were found as in Test 1. In Test 2, the recirculation rate was 39 percent less than in Test 1, but gave a computed apparent dispersivity 153 percent that of Test 1.

The low recirculation rate of Test 2 was believed to be the result of siltation in the aquifer immediately surrounding the borehole of Tracer Well 1, which reduced the hydraulic conductivity in the vicinity of the well. Subsequently, Tracer Well 1 was surged and pumped several times to clean out sediment and to increase its productivity. As a result, it was possible to perform Test 3 at a maximum recirculation rate of 15.5 L/s, but not at the earlier rate of 22.5 L/s of Test 1. An inverse relation of flow rate to pressure for the various tests was found (Figure 8).

Test 3 was run at a recirculation rate of 31 percent less than that of Test 1, but yielded a computed apparent dispersivity for tritium 83 percent greater than that determined by Test 1. The tritium pulse in Test 3 consisted of 12.2 Ci of tritiated water injected evenly over a period of 14.4 minutes (0.01 day). The bromide was also injected as a rectangular pulse of concentration versus time, over a period of 15.6 minutes, almost simultaneously with the tritium, and consisted of a solution of 414 kg of ammonium bromide (NH_4Br) in 860 liters of water. Breakthrough curves of the two tracers were nearly parallel (Figure 9); best-fit curve matching yielded apparent dispersivity of 27.4 m, porosity of 10 percent, and porosity-thickness product of 0.84 for tritium (Figure 10). The bromide curve fit yielded an apparent dispersivity of 30.5 m, porosity of 10 percent and porosity-thickness product of 0.84 (Figure 11). Neither curve showed sharp peaks for this test, which ran for 34 days. These results are summarized in Figure 12, which illustrates the inverse relationship between computed apparent dispersivity and recirculation rate in the case of tritium.

Examination of the closeness of fit of the breakthrough curves to synthetic curves in Tests 1, 2, and 3 (Figures 6, 7 and 10, and 11 respectively) shows how poorly the sulfur-35 data fit the closest synthetic curve. However, the tritium and bromide curves fit very closely.

The method of Grove (1971) used for breakthrough curve analysis for dispersivity was designed for application to only the breakthrough curve of the pumping well (Tracer Well 2 in this case). Therefore, breakthrough curves of Sample Well 1 and Tracer Well 3 could not be used for analysis and are not included. However, the arrival times of the breakthrough-curve peaks at these wells are plotted as functions of recirculation rate and pore pressure in Figures 13 and 14, respectively.

Sample Well 1 is located approximately 45 m from the injection well (Tracer Well 1). Tracer Well 3 is 70 m from

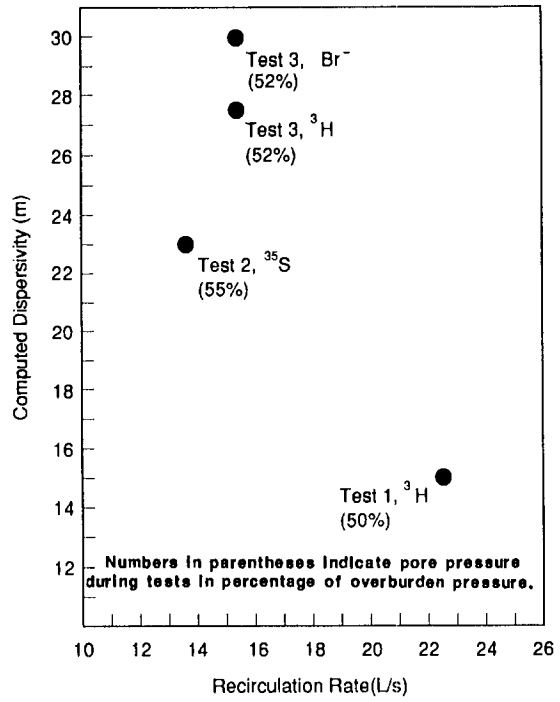

Fig. 12. Computed apparent dispersivity in each test versus recirculation rate of each test.

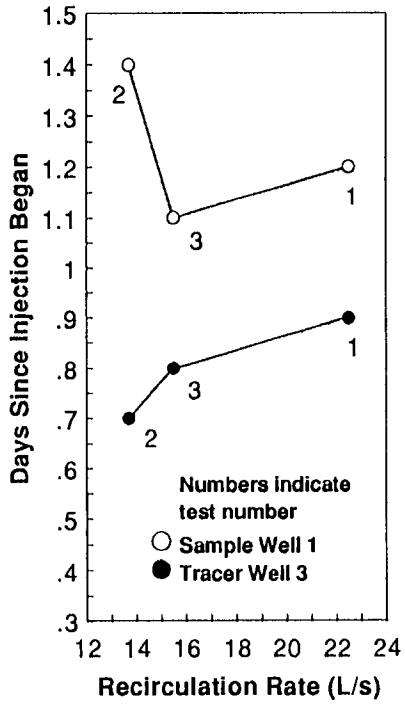

Fig. 13. Arrival times of breakthrough-curve peaks at Sample Well 1 and Tracer Well 3, versus recirculation rates during the three tests.

Tracer Well 1, or 1.6 times the distance of Sample Well 1. Yet, examination of Figures 13 and 14 reveals peak arrival times at Tracer Well 3 as much as 0.3 day earlier than at Sample Well 1 in Tests 1 and 3, and as much as 0.7 day earlier in Test 2.

Figure 13 shows a direct relationship between recirculation rate and peak arrival times at Tracer Well 3 in all three tests. The relationship for Sample Well 1 is inverse between Tests 2 and 3, and 2 and 1, but direct between Tests 3 and 1.

Figure 14 reveals for peak arrival times at Tracer Well 3, an inverse relationship with respect to pore pressure. In the case of Sample Well 1, the relationship is inverse between Tests 1 and 3, but direct between Tests 1 and 2, and also between tests 3 and 2.

The significance of all these relationships is discussed in the next section.

Interpretation and Discussion of Test Results

The most obvious relationship from the test results is the inverse relationship between apparent dispersivity and recirculation rate in the tritium tests, which is shown graphically in Figure 12. It is impossible to determine from only two tritium tests whether or not the relationship between computed apparent dispersivity and recirculation rate is linear at this site, but from observation of Figure 12 it is clear that neither the results of the sulfur-35 test (Test 2) nor bromide results of Test 3 fall on a straight line connecting the tritium results.

The relatively large difference in apparent dispersivity between the sulfur-35 and tritium tests is likely caused in large part by greater adsorption and/or retardation of the more active sulfate ion (SO_4^{--}) than that of either the

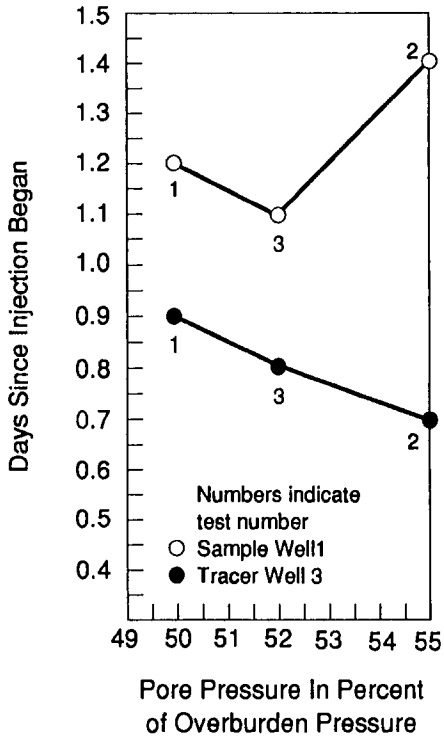

Fig. 14. Arrival times of breakthrough-curve peaks at Sample Well 1 and Tracer Well 3, versus pore pressures during the three tests.

bromide ion (Br^-) or tritiated water. Adsorption or retardation differences between tritium and bromide can explain the 10-percent difference in computed apparent dispersivity between the two tracers for the same recirculation rate in Test 3 (Figure 12). The analytical method of Grove (1971) used here assumes that no retardation or adsorption occurs; these phenomena, if real, probably cancel out when studying the relative change in apparent dispersivity with recirculation rate for two different tritium tests, as discussed below.

Explanation of Differences in Tritium-Test Dispersivities

The 83-percent increase in apparent tritium dispersivity concurrent with a decrease in recirculation rate of 31.3 percent between Tests 1 and 3 cannot be explained by sorption because the same tracer substance was used in both cases. If one assumes the classical independence of dispersivity from velocity, then a change in recirculation rate (and hence a change in advective velocity) cannot explain the dispersivity difference either, if the flow directions were the same in all three tests. However, a different flow regime with different advective transport should result in a different apparent dispersivity value.

The most likely explanation for the phenomenon, considering the discussion in the references earlier, is changes in the aquifer properties such as fissure-aperture width and hence, changes in hydraulic conductivity, local flow rates, and directions which were caused by differences in pore pressure between tests. If the ambient pore pressure of a fissured or fractured aquifer is already relatively high, then a slight artificial increase or decrease in testing pore pressure can cause small changes in aperture width and, thus, large changes in hydraulic conductivity.

High pore pressures during the tests, when compared to pressures reported in the earlier references, would likely be more than adequate to open or enlarge passageways less important under natural pressures and gradients, and therefore shunt ground-water flow in different directions at different flow rates from those of natural unstressed conditions.

It then is very probable that any hydraulic conductivity stratification, and consequent velocity stratification that exists under natural conditions, can be greatly altered by testing pressures. Lateral spreading as well as velocity and hydraulic conductivity stratifications were likely to have been altered significantly from one test to another by different pressures, causing the large difference in computed apparent dispersivities.

There appears to be direct physical evidence of this phenomenon from two observations. In the first place, the sharp peaks observed on the Tracer Well 2 breakthrough curve in Test 1 (Figure 6) do not appear on the curves of subsequent tests, probably indicating changes in transport directions and speeds from those of the first test (Figures 6, 7, 10, and 11). It is very probable that increasing pore pressures in later tests widened individual fissures and fractures that were important transport pathways in the first test, and which produced the spikes; additional fissures and fractures could have been opened wider so that the total effect of additional and/or wider pathways would have caused a smoothing of the breakthrough curves from the later tests.

Second, a direct fracture or fissure pathway seems evident between the injection well (Tracer Well 1) and Tracer Well 3 (Figure 3), for which arrival times of tracer-pulse peaks decreased with increasing pore pressures during the three tests (Figure 14). Such a pathway would likely be widened by increasing pore pressure.

The fact that peaks arrived at Tracer Well 3 before arriving at Sample Well 1 (Figures 13 and 14) which is much closer to the injection well, also strongly indicates such a direct pathway between Tracer Well 1 and Tracer Well 3 which is not apparent between Tracer Well 1 and Sample Well 1. The latter pathway is obviously more diffuse than the first.

The inverse-then-direct relationships between peak arrival times in Sample Well 1, and both recirculation rate and pore pressure (Figures 13 and 14) are not clear, unless they are related to the effects of surging and cleaning of Tracer Well 1 between Tests 2 and 3. This activity apparently affected the permeability of the pathway between the two wells.

Conclusions

1. Differences in computed apparent dispersivities for different recirculating tests with tritium were caused by differences in speed and directions of flow resulting from changes in pore pressure between one test and another, which in turn caused changes in aperture widths and thus in hydraulic conductivities.

2. This penomenon was especially pronounced in tests where the sum of ambient and testing pore pressures was a significant percent of the overburden pressure. More tests of this kind should be run at different pressures in order to determine the acceptable pressure range for accuracy.

3. For this reason, apparent dispersivities, determined by forced-gradient tests run under such high pressures, do not appear to be equivalent to the natural dispersivities existing under nonstressed conditions. In addition, natural changes in potentiometric-surface elevation, with consequent pore-pressure changes, can affect dispersivity over time. Therefore, solute-transport models of such systems, using dispersivity obtained in the above manner at excessive pressures, are likely to yield erroneous estimates of predicted solute-transport rates and concentrations.

Inventory and Review of Aquifer Storage and Recovery in Southern Florida

By Ronald S. Reese

Abstract

Aquifer storage and recovery in southern Florida has been proposed on an unprecedented scale as part of the Comprehensive Everglades Restoration Plan. Aquifer storage and recovery wells were constructed or are under construction at 27 sites in southern Florida, mostly by local municipalities or counties located in coastal areas. The Upper Floridan aquifer, the principal storage zone of interest to the restoration plan, is the aquifer being used at 22 of the sites. The aquifer is brackish to saline in southern Florida, which can greatly affect the recovery of the freshwater recharged and stored.

Well data were inventoried and compiled for all wells at most of the 27 sites. Construction and testing data were compiled into four main categories: (1) well identification, location, and construction data; (2) hydraulic test data; (3) ambient formation water-quality data; and (4) cycle testing data. Each cycle during testing or operation includes periods of recharge of freshwater, storage, and recovery that each last days or months. Cycle testing data include calculations of recovery efficiency, which is the percentage of the total amount of potable water recharged for each cycle that is recovered.

Calculated cycle test data include potable water recovery efficiencies for 16 of the 27 sites. However, the number of cycles at most sites was limited; except for two sites, the highest number of cycles was five. Only nine sites had a recovery efficiency above 10 percent for the first cycle, and 10 sites achieved a recovery efficiency above 30 percent during at least one cycle. The highest recovery efficiency achieved per cycle was 84 percent for cycle 16 at the Boynton Beach site.

Factors that could affect recovery of freshwater varied widely between sites. The thickness of the open storage zone at all sites ranged from 45 to 452 feet. For sites with the storage zone in the Upper Floridan aquifer, transmissivity based on tests of the storage zones ranged from 800 to 108,000 feet squared per day, leakance values indicated that confinement is not good in some areas, and the chloride concentration of ambient water ranged from 500 to 11,000 milligrams per liter.

Based on review of four case studies and data from other sites, several hydrogeologic and design factors appear to be important to the performance of aquifer storage and recovery in the Floridan aquifer system. Performance is maximized when the storage zone is thin and located at the top of the Upper Floridan aquifer, and transmissivity and salinity of the storage zone are moderate (less than 30,000 feet squared per day and 3,000 milligrams per liter of chloride concentration, respectively). The structural setting at a site could also be important because of the potential for updip migration of a recharged freshwater bubble due to density contrast or loss of overlying confinement due to deformation.

INTRODUCTION

Aquifer storage and recovery (ASR) in southern Florida has been proposed as a cost-effective water-supply alternative that can help meet the needs of agricultural, municipal, and recreational users and can be used for Everglades ecosystem restoration. Plans have been made to utilize ASR on an unprecedented scale

in the Central and Southern Florida Comprehensive Review Study as proposed by the U.S. Army Corps of Engineers and the South Florida Water Management District (1999). This review study is also known as the Comprehensive Everglades Restoration Plan (CERP). About 330 ASR wells have been proposed for southern Florida, each with an assumed capacity of 5 Mgal/d during recharge or recovery. Pyne (1995) has described ASR as "the storage of water in a suitable aquifer through a well during times when water is available, and recovery of the water from the same well during times when it is needed."

ASR technology has been tested and implemented in some areas of southern Florida; 26 ASR sites have been constructed and 1 is under construction (fig. 1 and table 1). The status for 10 of the sites is "operational testing," which is a multi-year period of regulatory review during the first phase of operation.

[1] Site numbers refer only to this report. Site locations are shown in figure 1.

During this time, the ASR well system is tested prior to being given a full operating permit by the Florida Department of Environmental Protection (FDEP). Three of the sites have been given an operating permit. Additionally, six sites are no longer active after experimental testing was completed (fig. 1). These sites were operated by government agencies including the U.S. Geological Survey (USGS), South Florida Water Management District (SFWMD), FDEP, and the Florida Keys Aqueduct Authority (FKAA). ASR is a relatively recent development in southern Florida, in terms of its use as a municipal or countywide source of water; 20 active sites in this category were constructed in the 1990's (with 14 of these sites having been constructed since 1996). The strategy for this use of ASR in southern Florida has been to store excess water available during the wet season and recover this water during the dry season when it is needed.

Existing and historical ASR sites in southern Florida are mostly located along the east and west coasts (fig. 1). At most sites, the proposed or planned purpose of the recovered water is to serve as a supplemental supply for municipalities. Under CERP, ASR wells will be constructed in inland areas around Lake Okeechobee, in central Palm Beach County, and along the Caloosahatchee River in Hendry County (U.S. Army Corps of Engineers and South Florida Water Management District, 2001). Recovered water is to be used for additional purposes that include maintaining water levels in Lake Okeechobee and wetland areas and reduction of surface-water flows to tide (estuarine and bay areas) during storm events.

The storage zone being used at most ASR sites is in the Floridan aquifer system (fig. 2). Shallower storage zones are in the mid-Hawthorn and sandstone aquifers of the intermediate aquifer system and the Biscayne aquifer of the surficial aquifer system. The proposed storage zone aquifer in the CERP ASR program is also in the Floridan aquifer system. This aquifer system is continuous throughout southern Florida, and its overlying confinement is generally good.

ASR wells are evaluated and operated through a cyclical process. Each cycle includes periods of injection (recharge) of freshwater into the ASR well, storage, and then withdrawal (recovery) with each period lasting days or months. In southern Florida, the recovery phase may commence immediately after the cessation of recharge with no period of storage, and depending on the source of water supply, municipal supply, or operational problems, the time between cycles may be extensive (months or years). After initial testing and under fully operational conditions, cycles continue but the duration of cycles and storage periods and the volume of water recharged during each cycle usually increase.

In southern Florida, ASR is largely used to store water in an aquifer that contains brackish water. Ambient ground water in the storage zone at most of the ASR sites in the study area is brackish (greater than 1,000 mg/L dissolved-solids concentration) to saline (greater than 10,000 mg/L dissolved-solids concentration); salinity appears to greatly affect the recovery of the recharged freshwater. The salinity of the recharged and recovered water is closely monitored, usually on a daily basis. Because of the high ambient water salinity of the storage zone, much of the recharged freshwater is not recovered largely due to dispersive mixing in the aquifer.

The recovery efficiency for each cycle is the total volume of water recovered, expressed as a percentage of the volume of water recharged. The salinity of water during recovery increases with time, and recovery is terminated at a salinity level that is predetermined by operational considerations. Generally, this limiting salinity level is at the potable water limit of 250 mg/L chloride concentration, or slightly higher if the recovered water is mixed with potable water at a water-treatment plant (WTP).

Few regional investigations of the hydrogeology of the Floridan aquifer system in southern Florida have been conducted, and those studies focused on issues unrelated to ASR. Lacking a regional ASR framework to aid the decision-making process, placement of ASR well sites in southern Florida have primarily been based on factors such as land availability, source-water proximity (preexisting surface-water canal systems or surficial aquifer system well fields), or proximity to a WTP. Little effort has been made to link information collected from each site into a regional hydrogeologic analysis. Additional tools and data are needed to make informed decisions that incorporate constraining hydrogeologic factors in the placement and construction of ASR sites in southern Florida.

