once the 97 ASR wells are already in place in the UF, it would be difficult to add wells in the APPZ without violating the pump pressure performance measure.	No response necessary.

IMC Comments	USACE Responses
Scenario 5: A scenario is recommended, referred to as (Scenario 4a) in this review report where the 191 wells removed from the APPZ should have been placed in the Lower Floridan aquifer (LF). It is not clear why this scenario was not tested or reported. Based on the familiarity of the reviewers with the Florida Aquifer System (FAS), this scenario would have ended with violation of the 100 psi requirement in the APPZ and UF in some of the wells that were already meeting this requirement under the previous scenarios because the aquifer is confined and pressure builds quickly under high pumping conditions. Thus, Scenario 5.	As mentioned in this comment, the addition of wells to the LF would probably not have resulted in a significant increase in available storage because of the hydraulic conditions of the aquifer. Because of the water quality conditions of the aquifer, recovery efficiency would have been low and only a small increase in recovery volumes would have been achieved. Once it was determined that the UF and APPZ together could not achieve the volumes set forth in the SFWMM-D13R, the PDT began looking for places to dispose of excess water, without expecting to be able to recover it. The BZ seemed like the best location for this.
The relevance of installing ASR wells in the BZ is not sufficiently explained. The BZ permeability is very high because of its cavernous nature and its anomalous extremely high permeability prevents pressure buildup in injection wells. However, the BZ is not suitable for ASR wells because the zone contains saltwater of concentration similar to that of seawater. The BZ has been used for years to store vast quantities of treated sewage injected into it in Miami, Fort Lauderdale, West Palm Beach and Stuart but the reviewers are not aware of anywhere where the BZ is being used to store fresh water.	As explained above, the recovery efficiency in the BZ is so low, that these wells cannot truly be considered ASR wells. These wells were meant to remove excess freshwater from the surface water system but were not expected to be able to store or provide freshwater when needed.

IMC Comments	USACE Responses
Due to the existence of the Floridan confining unit, and the lower middle confining unit which is located between the BZ and upper layers (UF and APPZ); and due to the cavernous nature of the BZ, the effect that ASR wells installed in the BZ may have on the upper layers is very limited as shown in the report. It is difficult to build up pressure in the BZ. Also, since TDS concentration in the BZ is similar to that of seawater, the assumption of 10% recovery efficiency is not reasonable. Thus total annual extraction rates will be even lower than estimated from the scenario. Is it consistent with the ASR objectives to pump freshwater into the BZ with TDS concentration close to or higher than seawater?	Scenario 5 has been removed from this report since it is so similar to Scenario 9. This removes the estimate of 10% recovery efficiency from the BZ and converts ASR wells in the BZ into disposal wells.
Scenarios 6-8: not detailed in the report as the PDT decided not to pursue these scenarios.	No response necessary.
Scenarios 9: In this scenario, the pump capacity was increased to 10 mgd at each ASR wells in the BZ in order to maintain the same total amount of injections. Recovery efficiency was reduced to 0% so that drawdowns decreased slightly. Again, because of the cavernous nature of the BZ increasing the pumping rate from 5 mgd to 10 mgd would have very little impact. The reason to develop this scenario for ASR is not clear.	With the removal of Scenario 5 (see above), Scenario 9 becomes more important.

IMC Comments	USACE Responses
Scenarios 10: Based on Scenario 9, the run simulated in this scenario further reduced recovery efficiency at each site so that the artesian pressure in the APPA area is less than 10% and maximum drawdown one mile each side is less than or equal to one (1) foot. In addition, recovery storage was reduced to between 1% and 4% of the SFWMM-D13R, so scenario 10 is more like storage system with no retrieval.	No response necessary.
Scenario 11: This is the final design that was selected by the PDT. According to the modelers, it meets all performance measure requirements other than the one (1) foot drawdown at one (1) mile distance from the well. This allowed to increase recovery efficiency at most sites so that total annual recovery storage increased between 12% and 60%. This scenario resulted in a design that located 94 ASR wells in the UF, 37 ASR wells in the APPZ, and 101 ASR wells in the BZ. The UF and APPZ wells will have 5 mgd each while the BZ wells will have 10 mgd capacity. Please describe what was the criteria to assign recovery efficiencies at each site. Also, based on the discussion, it seems that these efficiencies are different from recovery efficiencies expressed by the ratio of recovered over injected volume of water, please explain these differences. In Figure 4.146, recovery efficiency at Marcy and Port Mayaca (Lake Okeechobee basin) was reduced to 0%.	The assignment of recovery efficiencies to each proposed ASR site is described sufficiently in Section 2.6.1. The extraction percentages shown in Figure 4.146 are not recovery efficiencies. These are reductions to extraction rates which were used to reduce the impact to the APPA in St. Lucie and Martin Counties. These percentages were applied directly to the extraction rates and were unrelated to the injection rates or water quality. Although a 0% extraction percentage is equal to a 0% recovery efficiency, the reason for the reduction is different. Recovery efficiency is caused by poor water quality in the recovered water resulting the need to stop extracting. Extraction percentage is caused by the need to minimize drawdown impacts in St. Lucie and Martin Counties. Additional notes have been added to Figures 4.146 and 4.127 to clarify this.

IMC Comments	USACE Responses
Nevertheless, it is not clear about the rational of the PDT to select Scenario 11 as the final design. Is it required that 333 ASR wells must be installed as opposed to a number of wells that produce the same performance for CERP? Based on the analyses in this report, the reviewers concluded that ASR wells should only be installed in the UF and possibly the APPZ.	This analysis shows that installation of ASR wells at the specified sites in the UF and APPZ will not be able to fully meet the water storage needs of CERP or the water supplementation needs of CERP (as defined by SFWMM-D13R). Full water removal during wet periods can be achieved with the use of the BZ. No known number of ASR wells can be installed to produce the performance required for CERP while still meeting the regional hydraulic performance measures. This is explained in Section 8 of the report.
7. Does the analysis in Appendix A adequately address possible concerns with the location of the north, west, and south boundary of the model?	
The concern with the locations of the north, west, and south boundaries was previously provided to the modelers when the calibrated RASRM model was reviewed by the IMC. The review report from the IMC mentioned that when ASR wells are installed, some of the inland boundaries will be too close to the ASR wells and drawdown caused by ASR wells will extend to those boundaries. As mentioned in the report, in Figures 4.20, 4.39, 4.58, 4.77, 4.96, 4.115, 4.134 and 4.153, significant head changes extended to the western, southern and northern boundaries, indicating the use of inland specified head boundaries at these locations may be violated.	No response necessary.

IMC Comments	USACE Responses
However, as stated in the report, extension of western, southern and northern boundaries is not feasible for several reasons. Instead, the modelers conducted a series of numerical modeling, and calculated flux differences across these boundaries between the non-ASR well scenario and ASR well scenarios. The ideal situation would have been that there is no difference between these two conditions. However, Figures A.21 through 25 showed increases of flux across IAS/ICU, UF, APPZ, LF and BZ between the two conditions. This indicates that the inland specified head boundaries along the western, northern and southern boundaries do have effects on the interior heads of the model. The magnitudes of the increase are related to the magnitudes of the recharges and discharges of the ASR wells.	No response necessary.