This study is part of the USGS South Florida Place-Based Studies Program, which was established for the purpose of providing physical and biological science data and information on which to base ecosystem restoration management decisions. The purpose of

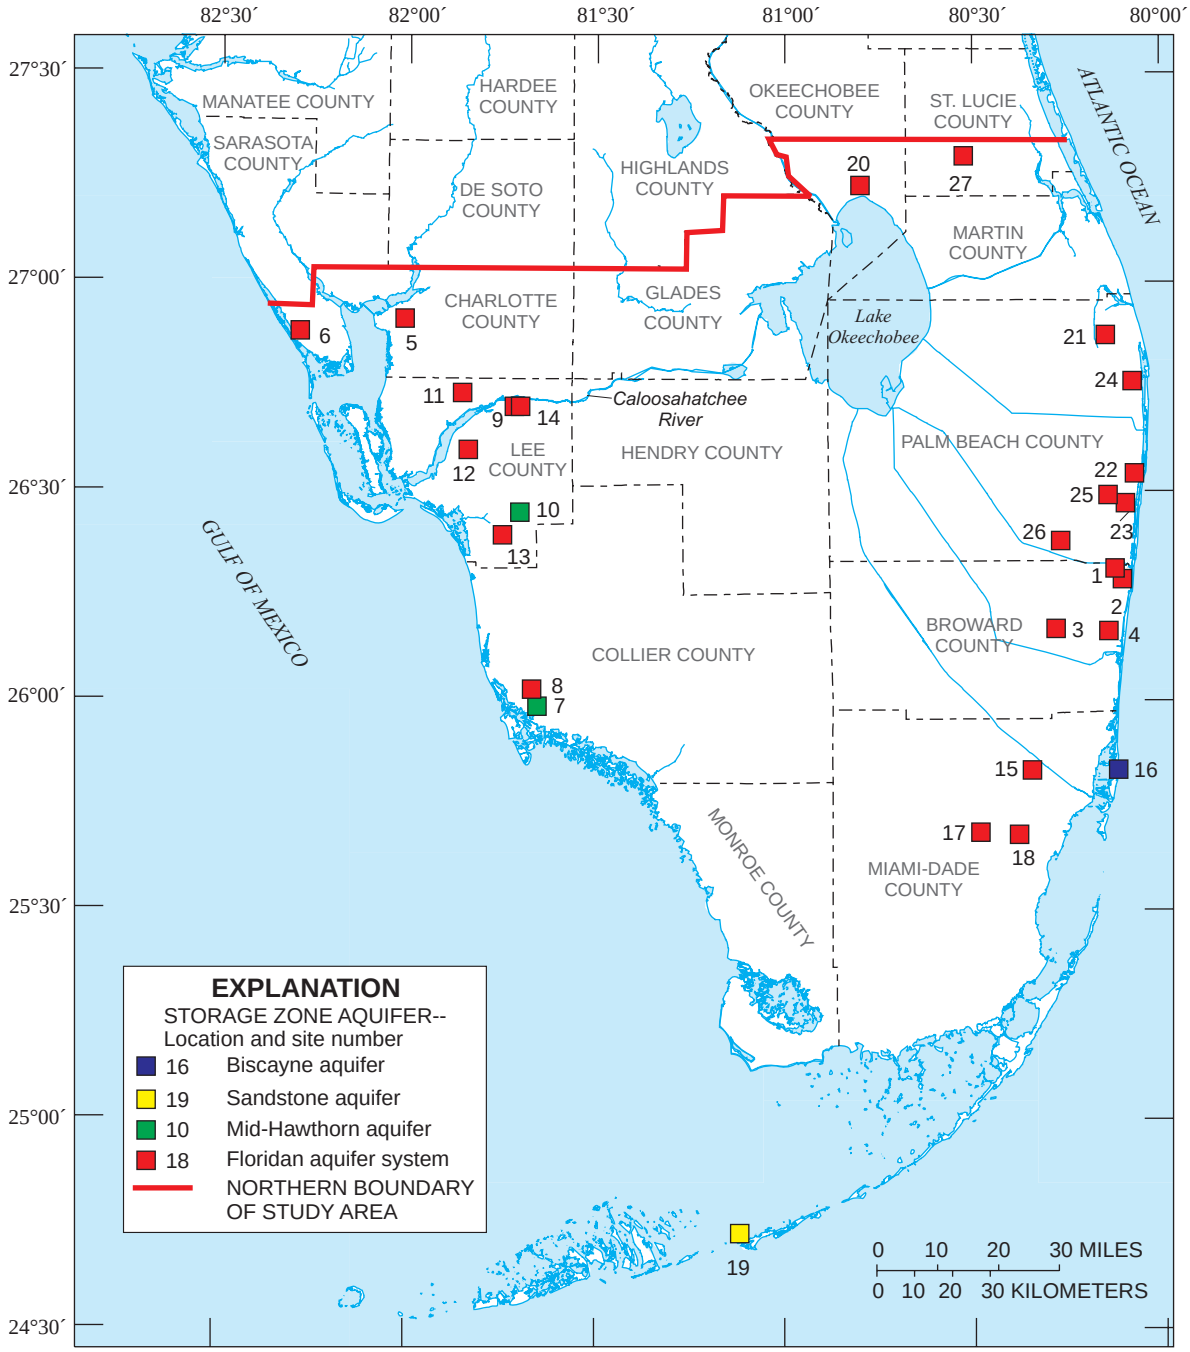

Figure 2. Storage zone aquifers for aquifer storage and recovery sites in southern Florida.

this study was to compile data on existing ASR sites in southern Florida and identify various hydrogeologic, design, and management factors that control the recovery of freshwater recharged into ASR wells.

Purpose and Scope

The purpose of this report is to inventory well construction, hydrogeologic, and operational data on ASR sites in southern Florida and assess site performance. A secondary purpose is to identify hydrogeologic, design, or management factors that influence the success of ASR. Recovery efficiency, defined as the percent of recharged freshwater that is recovered for each cycle, is used to evaluate this performance. Four ASR case studies are described to determine possible technical factors that influence the success of ASR.

The study area includes all of southern Florida and includes Charlotte, Glades, Lee, Hendry, Collier, Monroe, Miami-Dade, Broward, Palm Beach, and Martin Counties, and parts of Okeechobee and St. Lucie Counties (fig. 1). The 27 ASR sites located in the study area represent the source of data for this study. However, this report focuses on the 23 ASR sites in which the Floridan aquifer system serves as the storage zone. Principal hydrogeologic and construction related attributes determined for each ASR site are graphically and spatially illustrated to provide a comparative analysis.

Previous Studies

It has been nearly 20 years since Merritt and others (1983) provided a retrospective overview and status of ASR well development in southern Florida. Merritt and others (1983) presented data from three experimental ASR sites that are also included in this report, and Meyer (1989b) published additional data on experimental ASR sites in southern Florida. Other experimental ASR test data were obtained in reports or written communications for the Jupiter site (fig. 1, map no. 21; J.J. Plappert, Florida Department of Environmental Protection, written commun., 1977), the St. Lucie County site (fig. 1, map no. 27; Wedderburn and Knapp, 1983), the Lee County site (fig. 1, map no. 9; Fitzpatrick, 1986), the Hialeah site (fig. 1, map no. 15; Merritt, 1997), and the Taylor Creek/Nubbin Slough – Lake Okeechobee site (fig. 1, map no. 20; Quiñones-Aponte and others, 1996). Theoretical investigations into the feasibility of cyclic injection of freshwater in southern Florida have been described in reports by Khanal (1980) and Merritt (1985). Merritt (1997) also included numerical simulations of the salinity of recovered water in his study of Hialeah ASR site.

Some regional or local hydrogeologic studies of the Upper Floridan aquifer that encompass or include part of southern Florida are Bush and Johnston (1988), Meyer (1989a), Miller (1986), Reese (1994), Reese (2000), and Reese and Memberg (2000). The reports by Meyer (1989a), Reese (1994; 2000), and Reese and Memberg (2000) are specific to southern Florida.

Factors Affecting Optimal Recovery of Freshwater in Aquifer Storage and Recovery

Recovery of freshwater stored in brackish- to saline-water aquifers is controlled by a wide variety of factors that pertain to hydrogeologic conditions, well or well field design, and operational management. The hydrogeologic factors of a storage zone that are important to recoverability include (1) ambient salinity, (2) aquifer permeability and distribution, (3) aquifer thickness, (4) confinement, (5) ambient hydraulic gradient, and (6) structural setting. Important design and management factors to consider are (1) thickness and location of the storage zone within the aquifer, (2) volume of injected water, (3) duration and frequency of cycles and cycle storage periods, (4) well performance problems such as wellbore plugging, and (5) multiple-well configurations. Most of these factors and their control on recoverability have been numerically simulated (Merritt and others, 1983; Merritt, 1985); however, conclusions on some factors, 95 discussed in the following sections, came from consulting reports and other literature.

Hydrogeologic Factors

During recharge of water by an ASR well, a radial zone of mixing forms around the well in the aquifer. This zone, referred to as the transition zone (Merritt, 1985), separates native water from an inner flushed zone containing mostly injected water, and this inner zone can be described as a freshwater bubble

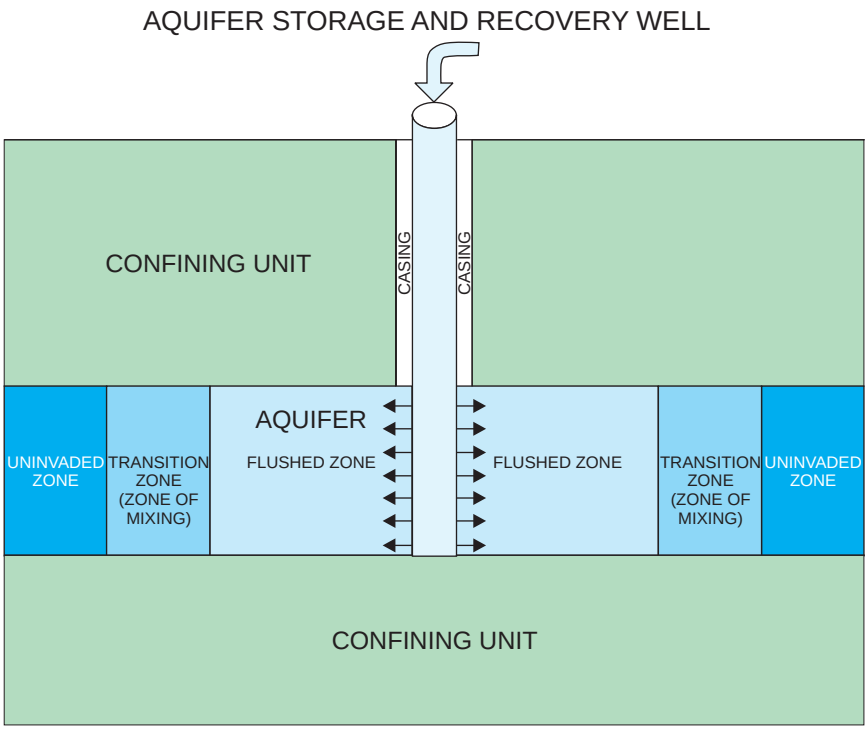

Figure 3. Aquifer storage and recovery well in a confined aquifer depicting idealized flushed and transition zones created by recharge. Flushed zone contains mostly recharged water.

(fig. 3). The degree of mixing between the injected and native water and the width of the transition zone is primarily controlled by hydrodynamic dispersion. Hydrodynamic dispersion or dispersive mixing refers to the effects of molecular diffusion and mechanical dispersion. Mechanical dispersion results from the unevenness of flow through porous media, and at flow velocities occurring during ASR recharge and recovery, this dispersion will dominate over diffusion.

The ambient salinity of water in the storage zone is of primary importance in controlling recovery of freshwater because of mixing with this water and potential buoyancy stratification. Buoyancy stratification occurs where the ambient salinity is high, provided permeability in the aquifer is also high (Merritt, 1985); the injected freshwater moves upward and flows out over the native ground water. During the recovery phase, such stratification increases mixing. Buoyancy stratification should be considered possible when the ambient ground water has a dissolved-solids concentration greater than 5,000 mg/L (Pyne, 1995); in the Floridan aquifer system of southern Florida this equates to about 2,500 mg/L chloride concentration (Reese, 1994). On the basis of numerical simulation, recovery efficiency has been shown to decrease with increasing salinity in saline aquifers only because of dispersive mixing in the transition zone – no buoyancy stratification (Merritt, 1985). Ambient water salinities modeled in Merritt's study, as defined by chloride concentration, were 2,000, 7,000 to 8,000, and 19,000 mg/L (seawater-like salinity).

The permeability or hydraulic conductivity of the storage zone may greatly affect recoverability. The probability of buoyancy stratification increases as permeability increases (Merritt, 1985). Additionally, mechanical dispersion is related to the distribution of permeability within the storage zone. Higher permeability can equate to higher dispersive mixing, and an increase in this dispersion lowers recovery efficiency (fig. 3). Thus, recovery could be better in a sand aquifer of uniform permeability where dispersion results primarily from flow through intergranular pore spaces, as opposed to a limestone aquifer having diffuse and conduit flow components, particularly if thin zones of high permeability occur within the limestone aquifer.

Loss of injected freshwater could occur if a storage zone is not well confined. Injected water may move upward or downward out of the storage zone, or saline water may move up into the storage zone during recovery.

Recovery efficiency is greater in a thin aquifer than in a thick aquifer because of the lower vertical extent of the transition zone along which mixing occurs. However, this effect can be partially offset by increasing the volume of water recharged during a cycle. Minimizing the thickness of the storage zone within a thick aquifer can also be beneficial depending on the aquifer's distribution of vertical hydraulic conductivity.

Downgradient movement of a bubble of recharged water due to the background hydraulic gradient could reduce recovery efficiency. Based on an estimated gradient at the Hialeah ASR site in the Upper Floridan aquifer, reduction in recovery due to this effect was simulated to be minor for a storage period of 6 months, but not for 5 years (Merritt and others, 1983). The average velocity of ambient flow, referred to as the average linear velocity, is a function of both hydraulic conductivity and porosity as well as the background hydraulic gradient (Freeze and Cherry, 1979).

The structural setting of the storage zone at an ASR site could be important to recovery (Water Resources Solutions, Inc., 1999a). Freshwater recovery at a site located in an area that is structurally high or where the dip is low could be more favorable than in an area that is in a structural depression or where the dip is relatively high due to the tendency of the bubble of recharged water to move updip because of buoyancy forces. This factor is likely to be more important as the contrast in salinity and fluid density increases. Structural deformation may influence storage zone confinement due to fracturing, faulting, or vertical dissolution features.

Design and Management Factors

The location of the storage zone relative to the aquifer may be important. If a storage zone extends over only a portion of an aquifer's thickness, this could negatively affect recovery. Merritt (1985) simulated recovery in a case where the ASR storage zone extended only over the lower part of the important flow zone (zone with high permeability) near the top of the Upper Floridan aquifer. Results indicated that recovery efficiency was virtually unaffected compared to the case with the well open to the full thickness of the zone. However, the low ambient salinity (1,200 to 1,300 mg/L chloride concentration) and the moderate hydraulic conductivity values that were used in the simulation prevented any appreciable buoyancy effects from occurring (effects that could cause vertical flow and mixing to increase).

The volume of injected water affects the recovery efficiency. On a per cycle basis, recovery efficiency generally increases as the total volume of injected water increases (Merritt, 1985). However, the effect is much less beneficial when interlayer dispersion (the transverse dispersion between layers of differing hydraulic conductivity in the aquifer) increases. Interlayer dispersion causes mixing between injected and ambient waters in addition to the mixing in the transition zone.

Recovery efficiency increases with repeated cycles. Twelve successive cycles of injection and recovery, with recovery of up to only 250 mg/L chloride concentration for each cycle, were simulated for a variety of longitudinal and transverse dispersivity coefficients. Recovery efficiency improved substantially for all cases with repeated cycles, but the rate of improvement diminished with increasing cycles (fig. 4). Recovery efficiency improves with repeated cycles because much of the recharged water from a previous cycle is left in the aquifer, and during the next cycle, recharged water mixes with water of a lower salinity.

Well plugging can occur during recharge in the Upper Floridan aquifer, reducing the recharge rate and freshwater recovery. This plugging is usually caused by deposition of particulate matter in the injected water or by the formation of a precipitate or sludge caused by reactions that occur at the wellbore face or in the aquifer. One method used to restore formation injectivity is periodic backflushing of the well during the recharge phase. At the Hialeah site, well backflushing produced very fine particles of calcite and an iron compound that had precipitated (Merritt, 1997). Plugging at the Lee County site is attributed to suspended material in the injected water and bacteriological growth at the open borehole face (Fitzpatrick, 1986). Well plugging may affect one flow zone in an open-hole interval more than another, reducing overall recovery. During recovery, the less affected zone contributes most of the flow, and the salinity of water from this zone exceeds the limiting salinity level before all the recoverable freshwater from the plugged zone is obtained.

Various numbers and configurations of multiple storage wells at a site were modeled by Merritt (1985). In that study, the number of wells were varied from one to nine, and the well patterns were varied from a linear array to eight wells in an octagonal pattern with an additional well in the center. Greatest recovery efficiencies were attained in arrays consisting of a central well surrounded by perimeter wells. Though in all cases, the recovery efficiencies for the multiple-well configurations were no better than the single-well case injecting the same total volume as the array of wells. Recovery efficiency could improve, however, when the total volume injected increases as the number of wells injecting at a site increases.

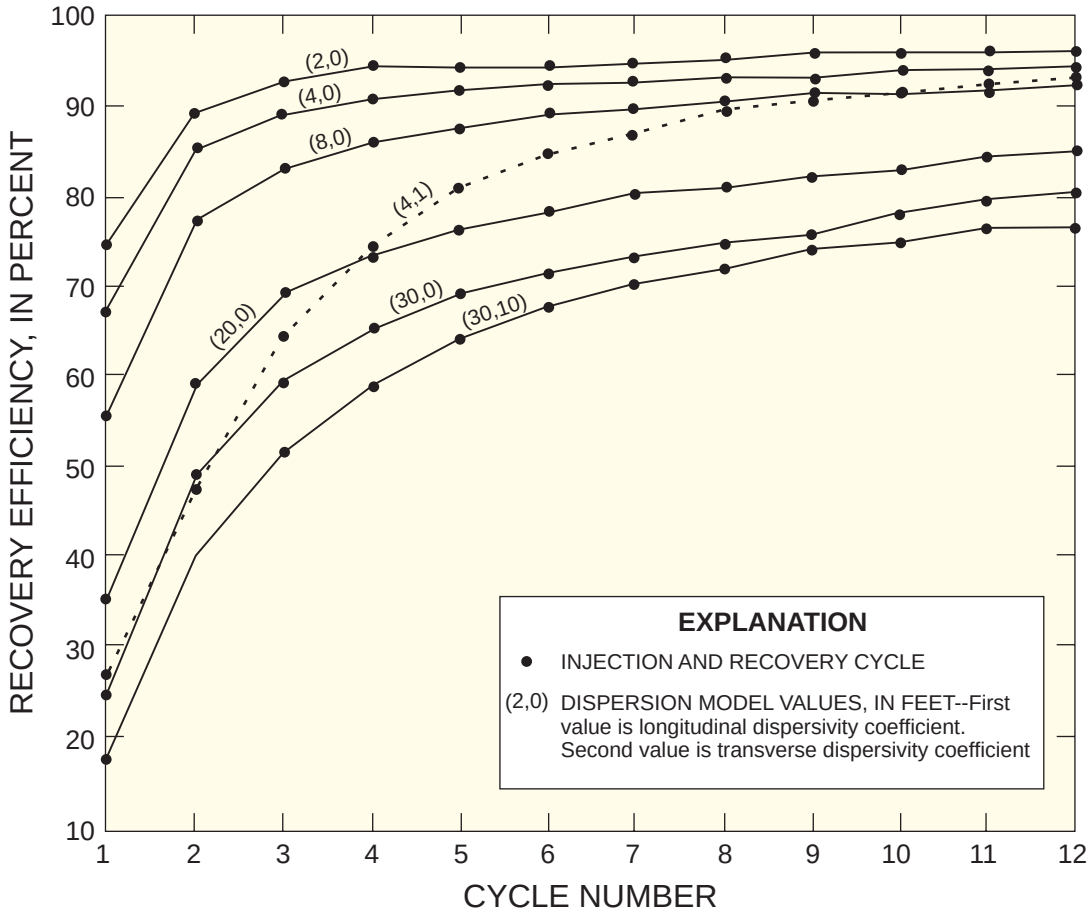

Figure 4. Simulated improvement of potable water recovery efficiency with successive injection and recovery cycles for a variety of dispersion models. The Upper Floridan aquifer at the Hialeah aquifer storage and recovery site was used in the design of the model (modified from Merritt, 1985).