IMC Comments	USACE Responses
As found in the numerical experiments, the flux change (increase / decrease) are larger when the model approaches steady state and larger where closer to ASR wells. Therefore, in addition to calculating flux changes across questionable boundaries, it is suggested cropping a smaller box around the area of interest (i.e., APPA) and calculating flux changes across the box boundaries between non-ASR and ASR conditions. Any quantifications and justifications about the magnitude of flux changes would be helpful.	When a specified head boundary condition is applied to a model boundary, the assumption is that there is an infinite source/sink of water at that location. The model removes or adds whatever volumes of water are necessary to ensure that the head remains at the specified value. If the boundary is set too close to the ASR wells, the specified head assumption is violated since the head will not remain constant. The purpose of this analysis was to determine the validity of the specified head boundary condition. If the fluxes through the boundary remained constant despite the addition of interior pumping, then we could be assured that the boundaries were set at a sufficient distance that they would not impact the head results inside the model. If the fluxes are calculated across the boundaries of a smaller box around the area of interest, as recommended by the reviewer, the fluxes would definitely be larger than at the model boundary, but this would not tell us anything about the validity of boundary conditions since the boundaries of a smaller box would not coincide with a model boundary. Since the heads at the location of a smaller box are allowed to vary, there is no violation of assumptions in allowing the flux to vary.
8. Is the Monte Carlo methodology (including the calibration checks) adequate for the reasonable analysis of model uncertainty?	

IMC Comments	USACE Responses
The Monte Carlo methodology is one of the widely used methods to characterize uncertainties in numerical models. The key point of the method is to use a large number of samples (or to run a number of simulations) so that realizations of the parameter fields using their probability density functions could be used to determined uncertainties in the predictive response of the model. To run a number of simulations, computational time is one of important factor to consider.	No response necessary.
The modelers did some checks before applying the method to the RASRSM-D13R model. If simulations pass steady state and transient model check (NAP, 2011), then the input files (selected parameters) will be valid for the RASRSM-D13R. Therefore, statistical analysis for uncertainties in the model will be based on these simulations. The reason for the check is that RASRSM-D13R cannot be explicitly calibrated but appears consistent with the calibrated RASRM model through the conversion process.	No response necessary.
9. Is the selection of parameters for variation (and their probability distributions) in the Monte Carlo simulation adequate for a reasonable analysis of model uncertainty?	
There were six (6) groups of parameter combination used in these analyses.	No response necessary.
a) Uniform distribution: Porosity, longitudinal dispersivity and molecular. However, according to previous studies (Gelhar, 1992), dispersivity is usually represented as a log distribution and not as a uniform distribution as used in the model.	The range of acceptable values for longitudinal dispersivity was quite small (0.1 to 2.5), only 1.4 times a log scale. It was felt that the linear distribution would be more appropriate for a small range. Also, a log scale would have put additional weight on small values, which was not desired.

IMC Comments	USACE Responses
b) Log Distribution: ratios of longitudinal to transverse dispersivity, longitudinal to vertical dispersivity and horizontal to vertical conductivity for each aquifer.	No comment necessary
c) Hydraulic conductivity and specific storage: The modelers included the most sensitive parameters into the calibration model as pilot points, which is reasonable and doable. However, the method to vary hydraulic conductivity is questionable. First, the range shouldn't be too narrow to make them close to calibrated values (only ½ to 2 times was used in the report). Uncertainty from these parameters could be investigated with a wider range. Second, uniform distribution can only be applied to log-transformed hydraulic conductivity and log-transformed specific storage but not to their original values directly.	The range was set to be very narrow because there was a great amount of field data used during the calibration of the model. (See Figures 3.8-3.10, 3.34, 3.36 and 3,38 in the Calibration Report.) The purpose of the Monte Carlo was to determine the uncertainty in the results caused by uncertainty in the input parameters. Thus, the ranges and distributions of the input parameters should reflect their uncertainty. Since there was quite a lot of APT data in each of the aquifers, the uncertainty in the hydraulic conductivity was low compared to many other model parameters. The narrow range ensures that this low uncertainty is communicated to the Monte Carlo analysis. Secondly, although a log transform is generally used for hydraulic conductivities, it was not used in this case because the range of values was less than one log cycle. Log distributions were applied to the specific storage values as explained in Section 6.1.3.
d) Invertible distribution: horizontal anisotropy of hydraulic conductivity.	No response necessary.

IMC Comments	USACE Responses
e) Initial (starting) conditions for TDS and temperature: The initial TDS concentrations and temperatures were not discussed in the model set-up section, but they are considered as one of the uncertainties in the numerical model. As mentioned before, initial TDS and temperature should be carefully determined before running a coupled variable-density transient flow and transport model. During randomizing the initial TDS and temperature, the values only vary between 80% and 120%, which means initial TDS and temperature used in the model are mostly close to their calibrated values. In addition, the model results would be very sensitive to the initial TDS concentration. The narrow range of variation of the value may be reasonable, but the question is how the initial TDS (and temperature) have been determined when running Scenario 1.	This comment was made previously and has been discussed above. In addition, a new section, 2.7, has been added to the report to discuss initial conditions, including TDS.
f) Multiplier (0.5 to2) was applied to change the thickness of the BZ.	No comment necessary.
For a specific model run, there is a combination of all input parameters such as hydraulic conductivity, storage, dispersivity, etc. some of them may be correlated. It is not clear how the modelers selected randomized values from each of the parameters and make a combination to run a simulation. It was mentioned that there were 1485 parameters, but detailed information about combining randomized parameters would be helpful.	No correlation of the parameters was assumed and no combinations were made. All values were randomized with their own unique random value, generated by FORTAN.

IMC Comments	USACE Responses
As to the number of Monte Carlo simulations, in Figure 6.14, it shows that when the number of Monte Carlo simulations increases, half-width of 95% Confidence Interval decreases, but it approaches a constant when certain number of simulations is run. This is the basis of the Monte Carlo method, which means a large number of simulations may be needed to reasonably characterize uncertainty of the model. From Figure 6.14, a number between 1000 and 10,000 would meet this requirement. So, it seems at least a doubled number (1,650) of simulations are needed if running time allows.	The half-width of the 95% confidence interval approaches zero without ever arriving at zero. When deciding the number of Monte Carlo simulations necessary, the required precision must be balanced with the available resources and time. The 825 simulations run for this project brought the half-width of the 95% confidence interval within 3.5%, which is likely within the error of the model. Sections 6.3.2, 6.3.3 and 6.3.4 show that this confidence interval is quite small compared to the results and continued Monte Carlo simulations would lend little additional precision to the results. At 825 simulations, the point of diminishing returns has been reached. Finishing with 10,000 Monte Carlo runs would reduce the half-width of the 95% confidence interval to less than 1%, but it would take 3 years with current computer resources. That is a very expensive 2.5% improvement.
10. Are there any sources of uncertainty or error that are not addressed in the report, but which might adversely impact the usefulness of the model results?	