Hydrogeology

The three principal hydrogeologic units in southern Florida are the surficial, intermediate, and Floridan aquifer systems. These aquifer systems in the western part of the study area (Lee, Hendry, and Collier Counties) are described in figure 5. Water-bearing rocks in the intermediate aquifer system grade or pinch out to the east, and in southeastern Florida the intermediate aquifer system becomes the intermediate confining unit. The Floridan aquifer system consists of the Upper Floridan aquifer, middle confining unit, and Lower Floridan aquifer. Three of the aquifers used for ASR in southern Florida are shown in figure 5; namely, the sandstone and mid-Hawthorn aquifers of the intermediate aquifer system and the Upper Floridan aquifer.

The Upper Floridan aquifer is 500 to 1,200 ft thick in southern Florida (fig. 5; Reese, 1994 and Reese and Memberg, 2000). This aquifer is well confined above by thick units in the Hawthorn Group consisting of clay, marl, silt, or clayey sand; hydraulic head in the aquifer is above land surface. The middle confining unit of the Floridan aquifer system underlies the Upper Floridan aquifer and provides good to leaky confinement. This confining unit consists of micritic limestone (wackstone to mudstone), dense dolomite, and in some areas, beds of gypsum (fig. 5). The upper and lower boundaries of the middle confining unit are difficult to define, but its thickness has been estimated to range from 500 to 800 ft in southwestern Florida.

In southwestern Florida, the Upper Floridan aquifer includes the lower part of the Hawthorn Group, Suwannee Limestone, Ocala Limestone, and in some areas, the upper part of the Avon Park Formation (fig. 5). In southeastern Florida, the Suwannee Limestone and Ocala Limestone are commonly absent (Reese, 2000; Reese and Memberg, 2000). In both eastern and western areas, the top of the Upper Floridan aquifer usually is contained within a basal

Series		Geologic Unit		Approximate thickness (feet)	Lithology	Hydrogeologic unit		Approximate thickness (feet)

Hawthorn unit, which is defined by an overlying marker unit composed of micritic limestone or marl (fig. 5; Reese and Memberg, 2000). In some areas along the east coast, the Suwannee Limestone is either interpreted as being absent (Miller, 1986; Reese and Memberg, 2000) or present in the lower part of this basal Hawthorn unit.

The Upper Floridan aquifer generally consists of several thin water-bearing zones of high permeability (flow zones) interlayered with thick zones of much lower permeability. Commonly, only one or two major flow zones provide the bulk of the productive capacity. These flow zones are often less than 20 ft thick each and tend to be in the upper part of the Upper Floridan aquifer, typically at or near the top of the Suwannee Limestone, Ocala Limestone, and Avon Park Formation. Unconformities that formed at the end of the Oligocene and Eocene Epochs are present at these contacts (Miller, 1986), and zones of dissolution occur in association with these unconformities in southern Florida (Meyer, 1989a). In southwestern Florida, the most important flow zone tends to be associated with the top of the Suwannee Limestone, whereas in southeastern Florida it is the top of the Avon Park Formation or, if present, the top of the Ocala Limestone. In both of these areas, the basal Hawthorn unit lies above this contact.

The basal Hawthorn unit is shown in an east-west hydrogeologic section that extends across Palm Beach County near the southern end of Lake Okeechobee (figs. 6 and 7). This unit is thickest along

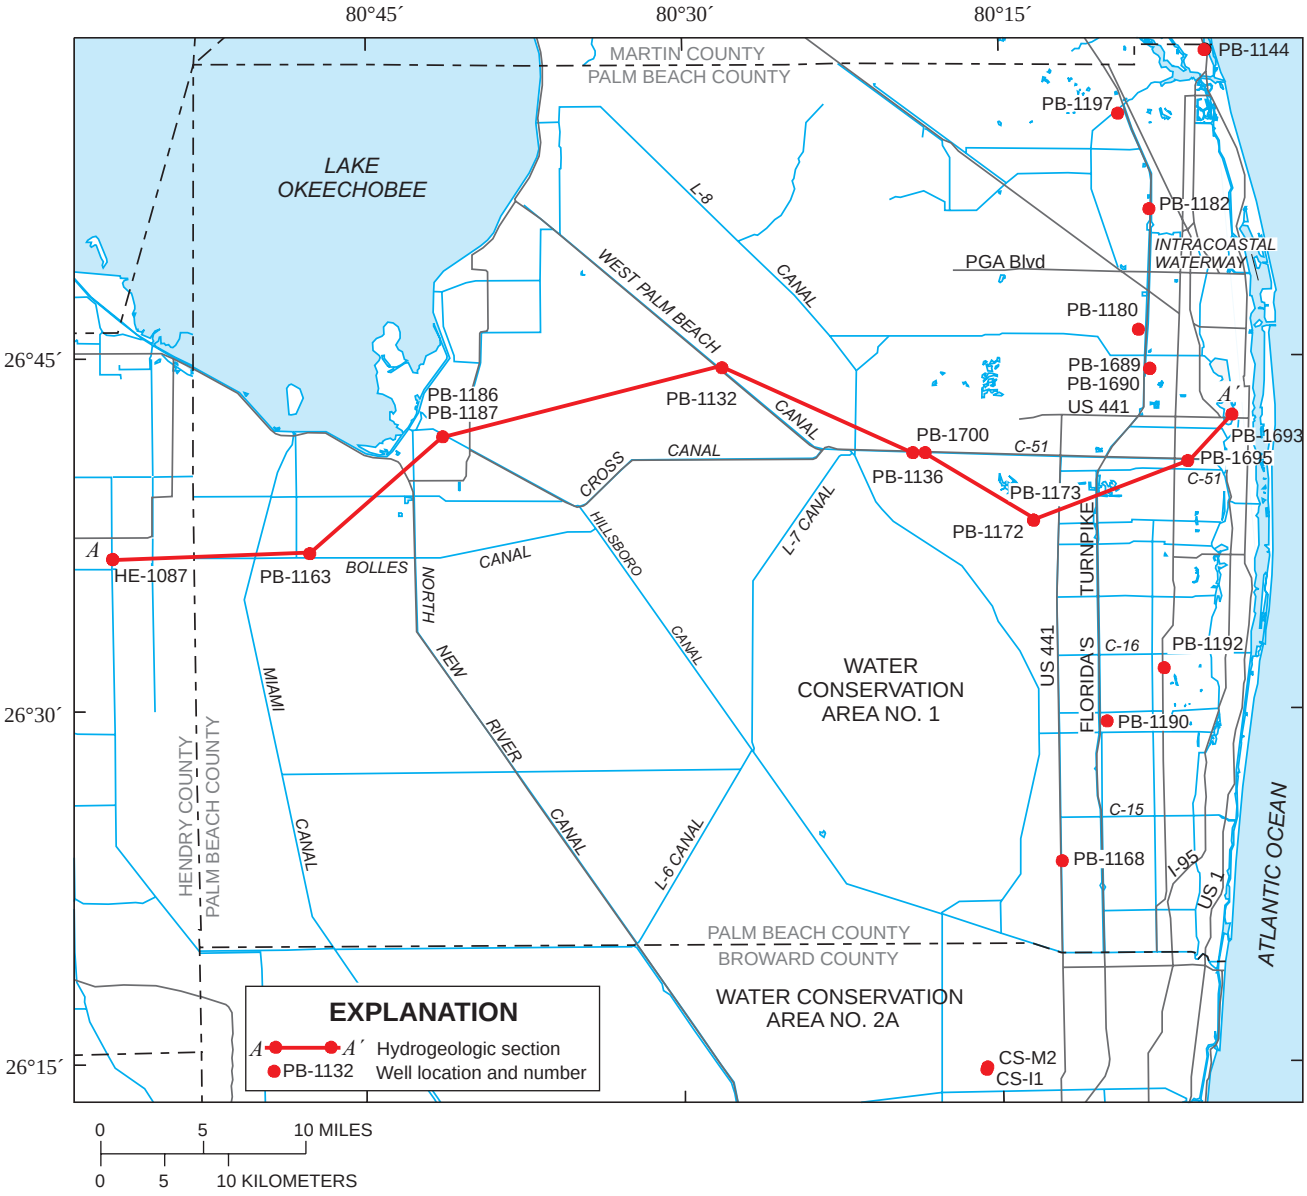

Figure 6. Trace of hydrogeologic section in Palm Beach County (modified from Reese and Memberg, 2000).

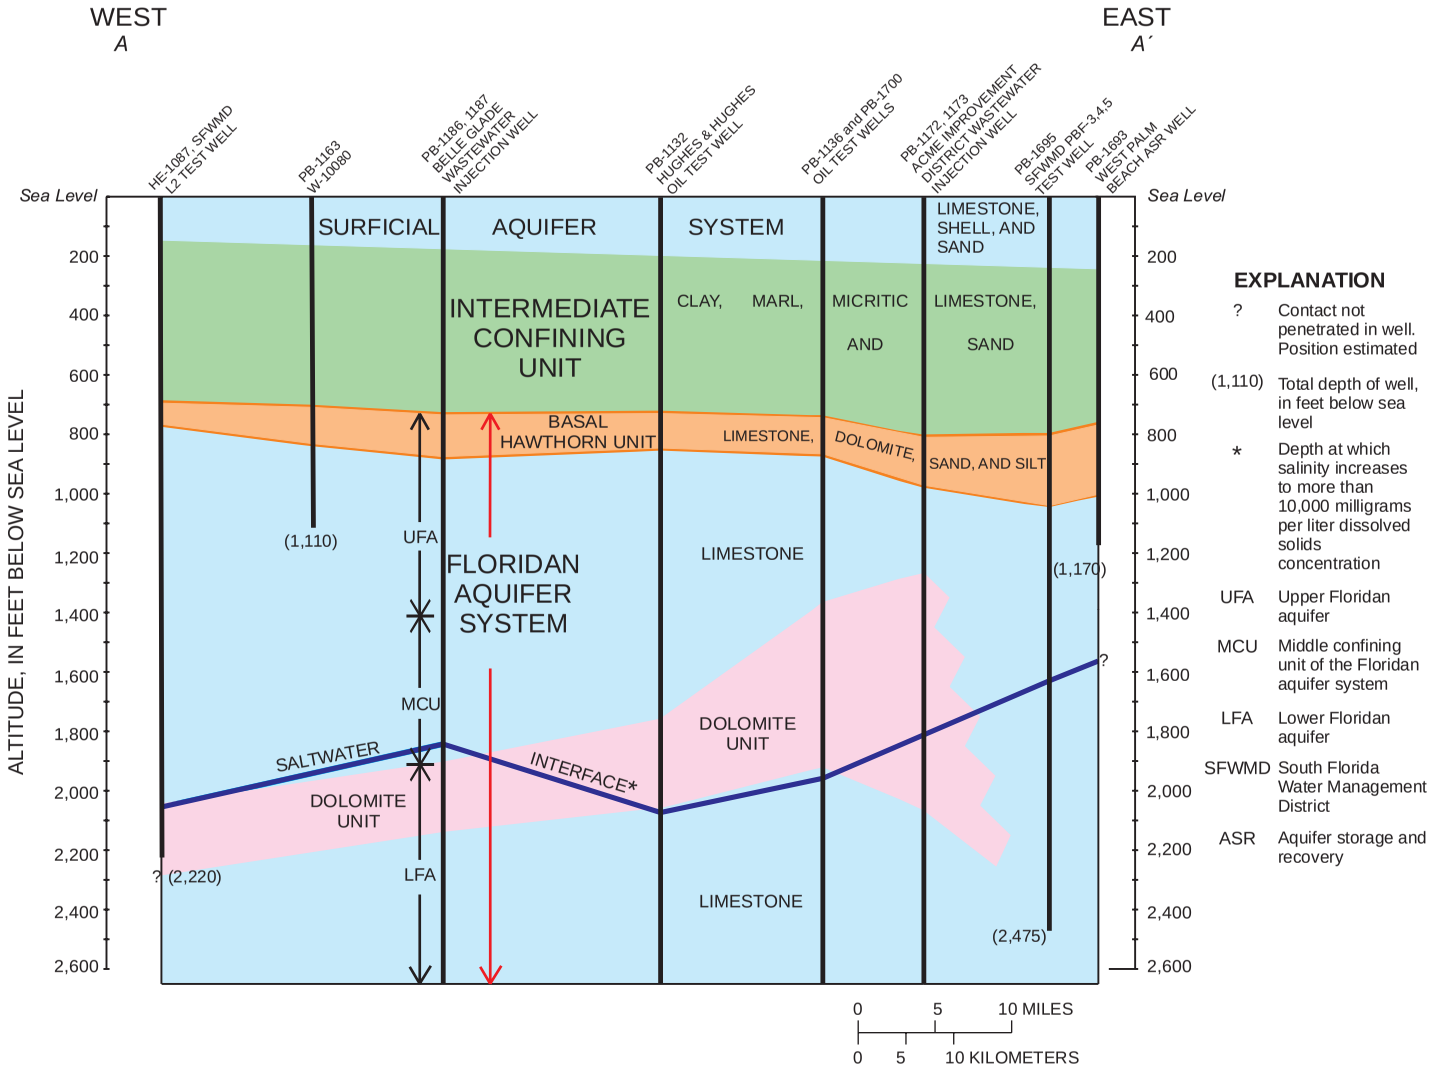

Figure 7. Hydrogeologic section extending east-west across Palm Beach County (modified from Reese and Memberg, 2000).

the coast and thins toward the center of the peninsula. Also shown on the section (fig. 7) are the depths of the saltwater interface in the Floridan aquifer system and a unit composed mostly of dolomite and dolomitic limestone referred to as the dolomite unit (Reese and Memberg, 2000). The saltwater interface (fig. 7) is defined as the depth below which total dissolved solids concentration is greater than 10,000 mg/L.

The dolomite unit of the Floridan aquifer system generally is considered to be within the uppermost permeable unit of the Lower Floridan aquifer in southern Florida (fig. 7; Meyer, 1989a). In some areas of Palm Beach County, however, the top of this unit is as high as 1,200 to 1,300 ft below sea level, as shown (for example) by wells PB-1172 and PB-1173 in figure 7. In these areas, it is uncertain whether all of the dolomite unit would be included in the Lower Floridan aquifer.

The altitude of the basal contact of the Hawthorn Group (same as the base of the basal Hawthorn unit) was mapped for most of southern Florida in three previous studies (Reese, 1994, fig. 6; Reese, 2000, fig. 7; and Reese and Memberg, 2000, fig. 6). Determination of the depth of this contact was primarily based on lithology and gamma-ray geophysical log patterns. As described above, this contact does not necessarily correspond with the top of the Upper Floridan aquifer, but the most important flow zone(s) in the Upper Floridan aquifer is typically associated with the contact. The altitude of this contact varies considerably in southern Florida, ranging from less than 600 ft to greater than 1,200 ft below sea level. Local relief can be as much as several hundred feet, particularly in southwestern Florida.

Complex structure in the Hawthorn Group has been identified in Lee and Hendry Counties along the Caloosahatchee River (Cunningham and others, 2001). The wavy configuration patterns of seismic reflection data show this structure, and these patterns are probably related to karstic collapse of deeper limestone that could be in the Floridan aquifer system.

Acknowledgments

A number of individuals, private consulting firms, water utilities, and regulatory agencies assisted in this study by providing data and technical input. Maintenance supervisor John Reynolds of the Boynton Beach East WTP and lead operators Guy Bartolotta (Broward County WTP 2A), John Cargill (Fiveash WTP), and Howard Erlick (Springtree WTP) were very helpful in providing information and conducting tours of their sites. Steve Evans, Water Quality Supervisor at the Boynton Beach East WTP, was especially helpful in providing detailed water-quality records of all cycles for the ASR well. Offices of the Underground Injection Control Program of FDEP in West Palm Beach, Ft. Myers, and Tallahassee graciously provided additional ASR technical information and data. Mark Pearce of Water Resource Solutions, Inc., Cape Coral, Fla., provided helpful technical input.

INVENTORY OF WELL AND TEST DATA

Well data were inventoried and compiled for all wells at existing and historical ASR sites in southern Florida, and cycle test data (also available for many sites) were synthesized. Consulting reports on the construction and testing of wells and on cycle testing provided much of these data. The consulting reports used to compile these data are listed in the selected references section at the back of this report.

Historical and current ASR sites are listed in table 1 along with the utility or operator of the site, the aquifer being used for the storage zone, site status, type of source water used for injection, and number of wells drilled at each site. The locations of these sites are shown in figure 1. The number of injection (storage) wells at each site ranges from one to five, and most sites have at least one monitoring well in the storage zone.

The type of source water used for injection in southern Florida has included treated drinking water, raw ground or surface water, and reclaimed water (table 1). Treated drinking water is the most common source water type, but raw ground water also is used, or has been proposed for use, at a number of sites on the east coast. The source water planned for the CERP ASR program is raw or partially treated ground water or surface water (table 1, Western Hillsboro Canal, site 1). Special permits, obtained through the FDEP Underground Injection Control program and the U.S. Environmental Protection Agency, are required to inject raw surface or ground water because these waters sometimes exceed maximum contaminant levels for primary or secondary drinking water standards for some constituents.

Construction and Testing Data

Construction and testing data were compiled into three main categories. These categories are well identification, location, and construction data; hydraulic well-test data; and ambient formation water-quality data.

Well Identification and Construction Data

For the purpose of this study, all ASR storage and associated monitoring wells were assigned a USGS number, and data from these wells have been stored as part of the USGS Ground-Water Site Inventory (GWSI) database. Well identification, location, and construction data are given in table 2 (at end of report). The construction information includes total hole depth, ending date of construction, casing depth and diameter, type of each casing string set in the well, and the completed (constructed) open interval and its diameter. In most cases, the completed interval is open hole, but a gravel-packed screen was installed in a few wells. At many sites, the first well drilled was plugged back to the selected storage zone after being drilled deeper to test other potential zones or to determine water-quality changes with depth. In many instances, the latitude and longitude provided herein were obtained from the construction permit, and this location is representative of the storage well only; however, in some instances, the latitude and longitude were more precisely determined for all wells at a site by the use of a hand-held global positioning system (GPS) (see footnote 1 in table 2 at end of report).

The thickness of the open interval ranges from 45 ft at the Marco Lakes (well C-1206) and Marathon (well MO-189) sites to 452 ft at the West Well Field site (well G-3706) (fig. 8; table 2 at end of reort). Open intervals for ASR wells in the Floridan aquifer system average 172 ft thick. The diameter of the open interval ranges from 5.125 in. at the St. Lucie County site to 29 in. at the West Well Field site in Miami-Dade County. Large diameter open intervals are constructed for the purpose of obtaining a high rate of flow. Each of the storage wells at the West Well Field site is designed for a pumping rate of up to 5 Mgal/d.

Hydraulic Well-Test Data

Reported data describing hydraulic tests were compiled for ASR well systems. The data include the reported results of packer tests conducted during drilling, step drawdown tests, single-well constant rate recovery tests, and multiwell constant rate tests (table 3 at end of report). Tests of other permeable intervals at a site that are shallower or deeper than the interval selected to be the storage zone are also included (table 3 at end of report). Water-level data were not analyzed as part of this study; rather, all of the analytical results given in table 3 (at end of report) came from consulting reports in the selected references listed at the back of this report.