IMC Comments	USACE Responses
The modelers discussed a number of uncertainties from model setup, conversion of calibration model to D13R model, ASR pumping data, and performance measures. One of the important uncertainties is the recovery efficiency. Throughout the report, the modelers did a series of numerical experiments to rearrange and renumber the ASR wells within aquifers and to assign various recovery efficiencies at ASR wells, in order to meet performance measures set by the PDT and to let the ASR system function properly. It is noticed that as much as 100% recovery efficiencies were assigned for a few ASR wells in the final scenario, but in reality, this 100% recovery efficiency is unreasonable, and it is likely that the water recharged into the aquifer system cannot be recovered or would disappear in fractures in the aquifer due to uncertainties in characterizing the aquifer system. Please clarify what these efficiencies represent.	No ASR wells were assigned 100% recovery efficiency. It is possible that the reviewer is referring either to extraction percentage (Figure 4.146) which is the comparison of actual extraction rates to assigned extraction rates, or to comparisons of SFWMM-D13R assigned rates and RASRSM-D13R assigned rates as shown on Figures 4.162, 4.163 and 4.164. Additional text and notes have been added to clarify this.
11. Does the reviewer agree with the conclusions and recommendations?	
The assumption of 333 ASR wells is based on CERP modeling with the SFWMM which is greatly limited because it assumes no interaction with the UF. The ASR wells are intended to be installed in the UF which is a confined aquifer system. A confined aquifer with 333 wells pumping at 5 mgd results in a cone of depression and drawdown of the aquifer system that could not be simulated with the SFWMM.	No response necessary.

IMC Comments	USACE Responses
No information was presented on the TDS concentration and temperature conversion that was done when the RASRSM-D13R was developed for the time period 1965-1977. On page 3 of the ASR calibration report which preceded the report currently under review, the modelers state "The regional model will provide planning level information to address large scale issues such as the regional effect of the ASR well clusters on saltwater intrusion……and water quality." In the ASR impact report under review, the modelers stated on page 17 that unfortunately, the regional model is not able to address water quality migration and salt water intrusion because it cannot accurately portray TDS transport near wells and that the salinity at locations far from the ASR wells are highly dependent on transport parameters such as dispersion, which could not be calibrated due to lack of TDS time series data. Please explain how TDS concentration and temperature conversion were done in RASRSM-D13R for 1965-1977 using data from the RASRSM calibrated model. The reviewers question would like to know details of the parameters of the contaminant transport component of the RASRSM-D13R.	Section 5.2 and 5.3 of the calibration report provide transport parameter values used in the calibration report. Tables 6.1 and 6.2 provide ranges and distributions for transport parameters values for the Monte Carlo analysis. A new section (2.7) has been added to this report to clarify the selection of initial TDS conditions.

IMC Comments	USACE Responses
The modelers did a series of numerical experiments on the converted RASRSM-D13R model, based on assumptions especially on recovery efficiency. Recovery efficiency, which is a very important uncertain parameter, is not included into the Monte Carlo analysis. The modelers mentioned in the end that the regional model made a few assumptions such as aquifer conditions and recovery efficiency, so that when predicting local effect of the ASR wells system it is necessary to analyze closely using pilot points at proposed ASR sites and using local scale models.	The inclusion of recovery efficiency in the model was not as simple as inputing a single value in a text file. A change to the recovery efficiency involved a detailed calculation of stored water volumes with comparisons to flow rates. Inclusion of recovery efficiency in the Monte Carlo was deemed far too complicated. However, recovery efficiency only impacts the length of time that extraction occurs. A small variation (5%-10%) of the recovery efficiency would likely only have impacted Lake Okeechobee and Central Palm Beach basins, since these are the basins that return to zero stored volume during the model period (see Figures 2.1 through 2.5). Further, because recovery efficiency only affects extraction and not injection, it would have only minor impacts on the pump pressure analysis or on the "drawup" results since these occur during injection periods. Although the loss of artesian pressure in the APPA is a result of extraction rates, all ASR sites near the APPA have had extraction rates dropped significantly below the recovery efficiency in order to meet the performance measure, so a small change to recovery efficiency in the Monte Carlo would not have affected that performance measure. The only measurable impact of a small variation to recovery efficiency would be to the drawdown areas. This performance measure did not impact the selection of ASR wells. As mentioned by the reviewer, recovery efficiency is an issue that should be studied in detail at each individual site using pilot projects and local scale models.
A final design was found with 94 wells in the UF, 37 ASR wells in the APPZ and 101 ASR wells in the BZ. The final design in our view should only include wells in the UF and possibly in the APPZ especially since the ASR wells are needed for water supply from the UF to supplement water from the SAS.	Scenario 12 has been added which removes the BZ wells from Scenario 11.

IMC Comments	USACE Responses
Additional Comments: 1. Limiting heads to prevent rock fracturing As mentioned in the report, the method of Nick Geibel of USACE Omaha District was used to analyze and estimate the limiting heads in each aquifer. A concern on the calculations is that the static total head was taken from the February 2004 calibration model. Why simulated heads from one of the scenario runs (e.g., full design run) was not used for the calculation? Adding 333 ASR injection wells will increase head pressure locally and/or globally.	This analysis is explained more clearly in the 2012 Geibel report and this document (section 3.1) has been adjusted to more closely resemble that explanation. The term "static total head" as used in this report is called "ambient pre-fracture water pressure" in the Geibel paper. We discussed this comment with Mr. Geibel and he assured us that this term refers to the aquifer conditions before pumping begins. The increased head caused by the injection from 333 ASR wells is compared to the result of Equation 3.6.
2. Can this model be used to determine the optimum number of ASR wells that can be located in the Upper Floridan aquifer while avoiding locating wells in the boulder zone?	Scenario 2 provides one possible answer to this question.

Scenario 0a includes all of the 333 ASR wells specified by the SFWMM-D13R design but no density dependence. All are fully penetrating in the UF Aquifer.

This plot shows the highest pressure at each site which the pump would need to overcome in order to inject storage water during the 13-year simulation.

The PDT determined that it would be important to keep this pressure below 100 psi (indicated by the heavy black line).

Note that maximum pressures are shown for all aquifers and all sites even if ASR pumps are not located there for the current scenario.

Compare to Figure 4.17 in the main report.

Impact of TDS and Temperature Transport on Pump Pressure Performance Measure (D13R Scenario 0a)

Response to Comments, Production Scenario Report

- 5% - 10%
- 10% - 20%
- 20% - 50%
- 50% - 100%
- Loses artesian condition

Notes:

Scenario 0a includes all of the 333 ASR wells specified by the SFWMM-D13R design but does not include density dependence. All are fully penetrating in the UF Aquifer.

These plots show the maximum reduction in artesian flow at each model cell as a percentage when compared to the flow expected without the ASR project.

Permit rules require that the reduction in Saint Lucie and Martin Counties be less than 10%.

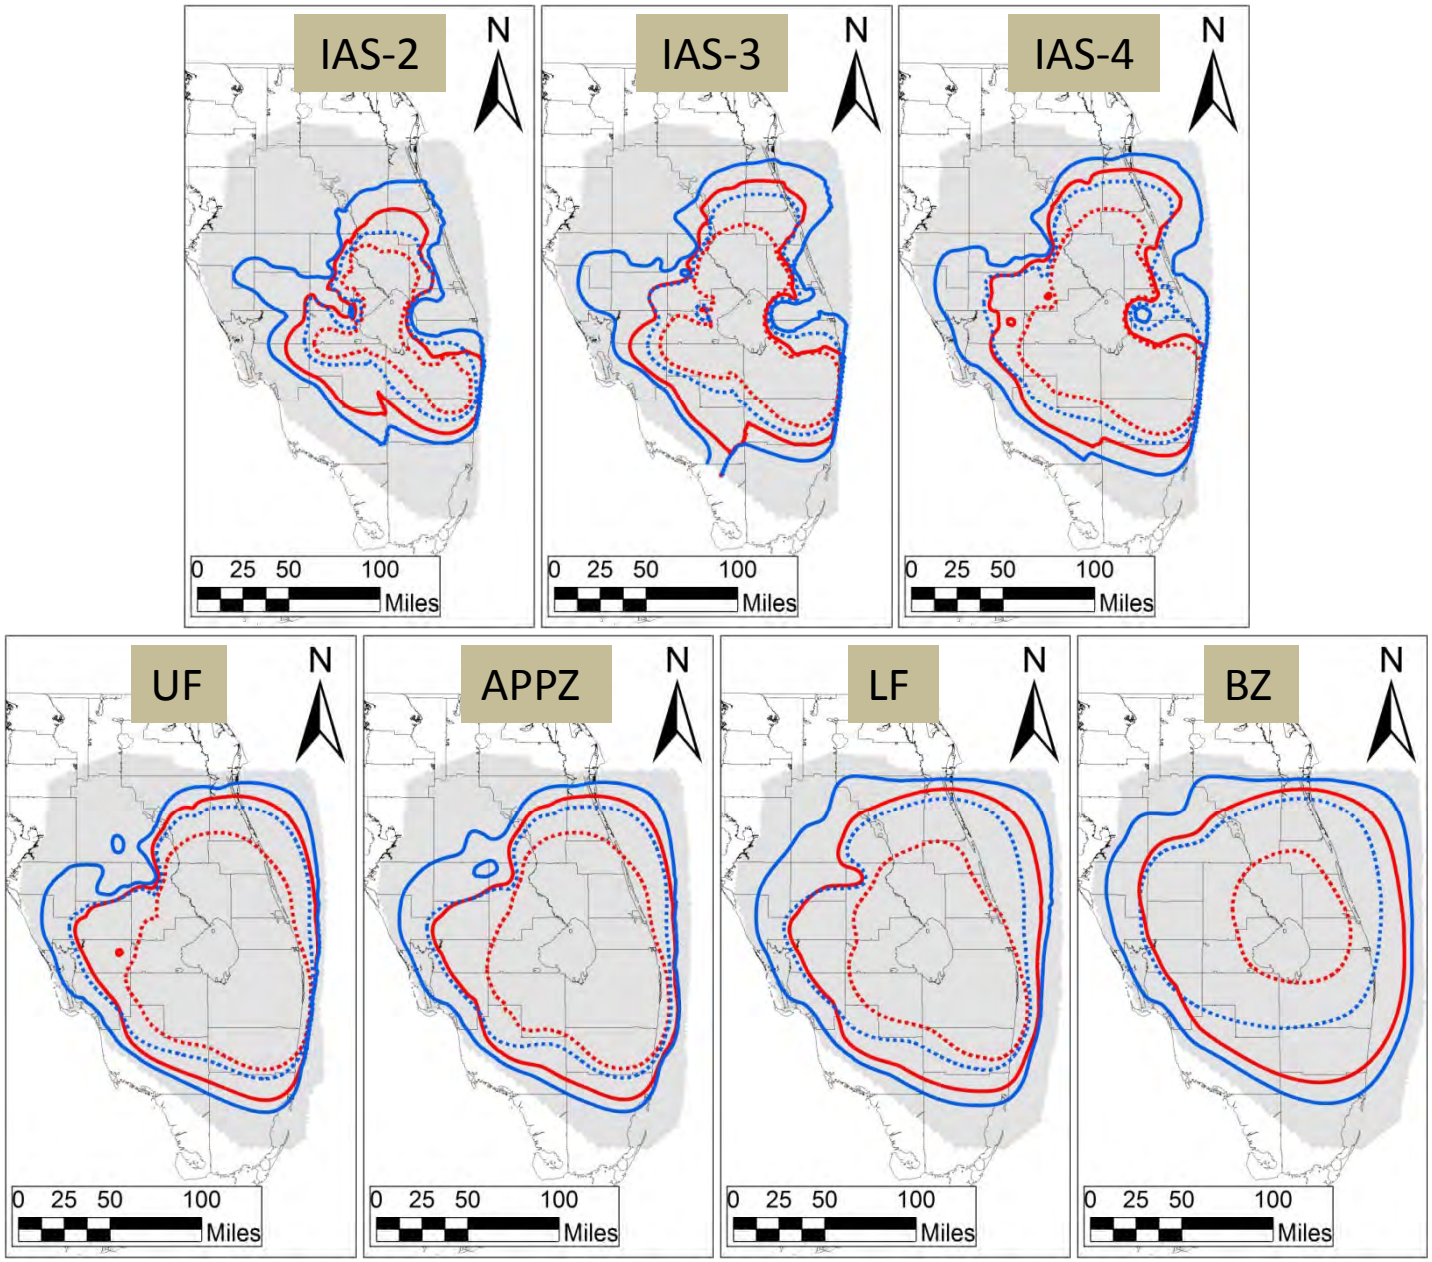
Compare to Figure 4.18 in the main report.

Impact of TDS and Temperature Transport on APPA Performance Measure (D13R Scenario 0a)

Response to Comments, Production Scenario Report

Figure B.13

June 2013



Legend

Maximum Drawdown
- 1 foot
- 5 feet

Maximum "Drawup"
- 1 foot
- 5 feet

Model Domain

Notes:

Scenario 0 includes all of the 333 ASR wells specified by the SFWMM-D13R design but does not include density dependence. All are fully penetrating in the UF Aquifer.

These figures show the extent of the areas where the maximum drawdown or "drawup" is greater than 1 foot or 5 feet.

The maximum condition does not necessarily occur at the same time for all regions of the model.

Compare to Figure 4.20 in the main report.