Some tests reported in table 3 (at end of report) are single-well step drawdown tests run to determine the specific capacity of a well. These tests provide insight into the productive capacity of a well and are used to determine the size and depth of a pump to be used in the well for a multiwell test or for long-term operation. At some sites, the transmissivity of the tested interval was estimated from a step drawdown test using the specific capacity at each step. At the Marco Lakes ASR site, transmissivity was determined during a step drawdown test of ASR-3 by analyzing the resulting drawdown data from nearby wells using the Cooper and Jacob (1946) solution. Transmissivity was estimated at the Boynton Beach East WTP site from a step drawdown test of ASR-1 using the Cooper and Jacob (1946) solution, but without any monitoring wells. Specific capacity determined from step drawdown tests of storage zones range from 2.7 gal/min/ft at the Marathon site to 390 gal/min/ft at the West Palm Beach site, well ASR-1 (table 3 at end of report). Specific capacity was reported to be 1,600 gal/min/ft on the basis of a multiwell test at the Taylor Creek/Nubbin Slough (Lake Okeechobee) site.

Packer tests are tests of open-hole intervals conducted during drilling using inflatable packers set on a string of drill pipe for the purpose of isolating the interval to be tested. Often, only specific capacity data are reported for packer tests (table 3 at end of report). However, transmissivity can be estimated either from the specific capacity results, or from analysis of the recovery of water level after a period of constant rate pumping during a packer test. This latter method, known as the Theis (1935) residual drawdown or recovery analysis, gives a more reliable estimate than the specific capacity method. Packer test results can be unreliable because of partial penetration, a low pumping rate, a short pumping period, or incomplete isolation of the interval tested (leaky packers).

Hydraulic properties determined from a multiwell, constant rate, drawdown test include transmissivity, storage coefficient, and leakance. Solutions commonly used to analyze water-level data from this type of test include Theis (1935) and Cooper and Jacob (1946) for confined aquifers and Hantush and Jacob (1955) and Walton (1962) for semiconfined, leaky aquifers. Depending on the amount of drawdown (pumping rate) and the degree of background variations in water level, such as tidal fluctuations,

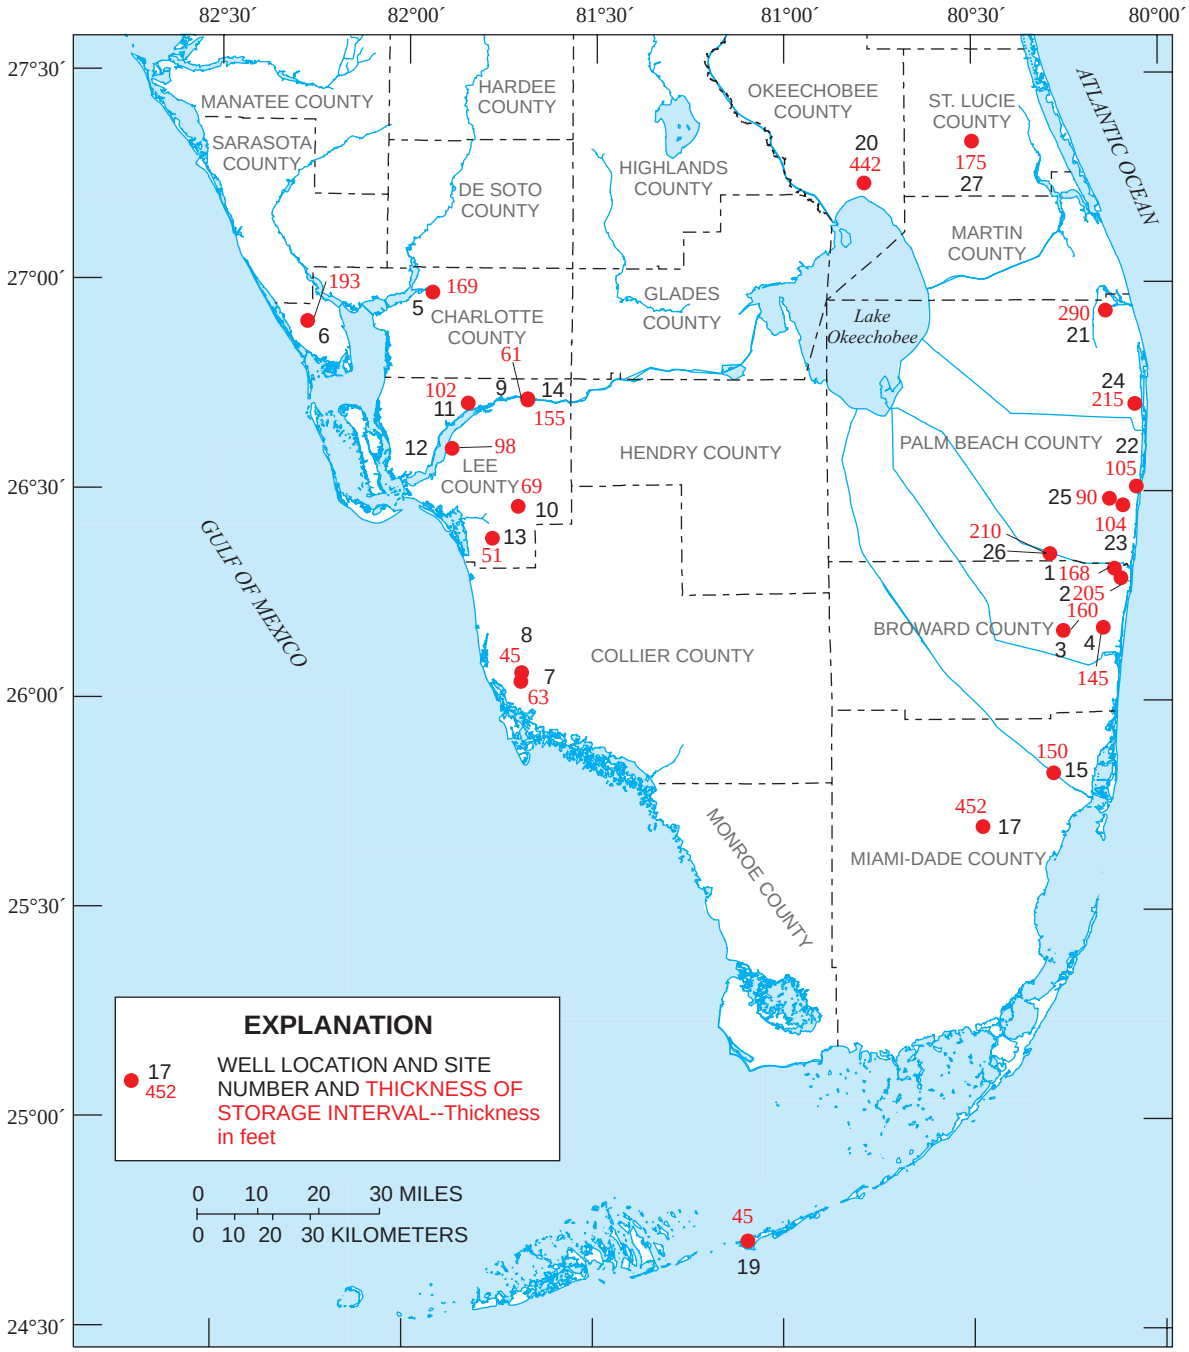

Figure 8. Thickness of open interval in storage wells at aquifer storage and recovery sites in southern Florida. All wells represent first storage well at each site (see table 2).

background water-level measurements should be made for at least 1 day prior to the beginning of the pumping test, and these measurements should be subtracted from the drawdown water-level data collected during the test. Single-well constant rate tests usually provide only an estimate of transmissivity, and solutions used to analyze the recovery water-level data from these tests include the Theis (1935) solution for residual drawdown and the Cooper and Jacob (1946) solution.

Multiwell constant rate tests of the storage zone were performed at 16 of the ASR sites (table 3 at end of report), and not including packer tests, single-well constant rate recovery tests of the storage zone were run at 4 sites, 2 of which also had a multiwell-test run. Constant rate test results could be affected by pretest well treatment designed to increase specific capacity. Acidization of the ASR well prior to the multiwell test was done at the Springtree WTP and West Well Field sites. The Western Hillsboro site planned recharge well (EXW-1) also was acidized after the reported step drawdown test (table 3 at end of report).

Hydraulic properties determined from tests of storage zones may apply only to the storage zone or to a thicker interval if the aquifer containing the storage zone is thicker than the storage zone. In the case where the aquifer is thicker than the storage zone, the hydraulic conductivity of a storage zone will be less than that obtained by dividing the transmissivity determined from a test by the thickness of the storage zone. However, in the Upper Floridan aquifer where thick zones of relatively low permeability separate flow zones, tests of part of the aquifer are typically not influenced by the entire thickness of the aquifer. Thus, the value of transmissivity obtained is less than the total transmissivity of the aquifer (Wedderburn and Knapp, 1983).

For 18 sites where the storage zone is in the Floridan aquifer system, the most reliable or representative values for transmissivity from storage zone tests were selected and then plotted on a map of southern Florida (fig. 9). In most cases, these values came from drawdown analysis of constant rate multiwell tests; if performed, the leaky aquifer solution was used. The storage zone is in the Upper Floridan aquifer in all cases, except at the Taylor Creek/Nubbin Slough (Lake Okeechobee) and the West Well Field sites. At the Lake Okeechobee site, this zone is in the Lower Floridan aquifer (Quiñones-Aponte and others, 1996), and at the West Well Field site, some of the mid-Hawthorn aquifer in addition to the upper part of the Upper Floridan aquifer is included in the storage zone. Transmissivity values range from 800 ft^2/d at the Lee County site to nearly 590,000 ft^2/d at the Lake Okeechobee site. The highest value in the Upper Floridan aquifer is 108,000 ft^2/d at the West Palm Beach WTP site. The average value for sites in the Upper Floridan aquifer is 21,100 ft^2/d, and values greater than 30,000 ft^2/d are considered to be high in this study.

The high transmissivity estimate at the Lake Okeechobee site (fig. 9) is a function of the large thickness of the open interval and the dominant lithology in this interval, which is dolomite. The storage zone contains several highly permeable flow zones that may have secondary fracture permeability. The open interval in the ASR well for the Lee County WTP site is confined to the lower Hawthorn producing zone of the basal Hawthorn unit (Reese, 2000). A second ASR site was later constructed at the same location (Olga WTP site). The Olga WTP site storage zone is deeper in the Upper Floridan aquifer and is contained within the Suwannee Limestone, about 150 ft below the top of this formation (Water Resources Solutions, Inc., 2000a). The estimated transmissivity for the Olga storage zone is 9,400 ft^2/d (fig. 9; table 3 at end of report).

Leakance of the tested aquifer was determined at eight sites in the Floridan aquifer system by multiwell aquifer tests, and values are higher than expected (table 3 at end of report). Leakance is a measure of the degree of aquifer confinement and is defined as the vertical hydraulic conductivity of a confining unit, *divided* by the thickness of the confining unit. However, leakance determined from an aquifer test applies to both the upper and lower confining units of the aquifer, unless it is known that one of the confining units is nonleaky. Leakance estimates ranged from 3.9×10^{-5} 1/d at the West Well Field site to 6.3×10^{-2} 1/d at the Deerfield Beach West WTP site. Leakance estimates less than 1×10^{-3} 1/d have been used to indicate confining conditions in the surficial aquifer system in southern Florida (Reese and Cunningham, 2000). Of the eight values determined for leakance (table 3 at end of report), five exceed this limiting value. Leakance was greater than 4.0×10^{-2} 1/d at the Deerfield Beach West WTP, Olga WTP, and the St. Lucie County sites. Leakance may also be high at the West Palm Beach WTP site. The confined aquifer Theis (1935) solution was used to analyze the multiwell-test data collected at this site, despite a large observed departure below the type curve during the latter part of the test indicating a leaky aquifer.

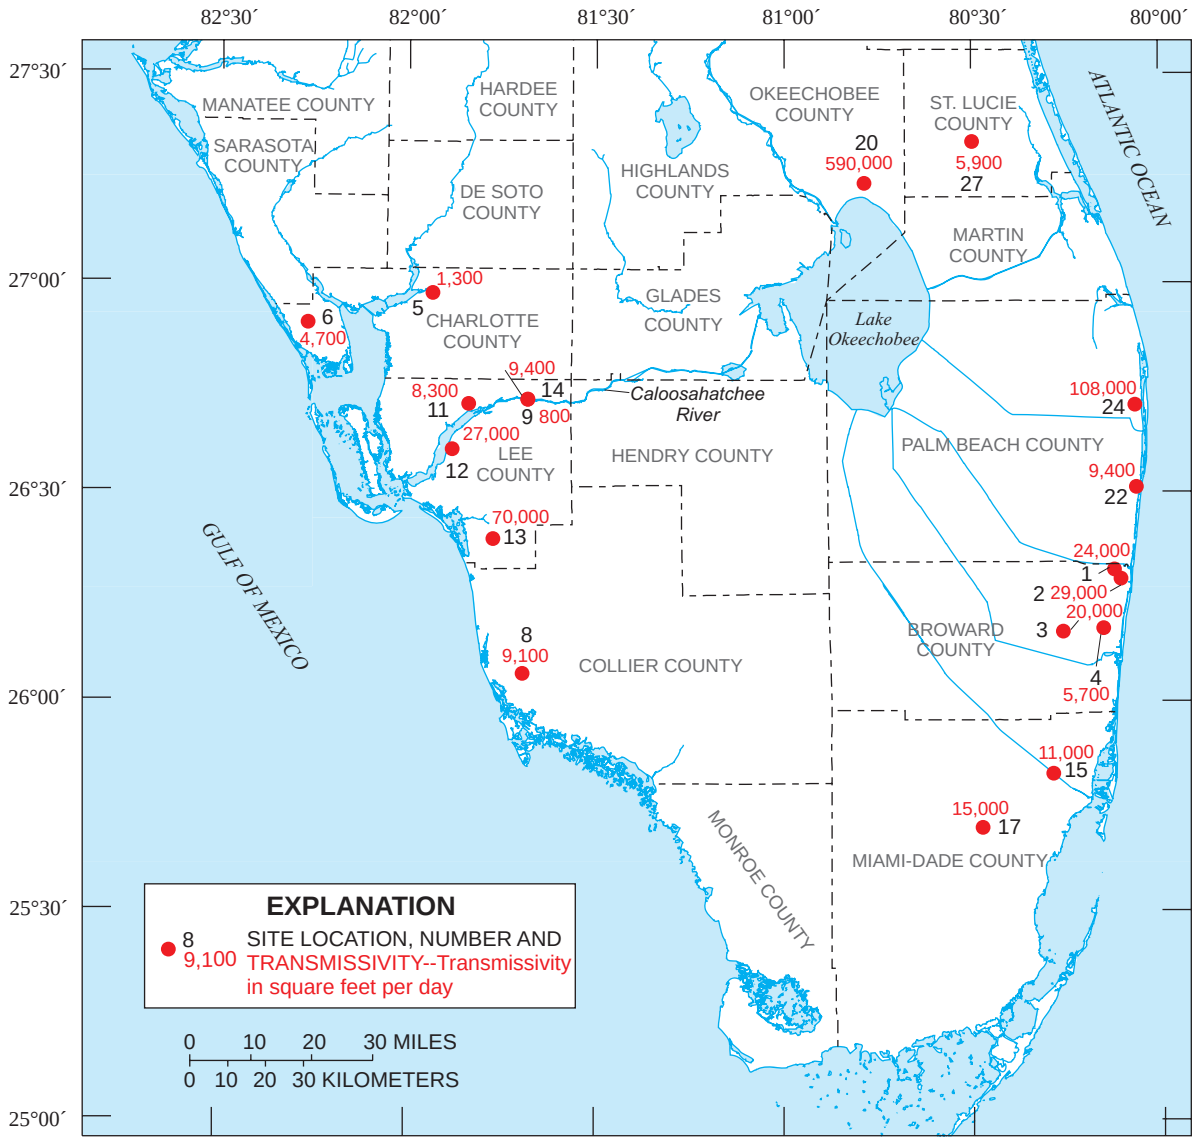

Figure 9. Transmissivity determined for storage zones in the Floridan aquifer system at aquifer storage and recovery sites in southern Florida. The production well used for the test at all sites was ASR-1, except for sites 15 and 27 where MW-1 was used.

The high leakance estimates from the Upper Floridan aquifer are probably best attributed to leakage from below the tested interval rather than from above because of the good confinement generally accepted as being present above the aquifer in southern Florida (Bush and Johnston, 1988). This leakage either originated from intervals lower in the Upper Floridan aquifer or from the middle confining unit of the Floridan aquifer system.

Ambient Water-Quality Data

Ambient water-quality data were collected from storage and monitoring wells at ASR sites (table 4). The inventoried data describe formation water salinity and include the sampled interval, sample date, specific conductance, dissolved chloride concentration, dissolved solids concentration, temperature, and dissolved sulfate concentration. The sampling methods, listed in order of increasing reliability, include (1) collected during drilling by the reverse-air rotary method, (2) collected from packer tests, (3) collected from a pump out test of an open interval below casing before final construction of the well, and (4) collected from a completed open interval. Intervals sampled include the storage zone, intervals deeper and shallower than the storage zone, and intervals that include more than the

Table 4. Ambient water-quality data collected from aquifer storage and recovery well systems in southern Florida

[1]Interval tested is the same (or about the same) as the storage zone.

selected storage zone (table 4). Upper Floridan aquifer ASR sites in southwestern Florida were usually sampled from shallower permeable zones of the intermediate aquifer system.

The chloride concentration of ambient water in ASR storage zones in the Floridan aquifer system is shown on a map of southern Florida (fig. 10). Samples used for this map were selected from table 4 based on the most reliable sampling method as described above. Chloride concentrations ranged from 500 mg/L at the Lee County WTP site to 11,000 mg/L at the Englewood South Regional WWTP site. At most sites, the chloride concentration ranged from about 1,000 to 3,000 mg/L, and the average concentration was about 2,300 mg/L. Storage zones containing water with 3,000 mg/L or greater were considered to have high chloride concentration in this study. The highest value found in the east coast area was 3,600 mg/L at the Springtree WTP site. The highest chloride concentration found in the upper part of the Upper Floridan aquifer in southern Florida based on three previous studies was 8,000 mg/L in northeastern Palm Beach County; the lowest concentration found was 400 mg/L in Lee County (Reese, 1994; Reese, 2000; and Reese and Memberg, 2000).