Impact of TDS and Temperature Transport on APPA Performance Measure (D13R Scenario 0a)

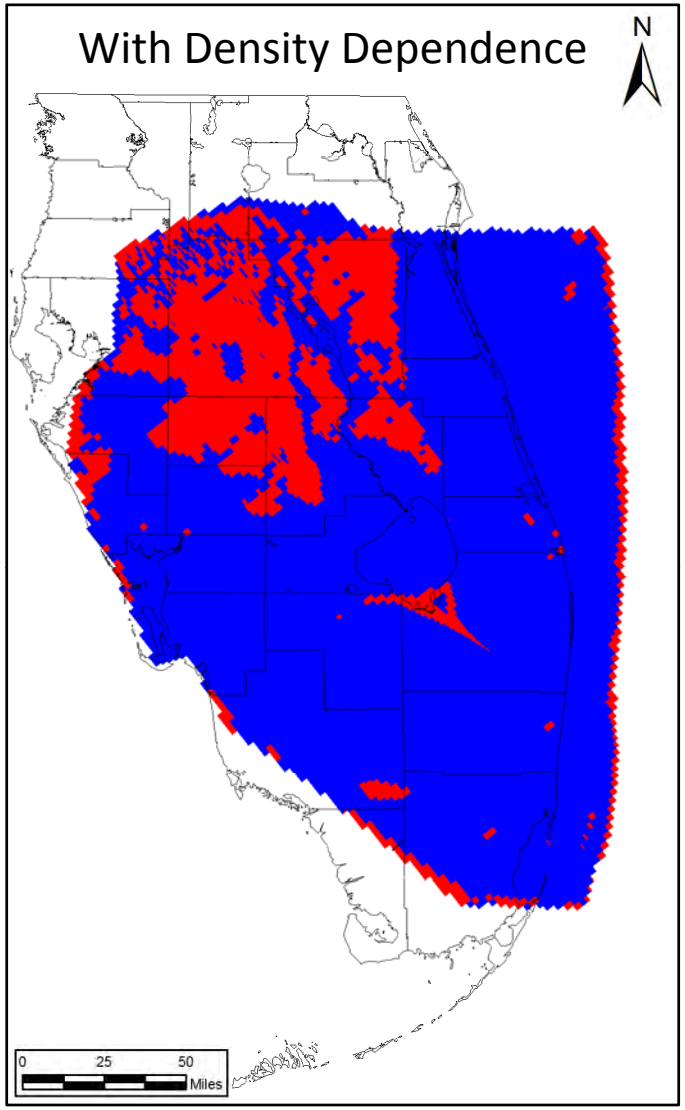
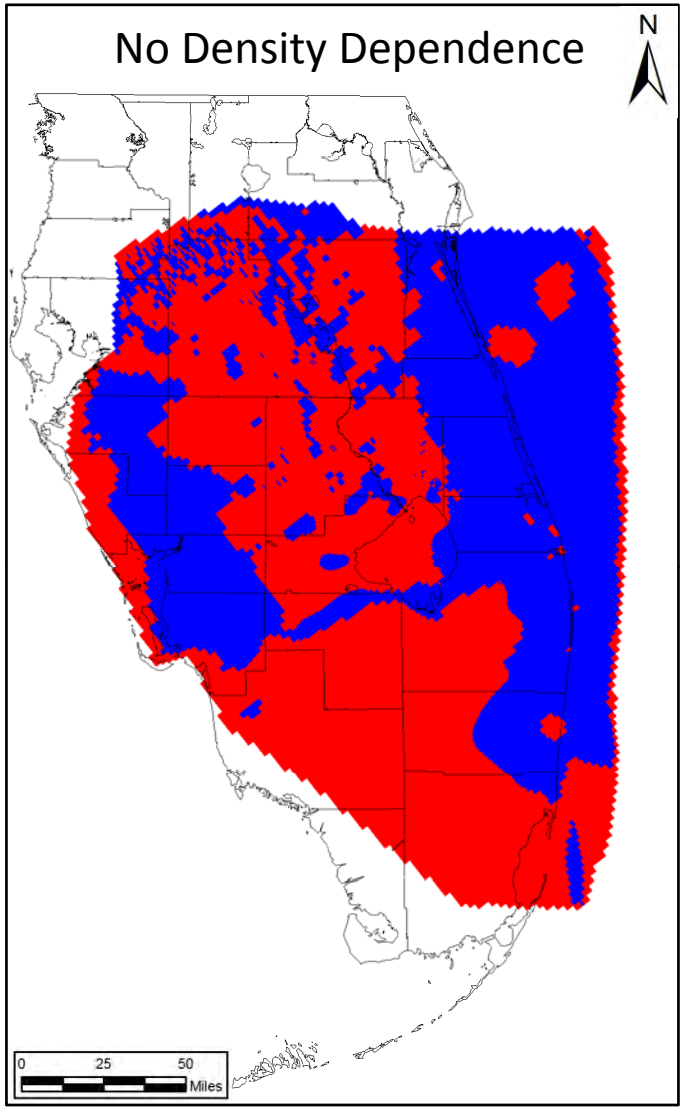
Figure B.31

June 2013





Legend

Downward Flow

Upward Flow

Notes:

This figure shows the locations of upward vs. downward flow in the MC1 when density dependence is included or removed in the February 2004 steady state calibration model.

When density dependence is included, the majority of the model domain has upward flow between the APPZ and UF layers.

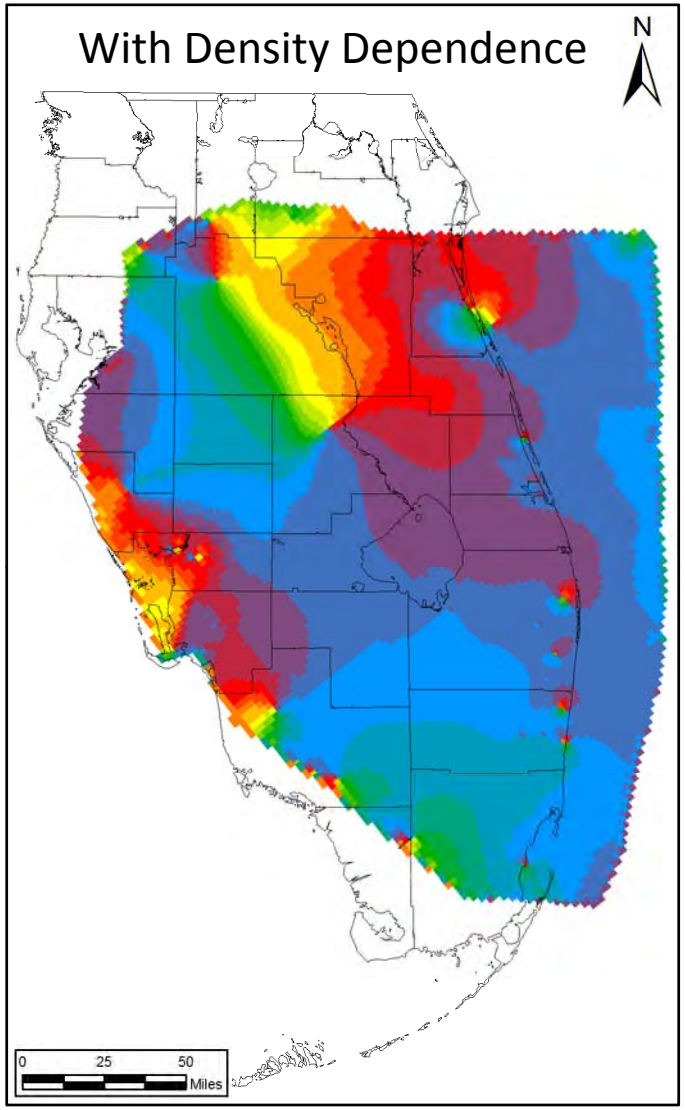
When the model is run without density dependence, the majority of the model domain has downward flow from the UF to the APPZ.