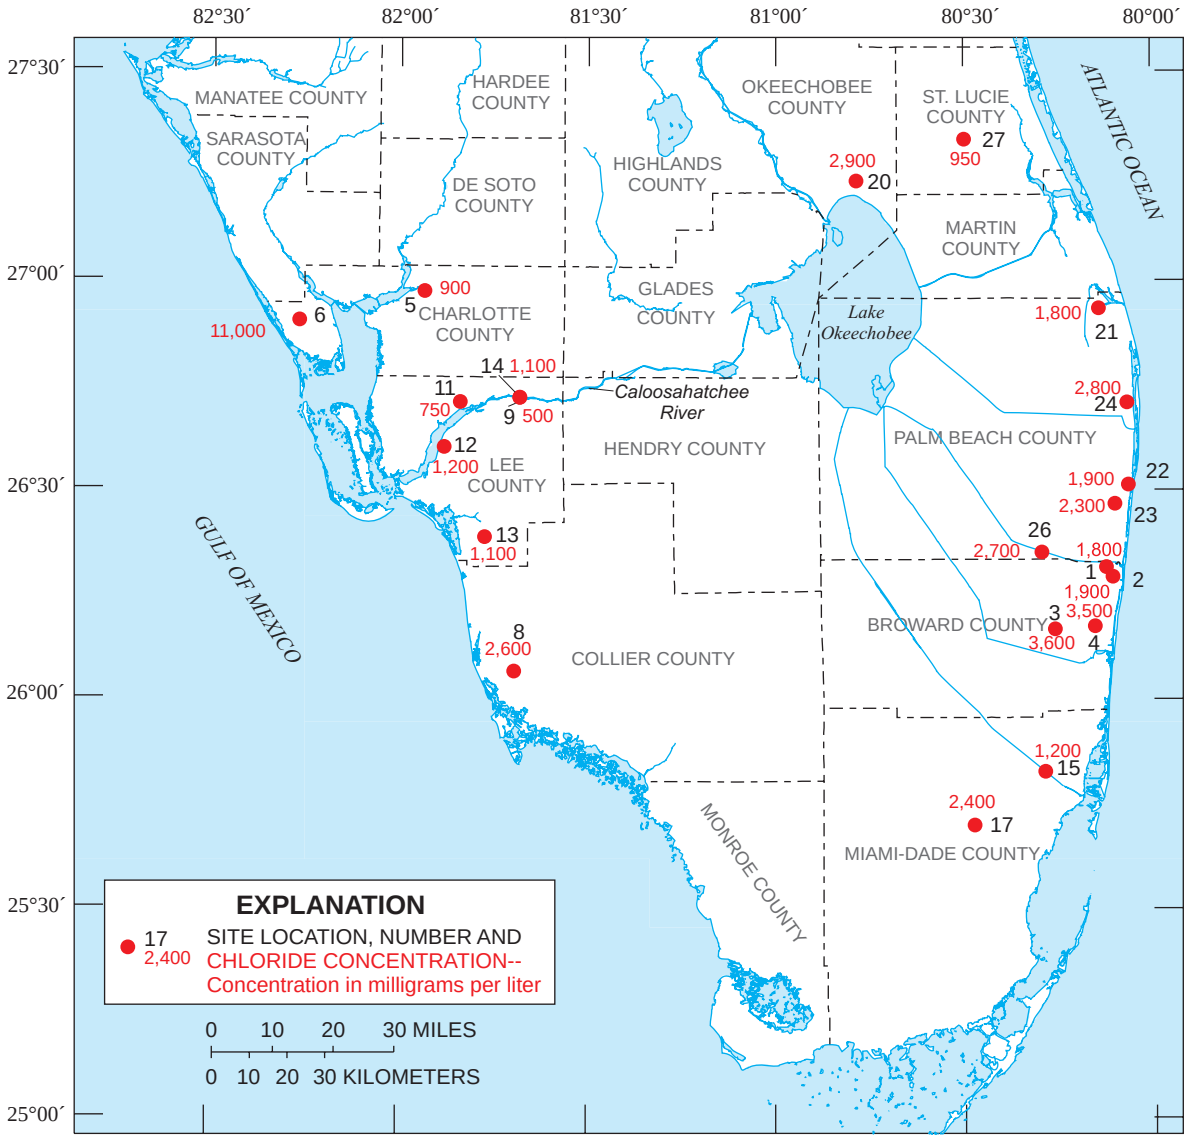

Figure 10. Ambient water salinity of storage zones in the Floridan aquifer system at aquifer storage and recovery sites in southern Florida.

Cycle Test Data

Cycle test information was obtained from consulting reports, other published reports, monthly operating reports (MOR) required by the FDEP as part of the permitting process during operational testing, and in several cases, from daily records provided by a WTP. These data were compiled and are given in table 5. All of the test data given are only for the first storage well (ASR-1) at a site, except for the West Well Field site. Only 18 of the 27 ASR sites listed in table 1 are included in table 5; other ASR sites have not initiated operational testing or test data were not available. Cycle testing at the Olga WTP and North Reservoir sites was postponed due to inadequate treated drinking water supplies that will be used for recharge. The number of days of storage in table 5 includes only the time between the recharge and recovery periods; it does not include days during the recharge period in which injection ceased due to a lack of source water or other operational problems. The MOR provided insufficient data to calculate recovery efficiencies at some ASR sites because the water quality of recharged and recovered water was not reported; these data are not required by the FDEP in the report.

Two recovery efficiency numbers were determined for each cycle (table 5). The first is total recovery efficiency, and it is the percent recovery at the end of the cycle. The chloride concentration of the recovered water at this point is also given in table 5. The chloride concentration at the end of the cycle is usually in the range of 250 to 400 mg/L. The second recovery efficiency number is the potable water recovery efficiency. It is the percent recovery when the chloride concentration of the recovered water reaches only 250 mg/L. Potable water recovery efficiency numbers (potable recovery efficiencies) are used in this report for performance comparisons between sites.

Chloride concentrations of recharged and recovered water for the West Palm Beach WTP site were not reported or made available, and only the total recovery efficiencies are given in table 5. At the West Well Field site, two storage wells were active during the second cycle and all three storage wells were active during the third cycle. However, water was not recovered from well ASR-3 during the cycle 3 recovery period. For cycle 3, recovery efficiencies were determined for individual storage wells and also for all three wells combined (table 5).

The Boynton Beach East WTP site underwent 16 recharge-recovery cycles (table 5). The Marathon site had 11 cycles, and the Marco Lakes and Springtree WTP sites had 5 cycles each; the number of cycles was 4 or less at all other sites. Additional cycles were conducted at the Manatee Road site, but were not reported. Recharge volume per cycle ranged from as low as 0.6 Mgal for cycle 1 at the Lee County WTP site, to as high as 714.33 Mgal during cycle 3 at the West Well Field site. The longest storage period was 181 days for cycle 3 at the Hialeah site.

The highest reported first cycle potable recovery efficiency was 47 percent for the Boynton Beach ASR site. The first cycle recovery efficiency of the Corkscrew WTP site is greater but is not considered here due to the potable nature of water in its storage zone. Except for the Jupiter site where no potable water was reported to be recovered on the first cycle, the lowest potable recovery efficiency was 2 percent at the San Carlos Estates site. Of the 16 sites in table 5 with potable recovery efficiencies calculated, 9 sites had a potable recovery efficiency of well over 10 percent during the first cycle. The seven exceptions include Fiveash WTP, Manatee Road, North Reservoir, San Carlos Estates, Lake Okeechobee, Jupiter, and St. Lucie County sites. Two of these, the Manatee Road and Jupiter sites, showed improvement to a level substantially higher than 10 percent in succeeding cycles. The Fiveash, San Carlos Estates, and Lake Okeechobee sites did not; however, few cycles were conducted at these three sites (two, two and four, respectively). Only one cycle was run at the North Reservoir and St. Lucie County sites.

Ten sites achieved a potable recovery efficiency exceeding 30 percent during at least one cycle; however, at the Shell Creek WTP site, the recovery efficiency diminished to 9 percent during the third cycle when the recharge volume was greatly increased. The highest potable recovery efficiency of 90 percent was during cycle 4 at the Boynton Beach East WTP site, but the recharge volume reported for this cycle could be too low. This recharge volume is based on flow totalizer equipment readings, but calculation of the recharge volume based on reported daily flow rates gives a higher number. The second highest recovery efficiency was 84 percent for cycle 16 at the Boynton Beach site. Recovery efficiency was 72 percent for cycle 4 at the Marathon site; however, the storage zone at this site is within a siliciclastic sandstone aquifer. Because of lower dispersive mixing, recovery from a siliciclastic aquifer may be larger, having only intergranular porosity as compared to carbonate rock storage zones that probably also have secondary, conduit type porosity (Merritt, 1985).

Table 5. Cycle test data from aquifer storage and recovery wells in southern Florida

[Test data at all sites, excluding the West Well Field site, are only for the first storage well at the site (ASR-1). *Data extracted from monthly operating reports and daily records provided by the water treatment plant. All other cycle test data are from consulting reports or other published reports. DS, dissolved solids concentration in mg/L (milligrams per liter); Mgal, million gallons; NA, not applicable; NR, not reported; WTP, Water Treatment Plant; >, greater than]

[1]Cycle 5 had 52 days of down time during the recharge period.
[2]Recovery efficiency estimated using a fictitious value for recharge chloride concentration.
[3]Recovery continued past the reported recovery volume, which had an ending chloride concentration of 250 mg/L.
[4]An additional 5.2 million gallons were recharged during the last 57 days of the storage period by trickle flow (50 gallons per minute).
[5]Conducted by CH_2M Hill.
[6]A specific conductance of 5,000 microsiemens per centimeter was used to terminate recovery for all cycles, which equals 1,385 milligrams per liter chloride concentration.
[7]Conducted by the U.S. Geological Survey.
[8]Injection rate for all cycles was 2,000 gallons per minute, and recovery rate was 1,000 gallons per minute.
[9]The recharge volume for cycle 4 could be too low, which would make the recovery efficiencies too high.

CASE STUDIES OF SELECTED AQUIFER STORAGE AND RECOVERY SITES

Detailed information regarding four sites is presented in this section. For the most part, the sites were selected on the basis of the number of cycles that were conducted. Two sites are located in southeastern Florida, and two are in southwestern Florida. The selected sites illustrate the contrast in hydrogeology between the coastal areas. Each case study includes a graphical representation of the hydrogeology at the site and well construction information.

Boynton Beach East Water Treatment Plant

The Boynton Beach East WTP ASR site located on the east coast in Palm Beach County is operated by Boynton Beach Utilities. The source of water for recharge is treated drinking water from the WTP. The location of the storage zone in relation to lithology, geophysical log signatures, and hydrogeologic units at the Boynton Beach site is shown in figure 11. Also shown are the location of flow zones as determined by flowmeter, fluid resistivity, and caliper logs for the interval extending from a depth of 804 to 1,200 ft below land surface. The flow zones in this interval primarily occur in the basal Hawthorn unit (Reese and Memberg, 2000) or near its base. The flow zones are thin, they tend to coincide with formation resistivity peaks possibly indicating cementation and secondary porosity, and they occur just below intervals of higher gamma-ray response. These intervals of higher gamma-ray response indicate beds high in phosphate sand content. The base of the Upper Floridan aquifer was not penetrated in the ASR well but is estimated to be at a depth of at least 1,500 ft below land surface.

The thickness of the storage zone open interval at the Boynton Beach site is 105 ft (fig. 9); transmissivity is reported to be about 9,400 ft^2/d (fig. 9; CH_2M Hill 1993), and ambient water had a chloride concentration of 1,900 mg/L (fig. 10). The site is located in a structurally high area along the east coast where the altitude of the Hawthorn Group basal contact is 930 ft below sea level (Reese and Memberg, 2000).

Cycle testing at the Boynton Beach site began in late 1992, and by early 2000, 16 recharge-recovery cycles had been conducted for an average of about 2 cycles per year (fig. 12). Potable recovery efficiency increased rapidly during the first four cycles to 90 percent per cycle; however, as noted previously, the 90 percent recovery for cycle 4 is questionable. During the next three cycles, recovery efficiency decreased to less than 30 percent, possibly because of longer storage periods. Recovery efficiency for cycles 8 to 16 generally increased to greater than 80 percent.

Percent recovery is plotted against the chloride concentration of recovered water during each cycle in figure 13. For most cycles, water was recovered until the chloride concentration in the recovered water slightly exceeded 300 mg/L (also see table 5). During cycle 14, however, recovery continued until chloride concentration increased to about 1,000 mg/L, contributing to a lower recovery rate for cycle 15. The data points for cycle 15 are shifted to substantially lower recovery percentages than for cycle 14 (fig. 13). The recovery efficiency for cycle 16 is the best obtained, with the exception of cycle 4, which has a recharge volume that could be higher than reported. However, the storage period for cycle 16 was only 4 days, and the recovery efficiency for this cycle could have benefited from the large recharge volume (111 Mgal) and incomplete recovery (recovery up to a chloride concentration of only 146 mg/L) for cycle 15.

Potable water recovery efficiencies for test and operational cycles at the Boynton Beach site appear to be greater than for all other Floridan aquifer system ASR sites in southern Florida. However, the number of cycles conducted at most other sites are limited, and the chloride concentration of the recharge water used at the Boynton Beach site is only about 50 mg/L (table 5). Several hydrogeologic, and design and management factors are favorable at this site that may explain the higher recovery efficiencies. The storage zone is located at the top of the Upper Floridan aquifer and is thin in comparison to the average storage zone thickness (about 180 ft) for wells in the Floridan aquifer system (fig. 8). Transmissivity and ambient salinity of the storage zone are moderate, being less than 30,000 ft^2/d and 3,000 mg/L of chloride concentration, respectively, and the site is located in a structurally high area.

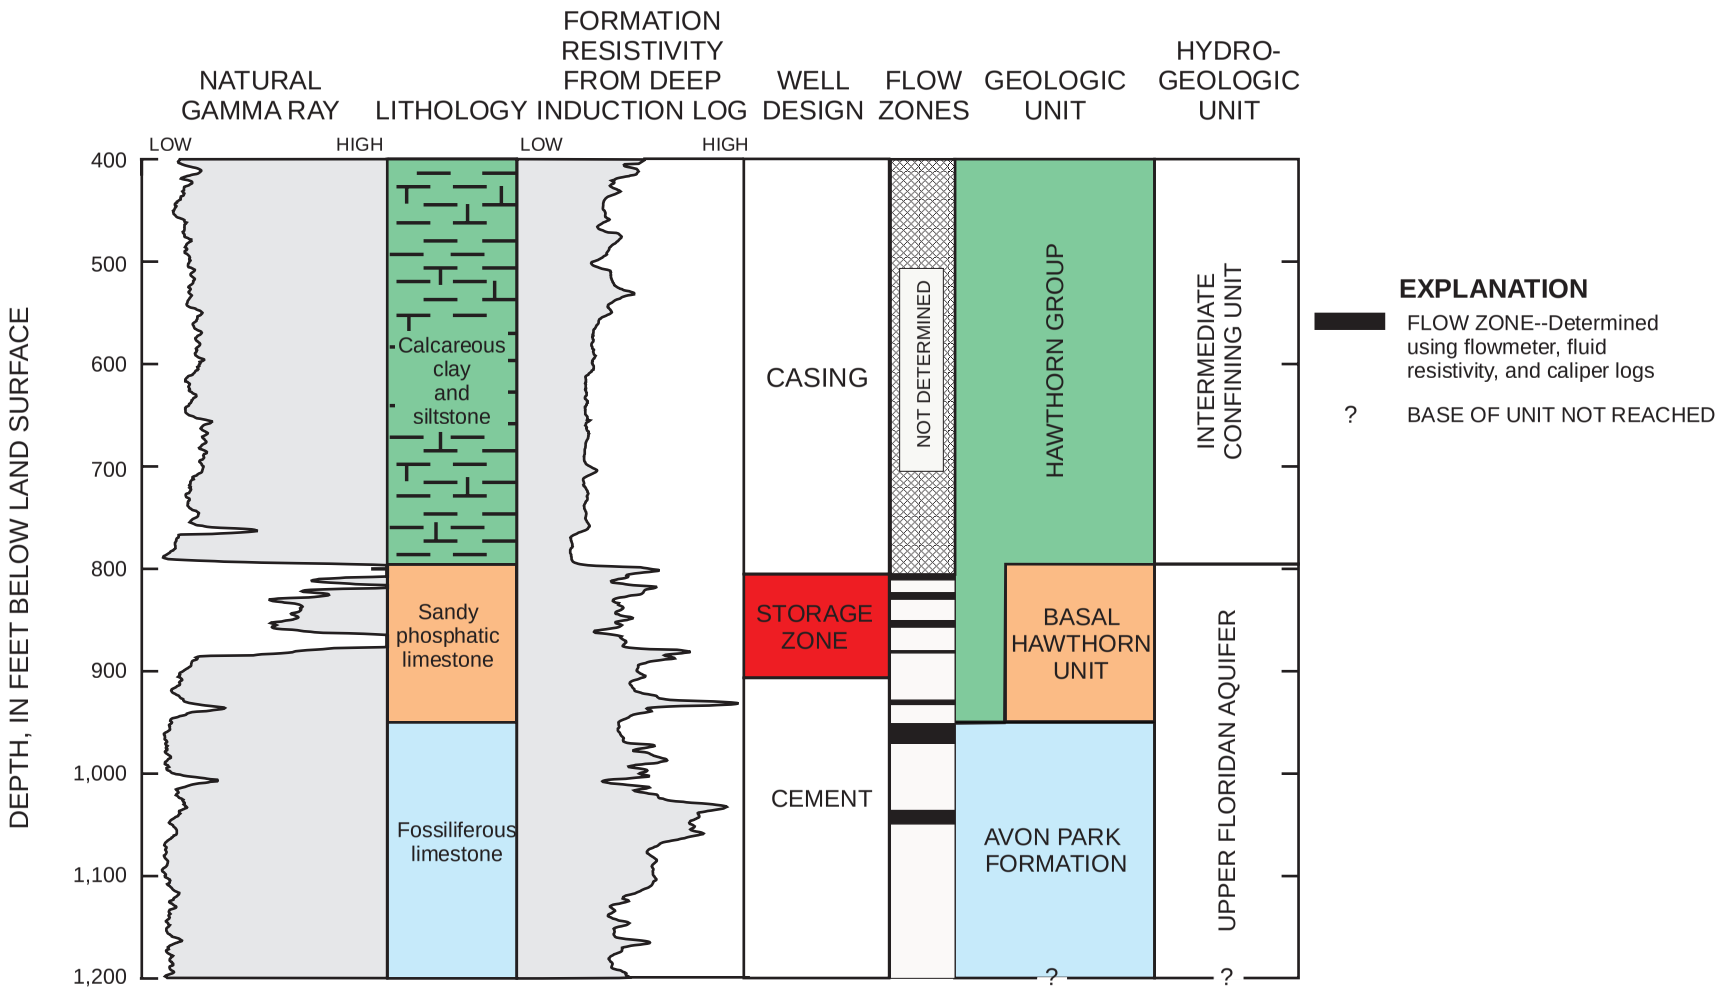

Figure 11. Location of the storage zone in relation to geophysical logs, lithology, flow zones, and geologic and hydrogeologic units for aquifer storage and recovery well PB-1194 at the Boynton Beach East Water Treatment Plant site in Palm Beach County.