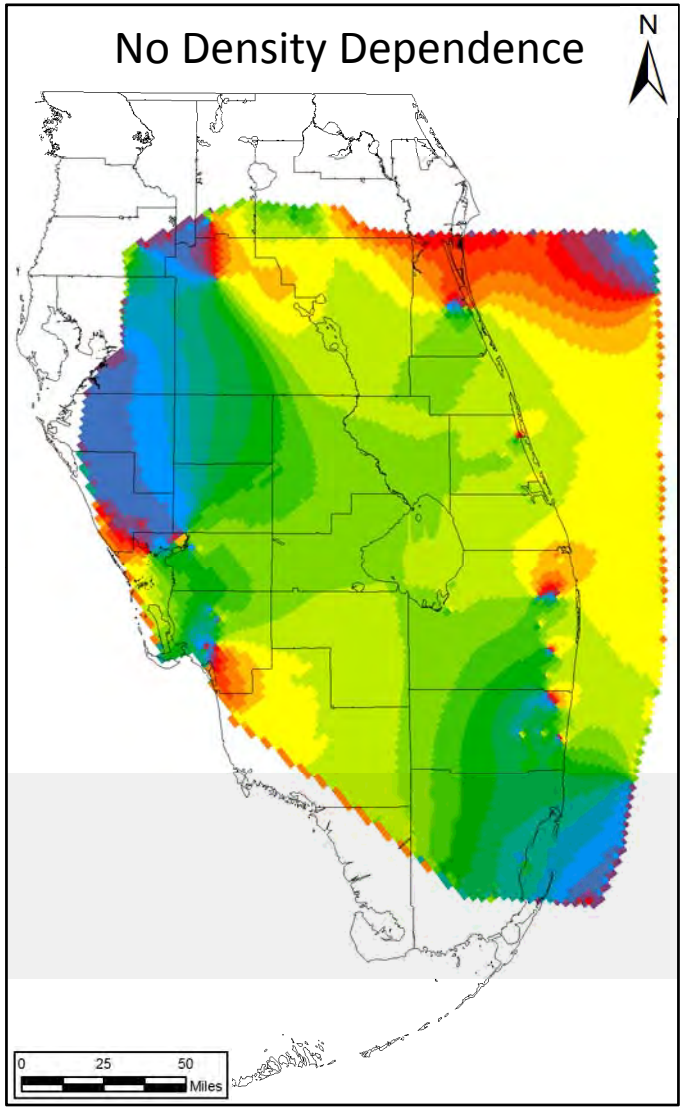
Impact of Density Dependence on Groundwater Flow Direction – MC1

Response to Comments, Production Scenario Report

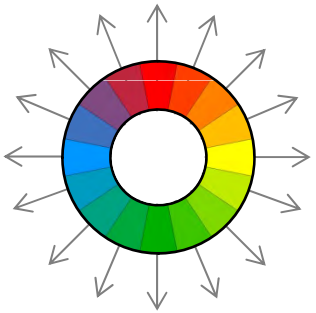
Figure B.32

June 2013





Horizontal Flow Directions



Notes:

This figure shows the horizontal flow directions for each cell of the with and without density dependence. The solution is from the February 2004 calibration model.

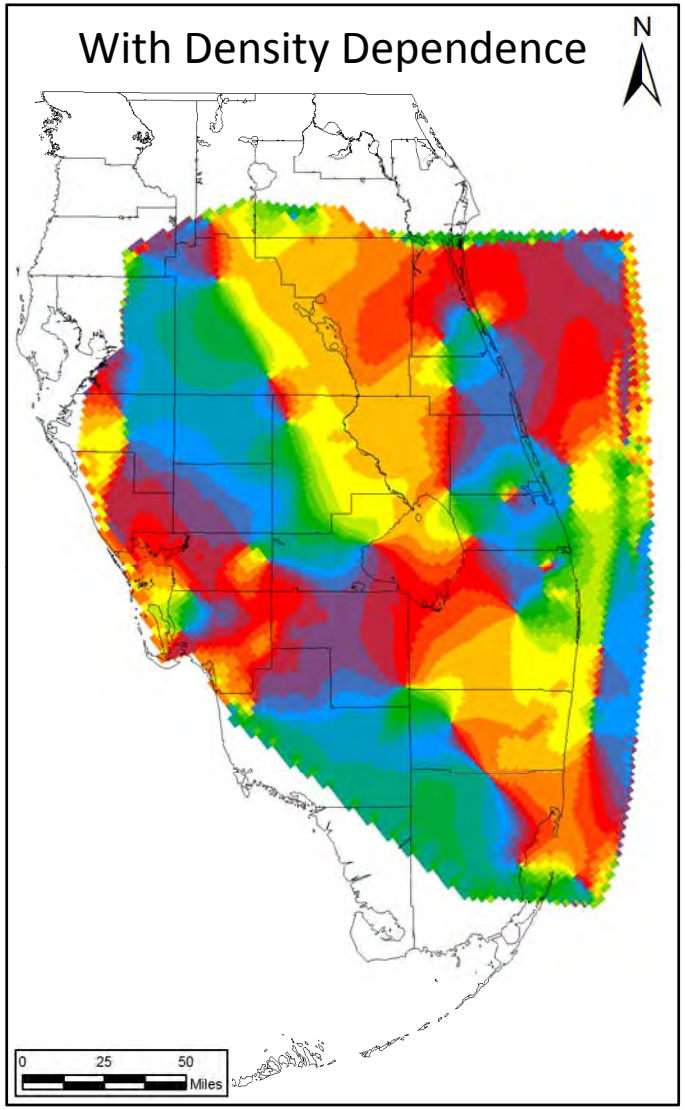
With density dependence, the majority of the model has flow towards the west and northwest, with some significant areas of northward flow. Without density dependence, nearly all the flow is towards the south, southeast and east.

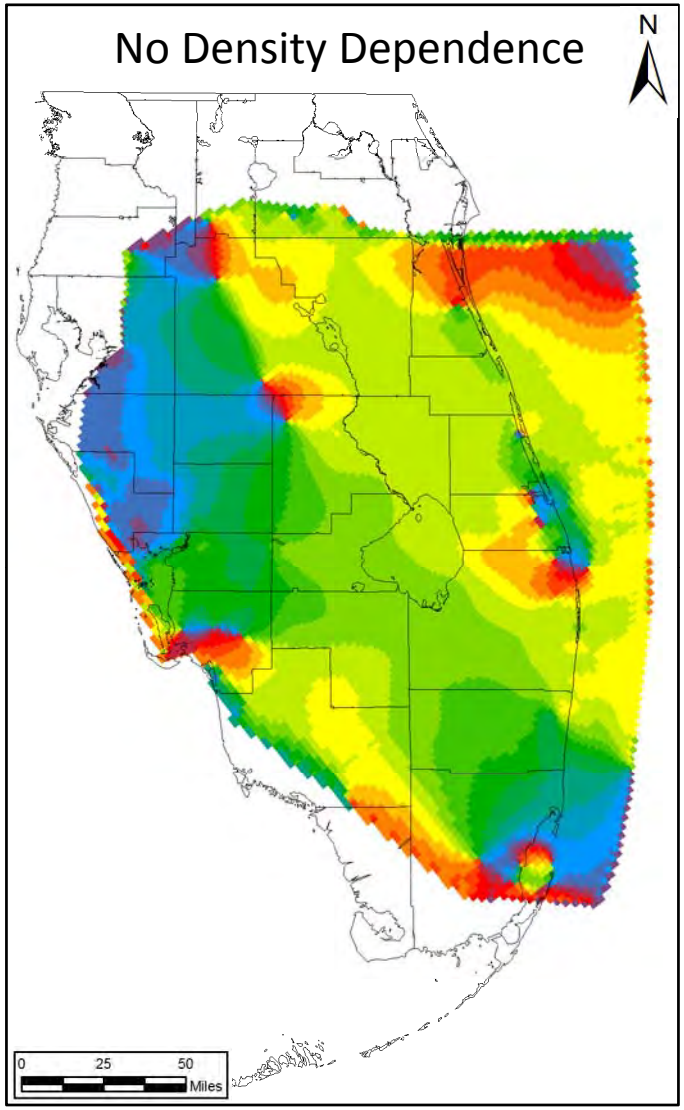
Impact of Density Dependence on Groundwater Flow Direction – BZ