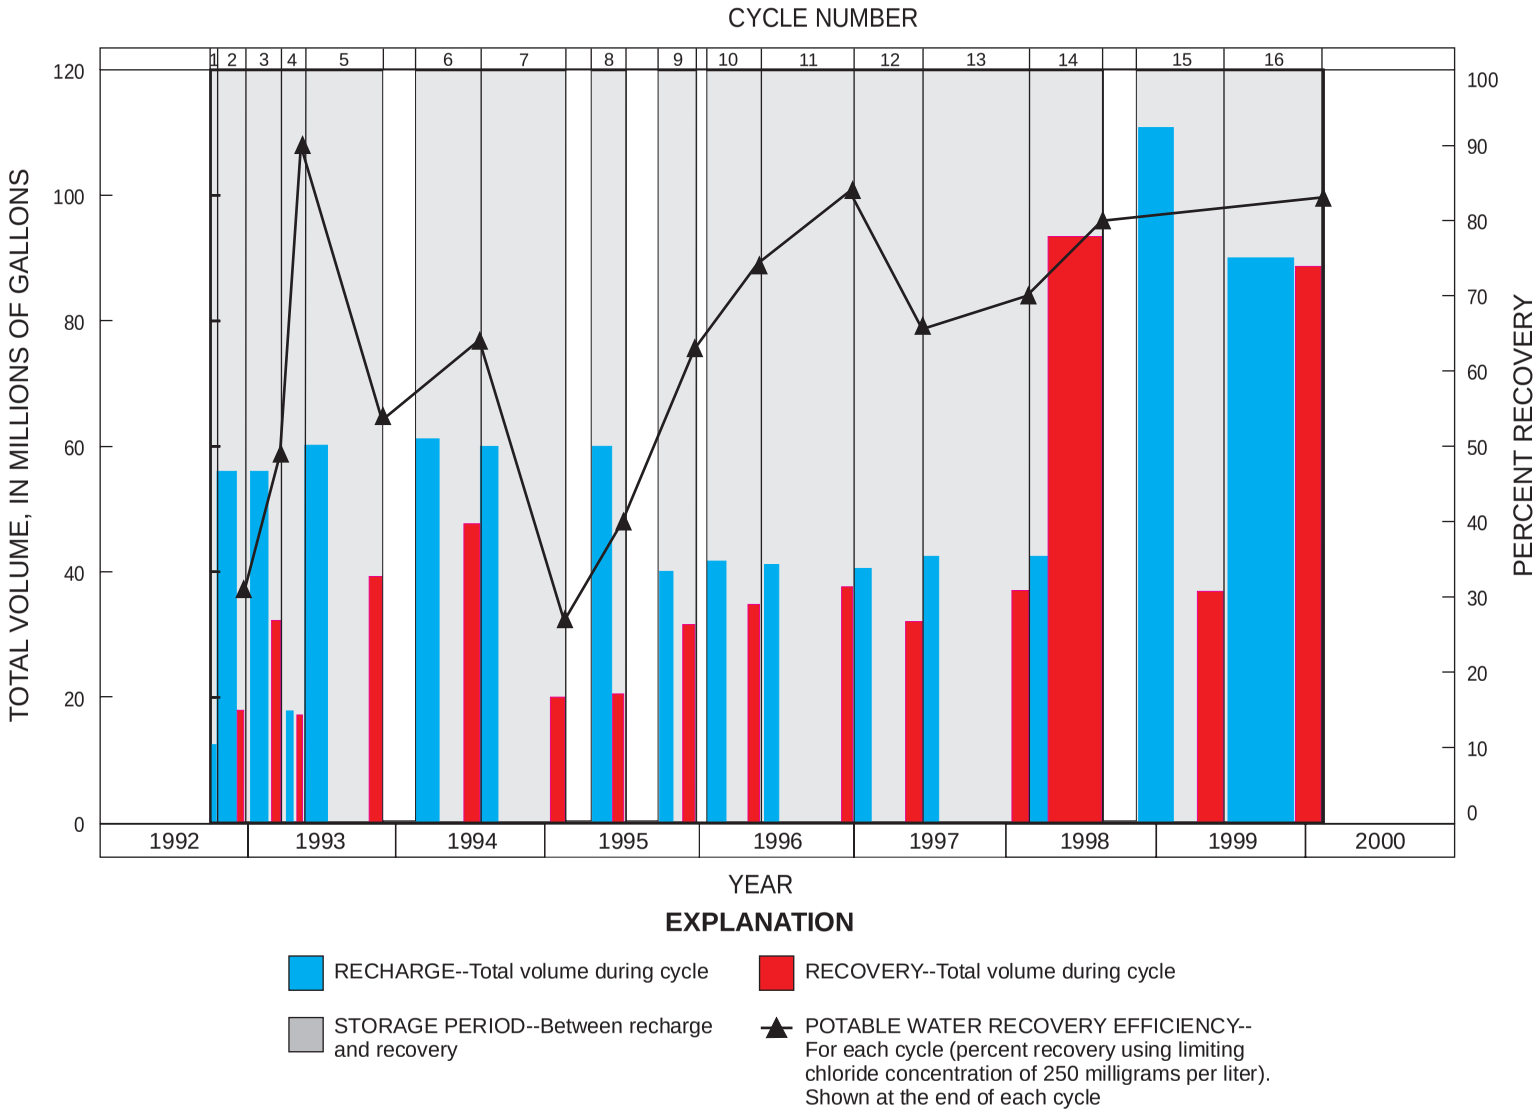

Figure 12. Operational cycles at the Boynton Beach East Water Treatment Plant site in Palm Beach County and relations of volumes recharged and recovered, time, and percent recovery for each cycle. Recovery for cycle 15 was 34 percent for an ending chloride concentration of 146 milligrams per liter.

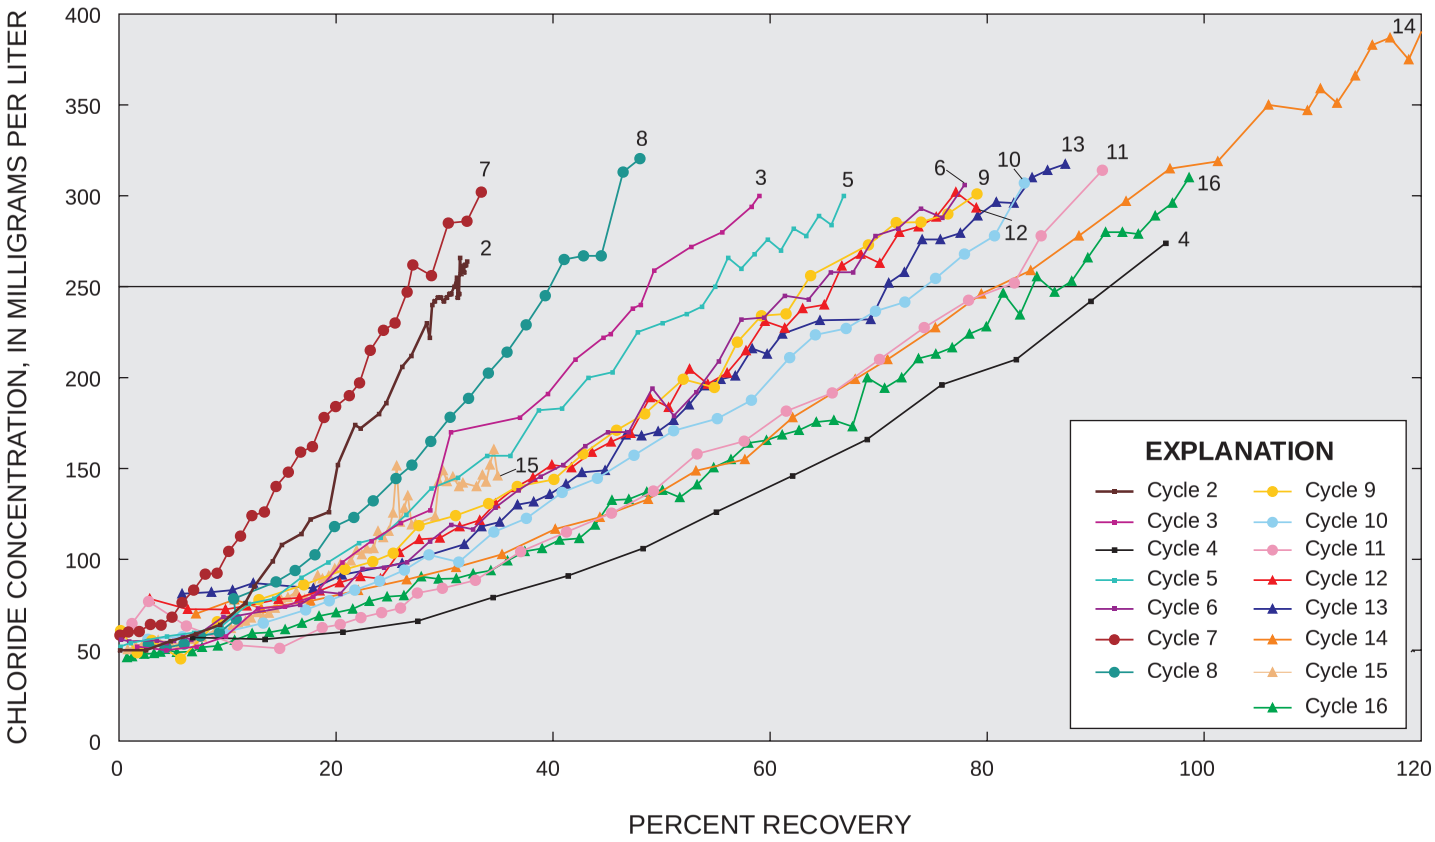

Figure 13. Percent recovery of recharged water during operational cycles in relation to chloride concentration of recovered water at the Boynton Beach East Water Treatment Plant site in Palm Beach County. Recovery for cycle 14 was continued until reaching a chloride concentration of about 1,000 milligrams per liter.

Springtree Water Treatment Plant

The Springtree WTP ASR site located in Broward County is operated by the City of Sunrise. Treated drinking water is used for recharge. The location of the storage zone in relation to lithology, geophysical log signatures, and hydrogeologic units at the Springtree site is shown in figure 14. Geophysical logs, such as the flowmeter, used to identify flow zones in the well were not run. Unlike the Boynton Beach site, the storage zone is not located at the top of the Upper Floridan aquifer. Casing was set through virtually all of the basal Hawthorn unit. The thickness of the storage zone open interval at the Springtree site is 160 ft (fig. 8). A photograph of the Springtree site wellhead site is shown in figure 15.

Storage zone transmissivity at the Springtree site is reported to be about 5,700 ft^2/d (table 3 at end

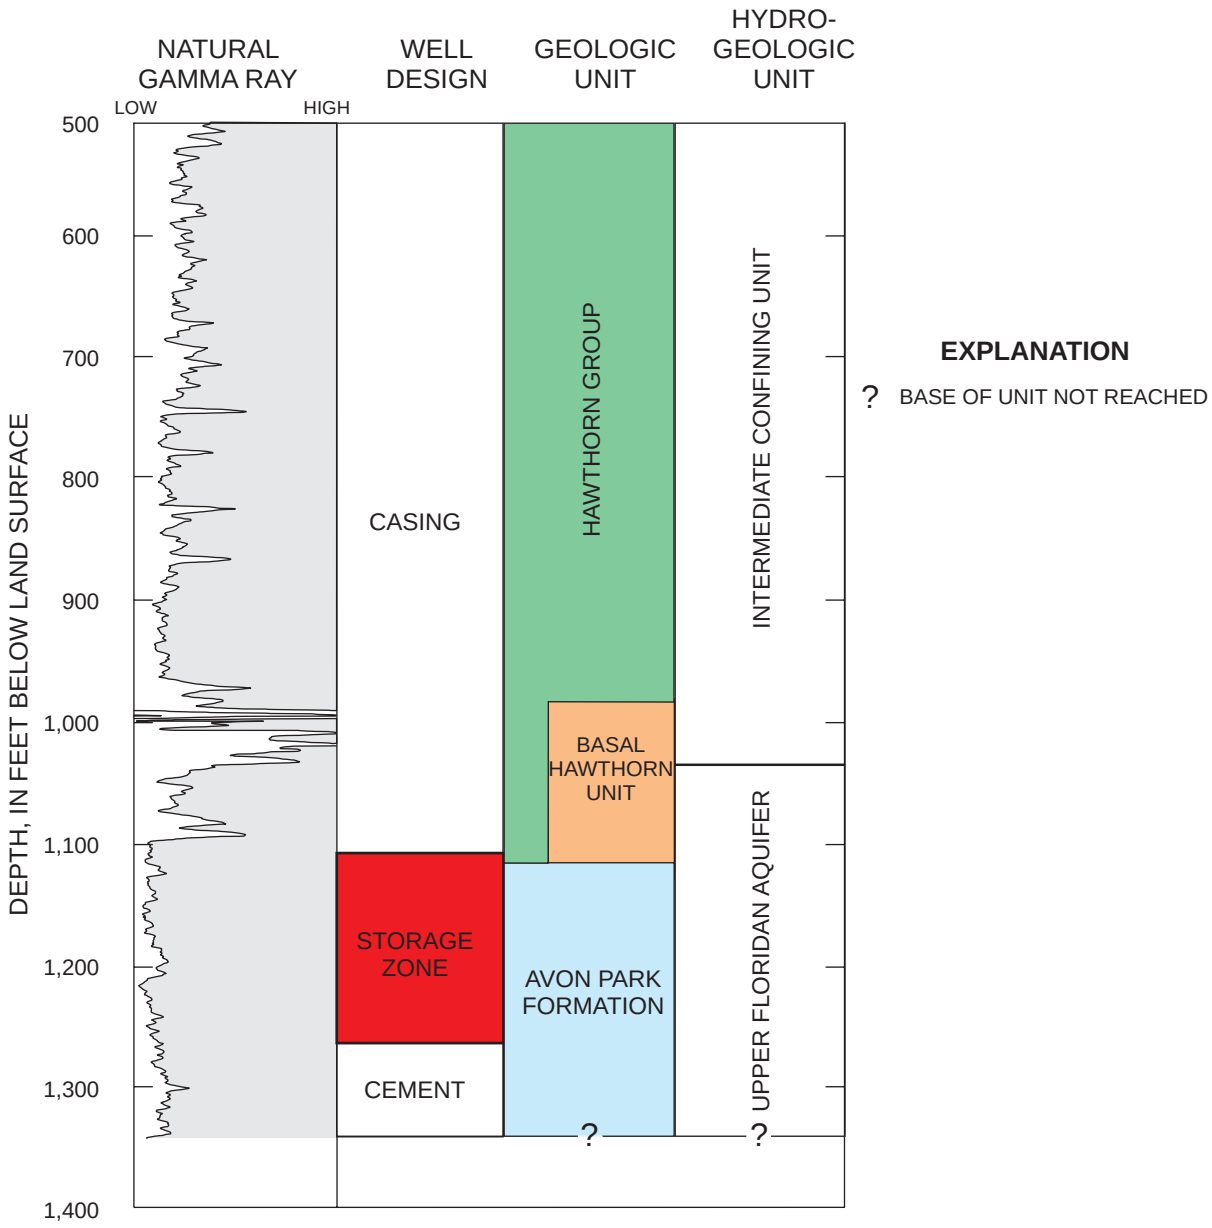

Figure 14. Location of the storage zone in relation to gamma-ray geophysical log and geologic and hydrogeologic units for aquifer storage and recovery well G-2914 at the Springtree Water Treatment Plant site in Broward County.

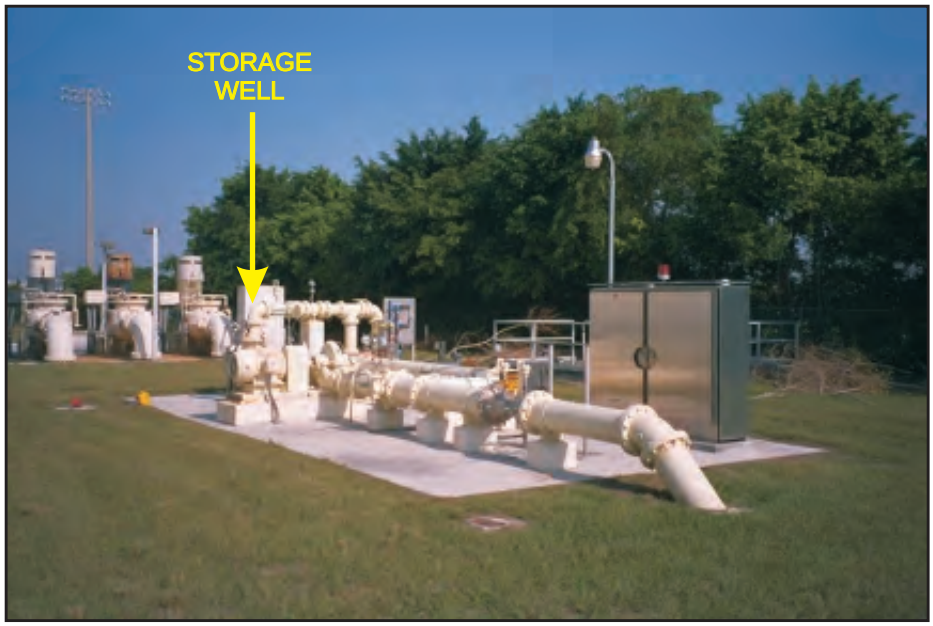

Figure 15. Wellhead piping, valves, and control system for the aquifer storage and recovery well at the Springtree Water Treatment Plant site in Broward County. Storage well on left side of concrete pad as shown by arrow.

of report; Montgomery Watson, 1998a). This value is lower than at surrounding sites (fig. 9), perhaps because only a small part of the basal Hawthorn unit is included in the open interval. The chloride concentration of ambient water in the storage zone is 3,600 mg/L (fig. 10). The altitude of the Hawthorn Group basal contact is 1,105 ft below sea level, and the site is located at the edge of a structurally low area (Reese, 1994).

Cycle testing at the Springtree site began at the end of July 1999, and five recharge-recovery cycles had been completed by the end of November 2000 (table 5). The ending chloride concentration for all cycles was 225 mg/L or less. The increase in recovery efficiency during the first four cycles was not as great as the Boynton Beach East WTP site, increasing from 20 percent for the first cycle to 37.5 for the fourth cycle. Although the volume recharged for the fifth cycle (120 Mgal) was at least three times that recharged in each of the first four cycles, recovery efficiency diminished to 27.5 percent. The lower recovery efficiencies at the Springtree site relative to the Boynton Beach East WTP site could be explained by high storage zone ambient water salinity and the storage zone position relative to the top of the aquifer.

Marco Lakes

The Marco Lakes ASR site located on the west coast in Collier County is operated by Florida Water Services for the City of Marco Island. The source of recharge water is partially treated surface water. The storage zone at the site straddles the contact between the basal Hawthorn unit and the Suwannee Limestone (fig. 16). The Suwannee Limestone is thick and well developed in the area, unlike southeastern Florida where the formation is thin or absent. The thickness and diameter of the open interval for the storage zone in well ASR-1 at the Marco Lakes site are 45 ft and 10 in., respectively (fig. 8; table 2 at end of report). By comparison, these dimensions are 44 ft and 12.25 in., respectively, for well ASR-2 (fig. 16; table 2 at end of report).

Transmissivity of the storage zone is reported to be about 9,100 ft^2/d (fig. 9; ViroGroup, Inc., 1998b). Storage zone ambient water is brackish; the reported chloride concentration is about 2,600 mg/L (fig. 10; well DZMW, table 4). Chloride concentration ranged from about 2,500 to about 3,700 mg/L in other wells completed in the storage zone at the Marco Lakes site (table 4). The site is located in a structurally high area where the altitude of the Hawthorn Group basal contact is 742 ft below sea level (Reese, 2000).