Response to Comments, Production Scenario Report

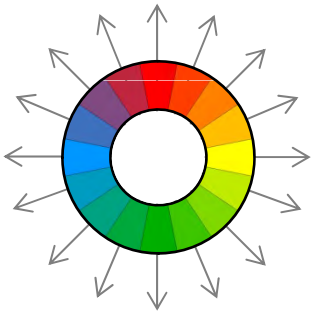
Figure B.33

June 2013





Horizontal Flow Directions



Notes:

This figure shows the horizontal flow directions for each cell of the LF (Layer 18) with and without density dependence. The solution is from the February 2004 calibration model.

Note that in western Polk County and many surrounding areas, density dependence does not impact flow directions. This is where the source of water is surface recharge and where the salinity is lowest.

The area around Lake Okeechobee shows a great difference in flow directions: with density dependence, the flow direction is mostly to the north and northwest; without density dependence it is mostly to the southeast.

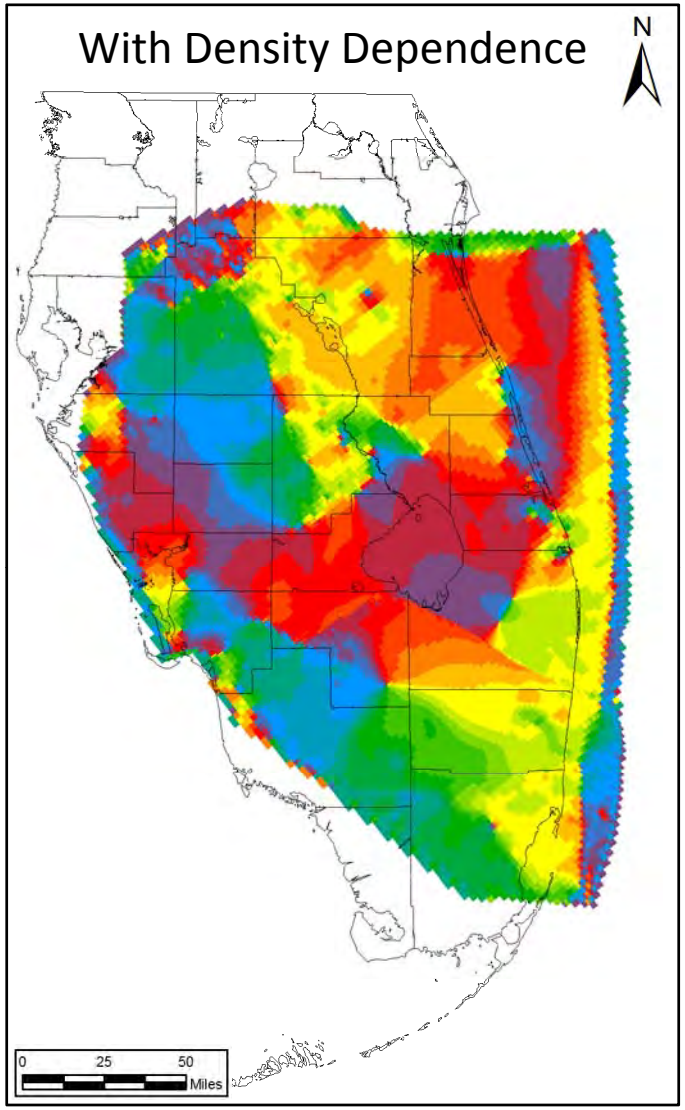
Note that without density dependence a great majority of the flow is towards the south, southeast and east. Density dependence causes much more variability in flow directions.

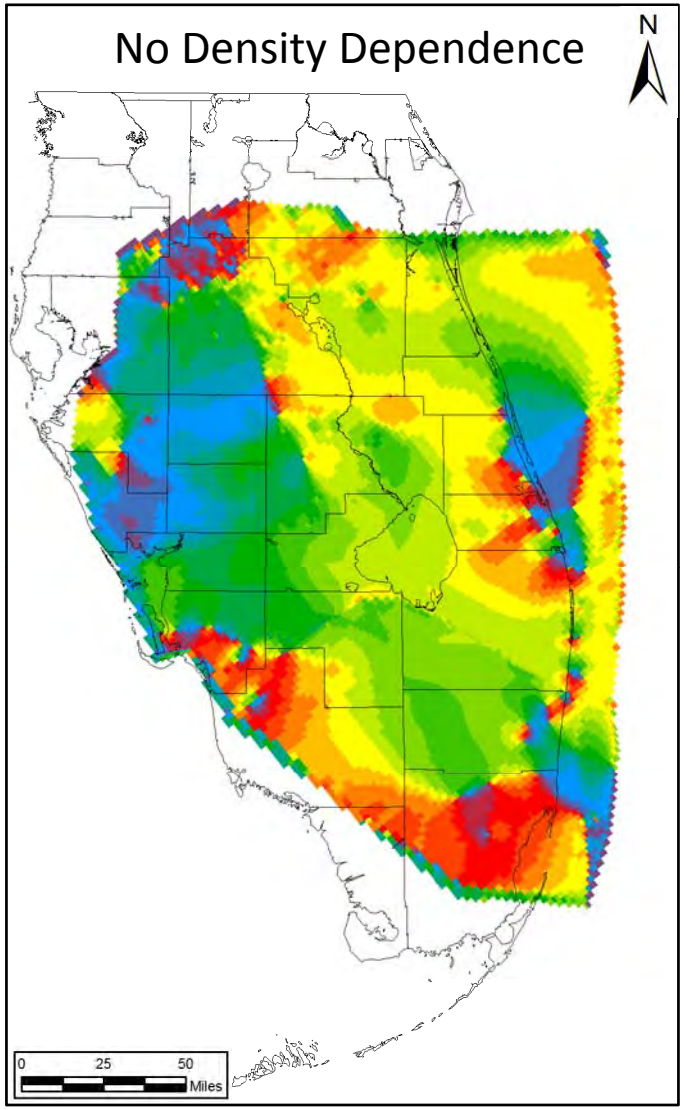
Impact of Density Dependence on Groundwater Flow Direction – LF

Response to Comments, Production Scenario Report

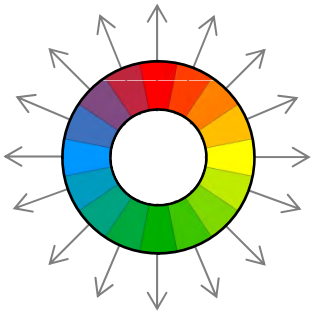
Figure B.34

June 2013





Horizontal Flow Directions



Notes:

This figure shows the horizontal flow directions for each cell of the APPZ (Layer 14) with and without density dependence. The solution is from the February 2004 calibration model.