Five recharge-recovery cycles were conducted at the Marco Lakes site in ASR-1 between June 1997 and July 2000 (table 5). The ending chloride concentration for the recovery period used for comparison of cycles was 350 mg/L (Water Resources Solutions, Inc., 2000d), and the recovery efficiencies at this chloride concentration level increased from 31 percent for the first cycle to about 51 percent for the fifth cycle. The total volume of water recharged per cycle

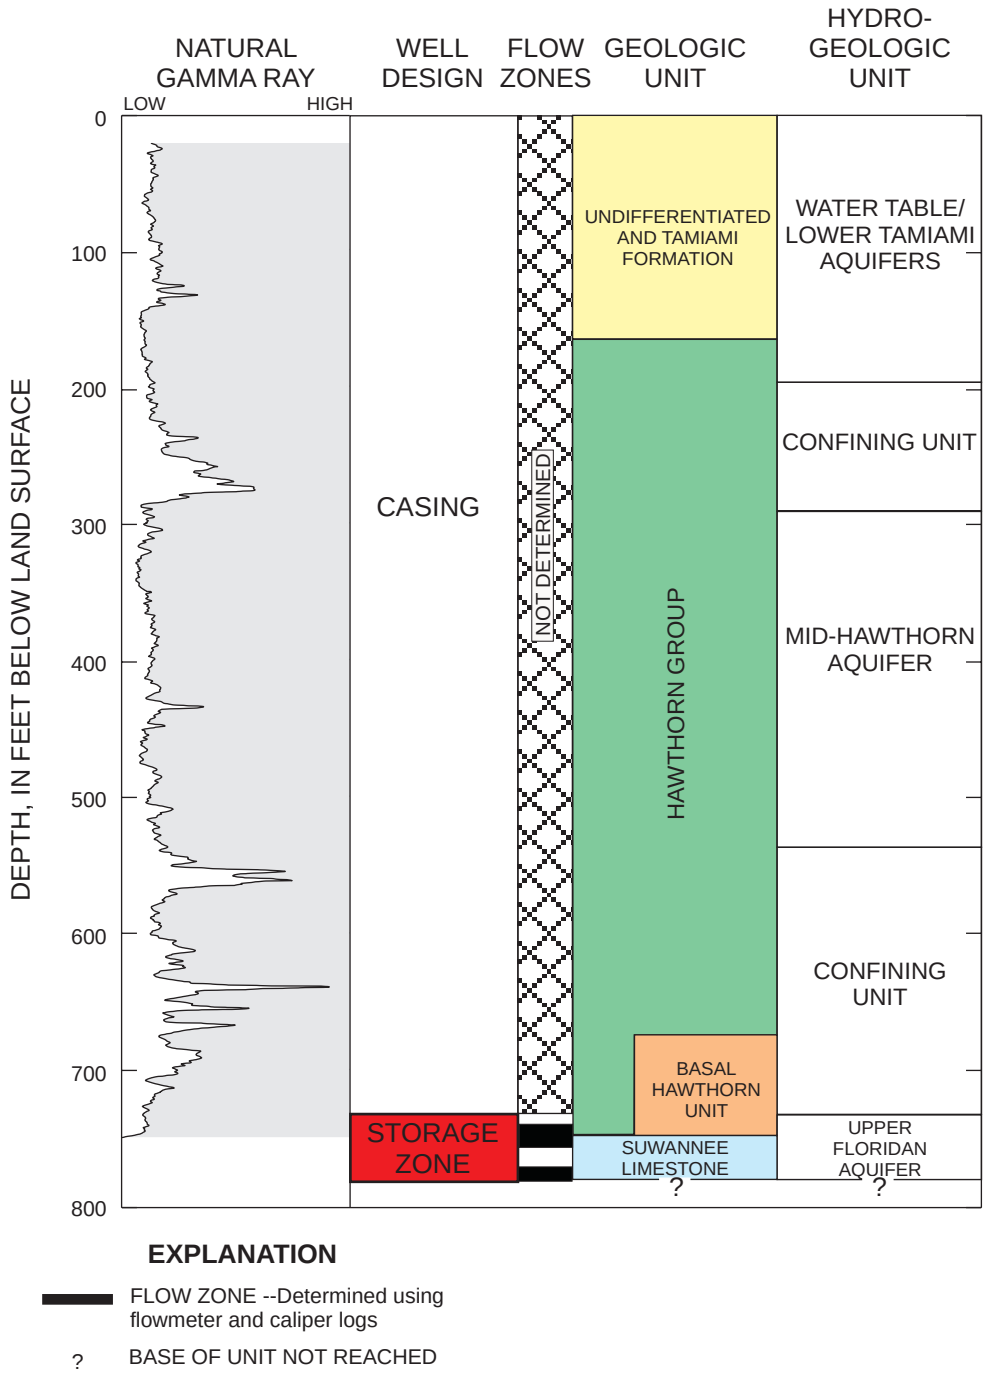

Figure 16. Location of storage zone in relation to gamma-ray geophysical log, flow zones, and geologic and hydro-geologic units for aquifer storage and recovery well C-1208 (ASR-2) at the Marco Lakes site in Collier County

increased from about 20 to 132 Mgal, respectively. The potable water recovery efficiency increased from 22 to almost 36 percent for the same two cycles.

Percent recovery was compared with the chloride concentration of recovered water during each cycle at the Marco Lakes site (fig. 17). On the basis of numerical simulation, the erratic recovery curve and poor recovery efficiency for cycle 2 is attributed to preferential well plugging during recharge of one of two receiving intervals (flow zones) in the storage zone (Water Resources Solutions, Inc., 1999c). Calcium carbonate is the likely precipitate causing plugging, and acidification of the recharge water prior to injection has reduced or eliminated the problem in later cycles.

The Marco Lakes recovery efficiencies at an ending chloride concentration of 350 mg/L rather than those at 250 mg/L concentration could serve as a better comparison with the Boynton Beach East WTP site potable recovery efficiencies. The chloride concentration of the recharge water at Marco Lakes averages

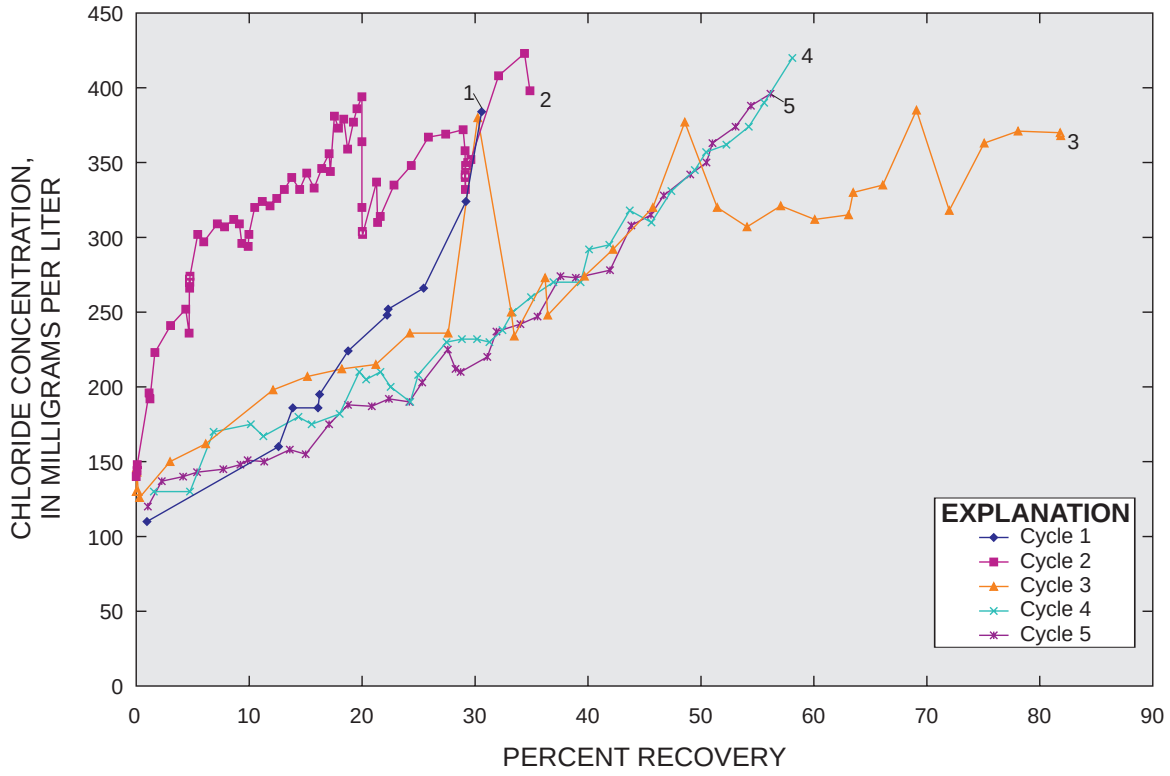

Figure 17. Percent recovery of recharged water during operational cycles in relation to chloride concentration of recovered water at the Marco Lakes site in Collier County.

120 mg/L (table 5), whereas the concentration at Boynton Beach averages about 50 mg/L. Perhaps calculations of recovery efficiencies based on a mass-balance approach would provide a better means of comparison between these two sites. These calculations would include the chloride concentrations of both the ambient and recharged water. Although the Marco Lakes site is in early phases of testing and operation, several factors could explain the moderate to good recovery efficiencies. The storage zone is thin and located near the top of the Upper Floridan aquifer (fig. 16). The storage zone has moderate transmissivity, and the site is located on a structural geologic high.

San Carlos Estates

The San Carlos Estates ASR site located near the west coast in Lee County is operated by Bonita Springs Utilities. Treated drinking water is used as the recharge water source. The storage zone at the site is located within the basal Hawthorn unit (fig. 18). The top of the Suwannee Limestone was not reached in any of the wells at the site. The thickness of the ASR well storage zone is only 51 ft (fig. 8).

Compared to the Marco Lakes site, transmissivity of the storage zone at the San Carlos Estates site is high; it is reported to be about 70,000 ft^2/d (fig. 9; CH_2M Hill, 1999b). The chloride concentration of ambient water in the storage zone is only 1,100 mg/L (fig. 10). The site may be located in a slightly low area structurally (Reese, 2000); however, additional wells that intersect the basal contact of the Hawthorn Group are required to confirm this setting.

Two cycles, one a short test cycle, were conducted at the San Carlos Estates ASR site (table 5). Despite a second cycle recharge volume of 138 Mgal, potable recovery efficiency has been no greater than about 3 percent. High transmissivity of the storage zone and the distribution of permeability within it may explain the poor recovery efficiency obtained thus far. Flowmeter log data indicate that most flow in the storage zone occurs within a 4-ft-thick interval between 698 and 702 ft below land surface (fig. 18). The high permeability of this thin flow zone may cause high dispersive mixing within the storage zone resulting in the poor recovery.

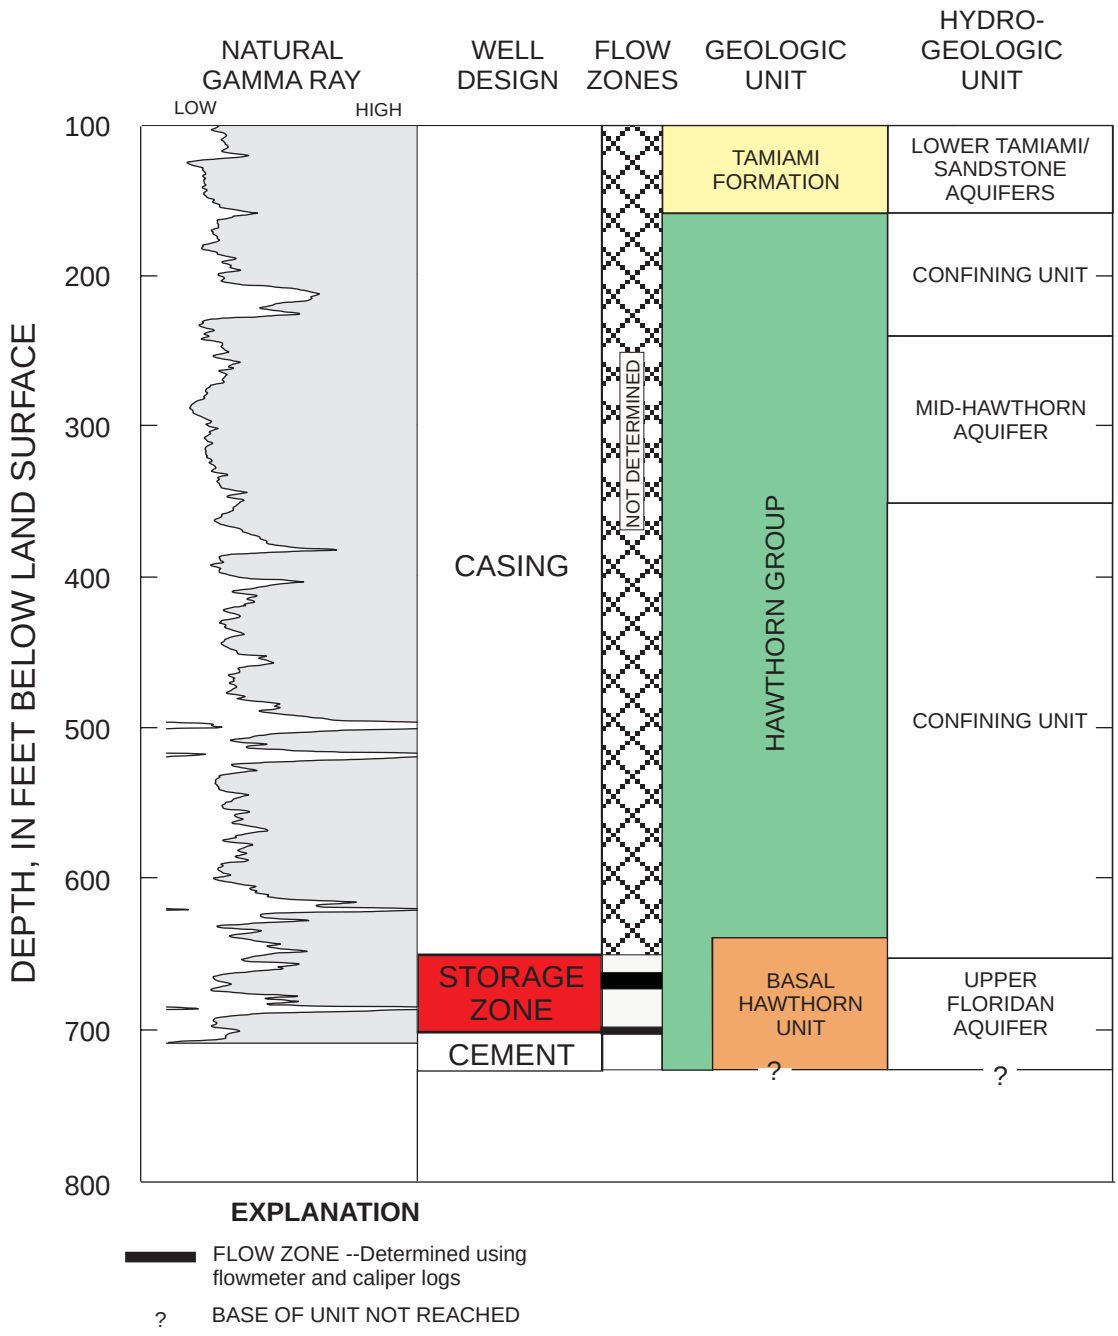

Figure 18. Location of storage zone in relation to gamma-ray geophysical log, flow zones, and geologic and hydrogeologic units for aquifer storage and recovery well L-5812 at the San Carlos Estates site in Lee County.

SUMMARY AND CONCLUSIONS

Aquifer storage and recovery (ASR) wells were constructed at 27 sites in southern Florida with most sites located in coastal areas. Twenty ASR were constructed by local municipalities or counties in southern Florida in the 1990's and 14 since 1996. Six of the 27 sites were experimental in nature and are no longer active. The storage zone at 23 of the 27 sites is contained within the Floridan aquifer system; of these 23 sites, 22 are in the Upper Floridan aquifer and 1 is in the Lower Floridan aquifer

Regional ASR in southern Florida has been proposed in the Comprehensive Everglades Restoration Plan (CERP) as a cost-effective water-supply alternative that can help meet needs of agricultural, municipal, and recreational users and help provide ecological benefits. About 330 high capacity wells have been proposed for southern Florida, with most to be sited inland, such as around Lake Okeechobee. Water salinity in the Upper Floridan aquifer, the hydrogeologic unit of interest in the CERP, is brackish to saline at all current ASR sites in southern Florida. The ambient salinity of water contained in the storage zone can substantially affect recovery of water recharged and stored.

This study was performed to inventory construction, hydrogeologic, and operational data on ASR sites in southern Florida and to compare site performance to hydrogeologic, design, or management factors that may influence their degree of success. Each ASR cycle includes periods of injection of freshwater, storage, and recovery, with each period lasting days or months. Potable water recovery efficiency of individual cycles at a site is the primary measure used to evaluate the performance of sites, and this efficiency is the volume of water recovered when chloride concentration reaches 250 as a percent of the volume recharged.

The basal contact of the Hawthorn Group lies close to the top of the Upper Floridan aquifer, and the most important flow zones in this aquifer commonly occur at or near this contact. The altitude of this contact varies considerably in southern Florida, ranging from less than 600 ft to greater than 1,200 ft below sea level. Local relief on this contact can be as much as several hundred feet.

Well data were inventoried and complied for all wells at existing and historical ASR sites in southern Florida. Construction and testing data were compiled into four categories: (1) well identification, location, and construction data; (2) hydraulic well-test data; (3) ambient formation water-quality data; and (4) cycle testing data. Intervals for which data were inventoried and compiled include the ASR storage zone interval and deeper and shallower intervals.

Factors important to efficient ASR operation vary widely between the sites. The thickness of the open storage zone ranged from 45 to 452 ft. Open intervals in the 150 to 200 ft range are most common. Transmissivity of the Upper Floridan aquifer storage zone for 17 sites ranged from 800 to 108,000 ft^2/d. Transmissivity at the Taylor Creek/Nubbin Slough (Lake Okeechobee) site, completed in the Lower Floridan aquifer, was reported to be 590,000 ft^2/d. Storage zone transmissivity for most sites ranged from 5,000 to 30,000 ft^2/d; greater than 30,000 ft^2/d is considered high. Leakance of storage zone confining units, determined from multiwell aquifer tests at seven sites in the Upper Floridan aquifer, ranged from 3.9×10^{-5} to 6.3×10^{-2} 1/d; of these, five had leakance greater than 1×10^{-3} 1/d, indicating that confinement is poor in some areas. These high leakance estimates are probably best attributed to leakage from below the storage zone rather than from above. Chloride concentration of ambient water from storage zones in the Upper Floridan aquifer ranged from 500 to 11,000 mg/L. At most sites, the chloride concentration ranged from about 1,000 to 3,000 mg/L; greater than 3,000 mg/L is considered to be high.

Cycle test data were compiled for 18 ASR sites, and potable water recovery efficiencies were calculated at 16 of these sites. To date, the Boynton Beach East WTP site has experienced the highest number of recharge-recovery cycles (16 cycles). Recharge volume per cycle ranged from as low as 0.6 to as high as 714 Mgal. Cycle 3 at the Hialeah site had the longest storage time (181 days). The highest potable water recovery efficiency for the first cycle was 47 percent at the Boynton Beach East WTP site, and except for one site with incomplete information, the lowest was 2 percent at the San Carlos Estates site. Nine of the 16 sites had a recovery efficiency above 10 percent for the first cycle, and 10 sites achieved a recovery efficiency above 30 percent during at least one cycle. The highest recovery efficiency achieved was 84 percent for cycle 16 at the Boynton Beach East WTP site. Recovery efficiencies for test and operational cycles at Boynton Beach appeared to be better than all other Floridan aquifer system sites. However, the number of cycles conducted at most other sites was limited, and the

chloride concentration of the recharge water used at Boynton Beach was low (about 50 mg/L).

The increase in potable water recovery efficiency during the first five cycles at the Springtree WTP site was not as favorable as at the Boynton Beach East WTP site. Recovery started at 20 percent for the first cycle and ended at 27.5 percent for the fifth cycle, despite a recharge volume for the fifth cycle (120 Mgal) that was three or more times greater than in all previous cycles. Recovery efficiencies at the Marco Lakes site for the first five cycles increased from 22 to 36 percent, with 132 Mgal recharged during cycle 5. However, these numbers may not be comparable to those from the Boynton Beach and Springtree sites because the chloride concentration of the recharged water at the Marco Lakes site was two or more times higher than at the other two sites, lowering the potable water recovery efficiencies.

Based on review of four case studies and review of data from other sites, several hydrogeologic and design factors appear to play a substantial role in the performance of ASR in the Floridan aquifer system in southern Florida. Recovery efficiency appears to be maximized if the storage zone is thin and located within the uppermost part of the Upper Floridan aquifer, and transmissivity (less than about 30,000 ft^2/d) and ambient salinity (less than 3,000 mg/L chloride concentration) of the ASR storage zone are moderate. The structural setting of a site could also be important because of the potential for updip migration of recharged freshwater or the lessening of overlying confinement due to deformation. Avoiding areas that lie within a structural low or which are structurally complex or have higher dip could improve recovery efficiency.