Note that in Polk County and many surrounding areas, density dependence does not impact flow directions. This is where the source of water is surface recharge and where the salinity is lowest.

The area around Lake Okeechobee shows a great difference in flow directions: with density dependence, the flow direction is mostly to the north and northwest; without density dependence it is mostly to the southeast.

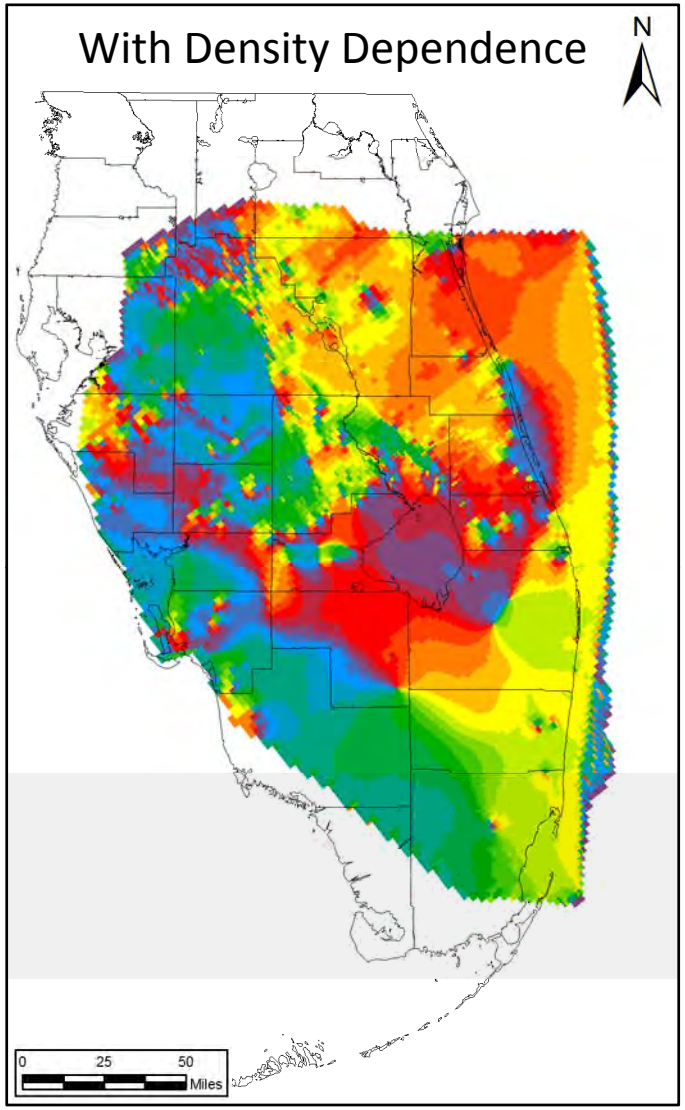
Similarly, the Everglades area, including Collier, Monroe and Miami-Dade Counties, the flow directions are mainly to the south and west with density dependence but are towards the north and northeast without density dependence.

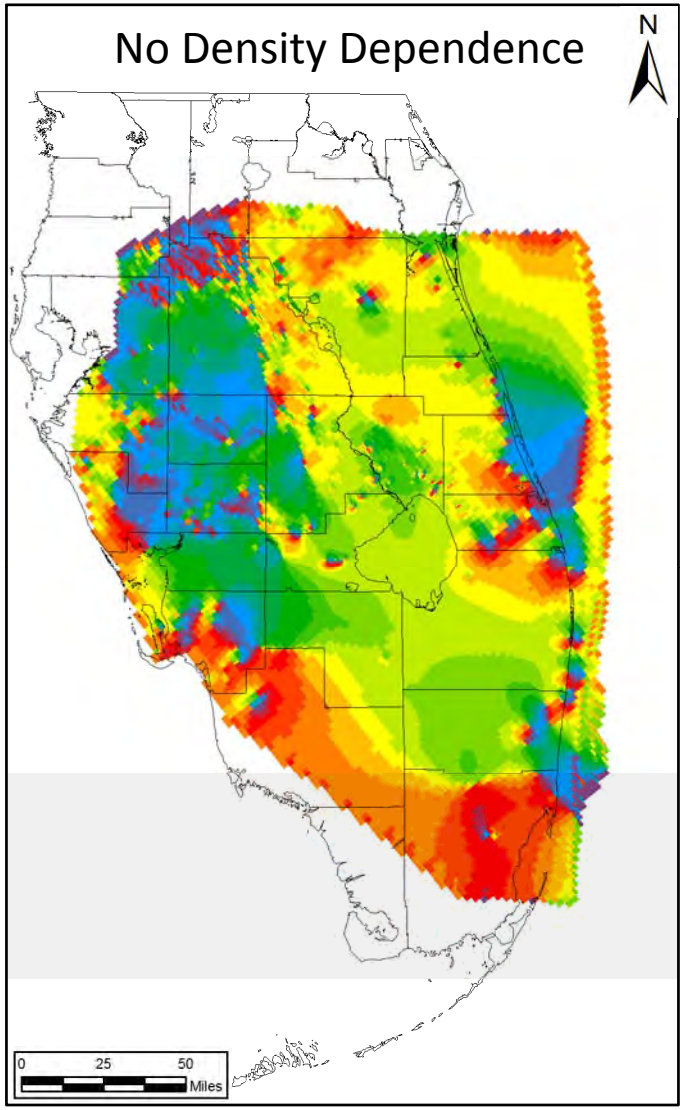
Impact of Density Dependence on Groundwater Flow Direction – APPZ

Response to Comments, Production Scenario Report

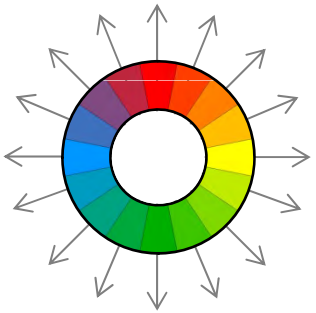
Figure B.35

June 2013





Horizontal Flow Directions



Notes:

This figure shows the horizontal flow directions for each cell of the UF (Layer 7) with and without density dependence. The solution is from the February 2004 calibration model.

Note that in Polk County and many surrounding areas, density dependence does not impact flow directions. This is where the source of water is surface recharge and where the salinity is lowest.

The area around Lake Okeechobee shows a great difference in flow directions: with density dependence, the flow direction is mostly to the north and northwest; without density dependence it is mostly to the southeast.

Similarly, the Everglades area, including Collier, Monroe and Miami-Dade Counties, the flow directions are mainly to the south and west with density dependence but are towards the north and northeast without density dependence.