11-90	MW-A	360-460	P, S	--	NR	NR	2,400	--	--	See comment	NR	NR	All of the step-drawdown tests are indicated to be packer tests; however, some could have been a test of an open interval below casing. For step test, transmissivity was determined at each step by an unspecified method in Walton (1970). Then an adjusted estimated value of transmissivity was obtained by plotting transmissivity against flow rate for each step. For the multiwell test, 670 gallons per minute was an injection rate

Longitudinal Dispersivity Data and Implications for Scaling Behavior

by Dirk Schulze-Makuch[1]

Abstract

Longitudinal dispersivity (α) data were compiled from 109 different authors for different types of geological media. The data were subdivided into different subsets. Dispersivity values for consolidated media were subdivided as basalts, granites, sandstones, and carbonate rocks, while unconsolidated sediments were subdivided into three reliability classes. The data sets provided here may provide ground water practitioners a preliminary guide to estimate dispersivity values at various scales and to guide and verify theories on scaling behavior. Based on the data set presented here, the relationship that empirically best described the dispersivity data in regard to scale of measurement was in the form of a power law. The scaling exponent for consolidated and unconsolidated geological media varied between 0.40 and 0.92, and 0.44 and 0.94, respectively. Higher reliability subsets of data for the unconsolidated sediments and more frequently tested rock formations indicate that the scaling exponent is at the lower end of the observed range, close to 0.5. No significant difference in scaling exponent was found among different media, and no clear evidence exists for the presence of an upper bound or asymptotic behavior on the relationship for any of the analyzed media.

Introduction

Longitudinal dispersivity (α) is used to represent the local variations in the velocity field of a ground water solute in the direction of fluid flow, if a Gaussian solution to subsurface transport is assumed. In a one-dimensional flow field, longitudinal dispersivity is multiplied by the average linear velocity, v, to describe solute dispersion. Then, the dispersion coefficient is the sum of the quantity αv and the effective diffusion coefficient. Longitudinal dispersivity has been frequently shown to increase with the scale of measurement (Pickens and Grisak 1981; Gelhar et al. 1985; Neuman 1990; Schulze-Makuch and Cherkauer 1997; Neuman and Federico 2003), owing to many independent processes, including advection, local dispersion and diffusion, the nonstationary nature of hydraulic conductivity fields, and sampling bias. While some general relationships have previously been proposed to quantify the dependence of dispersivity on measurement scale (e.g., Neuman 1990), none has been accepted in the scientific community because none provides a satisfactory solution. In this review paper, dispersivity data from 109 different authors were used to establish a relationship of longitudinal dispersivity with scale of measurement for specific types of geological media. It is beyond this study to describe the processes that result in the observed scale effect. The objective is rather to summarize data and subsets of data to guide and verify theories on scaling behavior and to provide a tool for practitioners and ground water modelers to help estimate the range of dispersivities to expect when performing "upscaling" procedures. In addition, the paper considers whether the observed increase in dispersivity with scale is related to the type of geological medium.

Methodology

Dispersivity data were accumulated from laboratory experiments, aquifer tests, and modeling results conducted by various authors. Dispersivities obtained from modeling results are not measurements in a physical sense but were included in the analysis if no other measurements on larger scales were available. The base data set for this investigation was formed from the data compilations by Gelhar et al. (1985, 1992). These data are briefly characterized in Appendix A; for additional information the reader is referred to the original data source. Additional data sources that were included in the analysis are presented in Table 1,

Note: If a range in scale is provided, the arithmetic mean is provided in the table. If a range in dispersivity is reported, then the geometric mean is provided in the table. Rating system for reliability is adopted from Gelhar et al. (1992). Reliability assignments are valid for the whole data set associated with a reference unless indicated otherwise.

which includes a brief characterization of aquifer material tested, type of test and tracer, and analysis method. The data were also grouped according to reliability, adopting the system used by Gelhar et al. (1992). Briefly, high-reliability data are assigned to group I, and the dispersivity values in that group are thought to be accurate within a factor of two. Low-reliability data are assigned to group III and are thought to be no more accurate than within one or two orders of magnitude. Intermediate reliabilities are assigned to group II. For a reported dispersivity value to be assigned to group I, each of the following criteria must have been met: (1) the tracer test was ambient flow with known input, diverging radial flow, or a two-well pulse test; (2) the tracer input was well defined; (3) the tracer was conservative (e.g., Cl^-, I^-, Br^-, tritium); and (4) the dimensionality of the tracer concentration measurements and the analysis of the concentration data were appropriate. Reported dispersivity values were assigned to group III if (1) the two-well recirculating test with a step input was used; (2) the single-well injection-withdrawal test was used with tracer monitoring at the pumping well; (3) the tracer input was not clearly defined; (4) the tracer breakthrough curve was assumed to be the superposition of breakthrough curves in separate layers when there was little or no evidence of such layers at the test site; (5) the measurement of tracer concentrations in space was inadequate; or (6) the equation used to obtain dispersivity was not appropriate for the data collected. For detailed information on the reliability criteria, please see Gelhar et al. (1992). Typical problems encountered in the dispersivity data analyses were mass input history unknown, nonconservative effect of tracer not accounted for, dimensionality of the monitoring not matched to the dimensionality of the analysis, and assumption of distinct geologic layers in analysis when their actual presence was not or not sufficiently documented. The assignment of reliability classes should not be taken as a judgment of the conducted tracer test and its analysis; it is intended simply to provide some quality assessment in regard to the parameter of longitudinal dispersivity (i.e., many tests were not conducted with the primary objective to characterize longitudinal dispersivity with the highest possible accuracy).

Since longitudinal dispersivity is a one-dimensional parameter, flow distance was chosen as an appropriate scale of measurement. For a laboratory experiment, flow distance was generally determined by measuring the length of the horizontally oriented core through which the tracer traveled (e.g., Schulze-Makuch 1996); for a field tracer test, by determining the distance between the injection and the withdrawal well (e.g., D'Alessandro et al. 1997); and for a computer simulation, by the horizontal flow distance between a ground water source and a sink. The scale for single-well injection tests and packer tracer tests was obtained by determining the radius of influence, which was calculated from the volume of water introduced (i.e., discharge or injection rate multiplied by the time interval) by assuming cylindrical flow to the well screen or packed interval, respectively. Many references provided the appropriate scale measure in the cited paper (e.g., Gelhar et al. 1985). If a range in scale of measurement was provided (generally ranges were small), the arithmetic mean was chosen for the analysis. If a range in longitudinal dispersivity was provided, the geometric mean was used (Table 1). The geometric mean was thought to represent a more suitable mean for dispersivity because the values varied commonly by an order of magnitude or more. Also, dispersivity, which is related to variations in hydraulic conductivity, is variable in space due to local heterogeneities, and it is generally recognized that the probability density function of hydraulic conductivity is lognormal (e.g., Freeze and Cherry 1979). If no scale of measurement was provided, it was calculated from the description of the experimental or aquifer test setup whenever possible. The obtained longitudinal dispersivity/scale of measurement data pairs were then sorted by type of geological medium to identify a relationship of dispersivity with geological medium as has been found for hydraulic conductivity data (Schulze-Makuch et al. 1999). Geological media analyzed were unconsolidated sediments, sandstones, carbonate rocks, basalts, and granites.

Results

Longitudinal dispersivity values obtained from laboratory tests, aquifer tests, and computer models were plotted vs. scale of measurement for each analyzed geological medium (e.g., Figure 1 for unconsolidated media). The plot shows that longitudinal dispersivity increases exponentially with scale of measurement. Plots for consolidated media show a similar scaling behavior (Figure 2). According to the conventional explanation for this scaling behavior as a tracer moves through the geological medium, more and more heterogeneities are encountered, and dispersivity increases with scale of measurement due to a combination of advective and diffusion-related processes. Results from a total of 307 longitudinal dispersivity determinations from a total of 109 authors are given in Table 1 and Table A1 in Appendix A. The scaling exponent for all data from the unconsolidated sediments was 0.81, with a 95% confidence interval of 0.11. The larger scale data appear to level off somewhat (Figure 1), and if an upper bound is interpreted to exist at a scale of ~2000 m the slope increases to 0.94. However, the resulting regression coefficient and 95% confidence interval is lower. Also, if the whole data set is subdivided into reliability classes, then the scaling exponent decreases with higher reliability classes (Table 2). Not enough tracer tests were conducted in consolidated rocks to allow an evaluation in reliability classes. Scaling exponents range here between 0.40 and 0.92, with a lower 95% confidence interval and higher regression coefficients generally associated with the lower scaling exponents (e.g., a scaling exponent of 0.40 for carbonates with a 95% confidence interval of 0.09; Table 3). High 95% confidence intervals are a result of too few data pairs and large dispersivity variations that can be expected from data that are derived from different aquifers at different locations. No statistically significant difference between unconsolidated and consolidated geological media could be shown.

The parameter c in Tables 2 and 3 equals the longitudinal dispersivity value of a specific medium at a flow

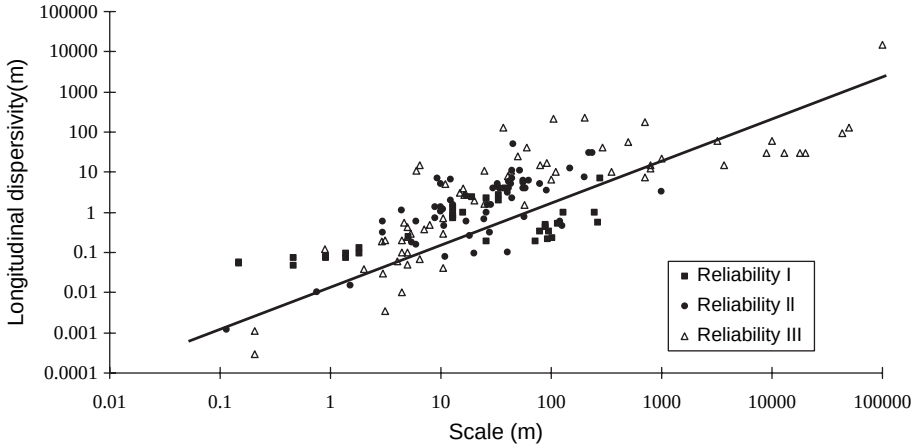

Figure 1. Relationship of longitudinal dispersivity to scale of measurement for unconsolidated sediments. The line represents the regression line for all data points (regardless of assigned reliability class) with a scaling exponent of 0.81 and a *c* value of 0.085 m.

distance of 1 m. This parameter can be considered to be a characteristic value for the geological medium, which is related to interconnectivity, type, and size of pores in porous-flow media, and fracture aperture and interconnectivity in fracture-flow media. Longitudinal dispersivities for a flow distance of 1 m are highest for carbonates with a *c* value of 80 cm.

The upper bound represents the volume at which a porous medium becomes the equivalent of a homogeneous medium, and thus longitudinal dispersivity remains constant with scale. This volume has also been referred to as the representative elementary volume. The determination of an upper bound is problematic because (1) the upper bound is strongly affected by values obtained from computer simulations, which are not physical measurements; and (2) each individual aquifer could have a unique upper bound, and the upper bound as determined from the method used here provides a mean value of an upper bound for a specific type of aquifer only. Based on the data analysis performed, none of the media appeared to exhibit an upper bound (Tables 2 and 3; Figures 1 and 2), at least not within the scale range for which the relationships were established.

Discussion

The scaling relationship of longitudinal dispersivity with scale of measurement below the upper bound can be described by the empirical power law

$$\alpha = c(L)^m \tag{1}$$

where α is longitudinal dispersivity (L), c a parameter characteristic for a geological medium (L^{1-m}), L the flow distance (L), and m the scaling exponent (slope of the line on the log-log plot). The mathematical model used here is simply based on the best fit found by the author, but it is consistent with (1) power law relationships of dispersivity with scale as suggested by others (e.g., Neuman 1990, 1995); (2) theoretical developments based on fractal concepts (e.g., Wheatcraft and Tyler 1988); and (3) relationships developed for the related parameter of hydraulic conductivity (e.g., Schulze-Makuch and Cherkauer 1997; Schulze-Makuch et al. 1999). The scaling exponent for all geological media analyzed lies between 0.40 and 0.94. This value is subject to several uncertainties. One is the limited number of data points available. Only a few

[4]Medium-characteristic parameter c (m).
[5]Upper bound of the relationship.
Note: Two interpretations are provided for unconsolidated sediments of all reliabilities. One with no upper bound, one with an upper bound. All large-scale values are of reliability III, thus not included in reliabilities I and II, and reliability I values only.

aquifer tests are designed to measure dispersivity in addition to the hydraulic conductivity or transmissivity of an aquifer. This uncertainty is quantified for each of the geological media analyzed by the 95% confidence interval about the exponent provided in Tables 2 and 3. The 95% confidence interval is typically high for media with few data points (e.g., sandstones) and low for media with many data points (e.g., unconsolidated sediments and carbonates). Another factor that introduces bias on the scaling exponent is the position of an upper bound. An upper bound (fractal cutoff limit) was proposed by Wheatcraft and Tyler (1988) on theoretical grounds in their model describing dispersion in a set of fractal streamtubes. It was also observed by Schulze-Makuch et al. (1999) for the scaling behavior of hydraulic conductivity data. The upper bound represents the scale at which the geological medium approaches the properties of a homogeneous medium. It is inferred by plotting dispersivity vs. scale of measurement (e.g., Figure 1) and validated by calculating regression coefficients and 95% confidence intervals for subsections of the data. Only the data for the unconsolidated sediments indicate the possible presence of an upper bound at ~2000 m (Table 2). However, this is thought to be unlikely, since it would widen the 95% confidence interval and increase the scaling exponent, while higher reliability data actually show that the scaling exponent is most likely lower. Gelhar et al. (1992) observed that reanalyses of data showed that improved interpretations most often lead to smaller dispersivities, which will lead to a smaller scaling exponent. This is exactly what was observed here as well.

Neuman and Federico (2003) proposed that the scaling behavior of dispersivity is observed because of the heterogeneous nature of the medium and because dispersivities are determined on the basis of traditional Fickian advection-dispersion models of solute transport, where dispersivity is treated as a constant. The observed increase of dispersivity with scale of measurement due to the heterogeneous nature of the medium is sometimes referred to anomalous or non-Fickian dispersion, while the increase based on inadequate modeling is referred to as "apparent" dispersivity. Neuman (1995) suggested a scaling exponent of 1.5 for longitudinal dispersivity, and Neuman and Federico (2003) attributed this value in part to non-Fickian dispersion (m = 1) and apparent dispersion (m = 0.5). They also hypothesized that longitudinal dispersivity eventually stabilizes at a constant Fickian asymptote, terming its earlier increase with travel distance preasymptotic. This type of behavior was also supported by stochastic analyses and numerical simulations

Table 3
Scaling Behavior of Longitudinal Dispersivity in Consolidated Rocks

Type of Medium	N[1]	n[2]	Slope of Exponent, m	Regression Coefficient[3]	95% Confidence Interval about Mean	c[4]	Upper Bound[5] (m)

performed by Gelhar and Axness (1983), Schwarze et al. (2001), Janković et al. (2003), and Dagan and Fiori (2003), among others. The data set analyzed here, which constitutes the largest data set of which the author is aware, does not support those claims. Moreover, the empirical scaling exponents found here are much lower than those previously reported, ~0.5 for this study vs. 1.5 found by Neuman (1995). The lower scaling exponent may be explained in part by more sophisticated and higher reliability methods used by various authors that reduce or eliminate apparent dispersivity (e.g., causing the observed trend of decreasing scaling exponents in higher reliability data; Table 2). An asymptotic behavior might be suspected in the unconsolidated sediment for all reliability classes above a scale of 2000 m, but it cannot be substantiated (Table 2). However, this study appears to be consistent with Neuman (1990) in that there appears to be no strong dependence on the type of geological medium in which the test was conducted. Hydraulic conductivity does exhibit a strong dependence on geological medium, of course (Schulze-Makuch et al. 1999), and longitudinal dispersivity should in theory do so as well because heterogeneities encountered in different geological media are different, and thus should be reflected by different scaling exponents. However, no statistically significant difference can be observed among the different media.

A significant difference among geological media, though, can be observed for the medium-characteristic parameter c, which is a measure of heterogeneity at a unit flow distance (1 m). It is largest for carbonate rocks with a value of 0.8 m, and lowest for unconsolidated sediment and sandstones with values of 0.01 m and ~0.009 m, respectively. This finding appears reasonable as carbonates can be extremely heterogeneous on small scales, exhibiting a wide range of porosities caused by vugs, fractures, and flow conduits with various types of fluid flow behaviors (porous flow, fracture flow, conduit flow, and combinations of these). Sandstones and sandy sediments, on the other hand, are quite often homogeneous on this scale but will exhibit major heterogeneities on larger scales due to facies changes, channel deposits etc.

Any analysis like this must be considered with caution. Large intrinsic errors are incorporated by using dispersivity values from different aquifers at different localities. It is necessary to keep in mind that each geological medium is unique with unique geometries that a solute will encounter along its flowpath, and thus each site will display its characteristic scaling behavior. Also, various authors use different assumptions and methods of analysis, which will cloud any effort to discern a generalized scaling behavior. Even if a generalized scaling rule is found, it cannot represent local expressions of geological facies such as channeling of flow, and thus detailed geologic mapping is required to quantify heterogeneities in the geological record (Anderson 1991; Neuman 1991). In addition, the analysis presented here did not try to achieve a representative poll of different geological media, as some geological types were overrepresented in the data sample considered here. However, given that most aquifer tests do not measure transport properties such as longitudinal dispersivity and the general paucity of tracer tests, the number of data accumulated here is thought to provide a valuable contribution to stimulate further investigations into the scaling behavior of dispersivity.

Conclusions

The scaling relationship of longitudinal dispersivity with scale of measurement below the upper bound can be described by the empirical power law $\alpha = c(L)^m$, where α is longitudinal dispersivity (L), c is a parameter characteristic of a geological medium (L^{1-m}), L is the flow distance (L), and m is the scaling exponent. Based on the 307 data pairs analyzed, the mean scaling exponent appears to be ~0.5, with no statistically significant difference between various geological media. The parameter c varies between ~0.01 m for sandstones and unconsolidated media, and 0.8 m for carbonate rocks. No upper bound on the relationships was apparent for a flow distance up to ~10,000 m for all media except for granites where this statement can only be extended to a flow distance of 100 m due to lack of data on regional-scale transport.

Acknowledgments

I appreciate the valuable comments made by the two anonymous reviewers on previous versions of this manuscript. Their constructive input significantly improved this work. I also thank Huade Guan, currently at the New Mexico Institute of Mining and Technology, and Colleen Rust, Washington State University, for data collection for this study.

Potential for Saltwater Intrusion into the Lower Tamiami Aquifer near Bonita Springs, Southwestern Florida

By W. Barclay Shoemaker *and* K. Michelle Edwards

Abstract

A study was conducted to examine the potential for saltwater intrusion into the lower Tamiami aquifer beneath Bonita Springs in southwestern Florida. Field data were collected, and constant- and variable-density ground-water flow simulations were performed that: (1) spatially quantified modern and seasonal stresses, (2) identified potential mechanisms of saltwater intrusion, and (3) estimated the potential extent of saltwater intrusion for the area of concern.

MODFLOW and the inverse modeling routine UCODE were used to spatially quantify modern and seasonal stresses by calibrating a constant-density ground-water flow model to field data collected in 1996. The model was calibrated by assuming hydraulic conductivity parameters were accurate and by estimating unmonitored ground-water pumpage and potential evapotranspiration with UCODE. Uncertainty in these estimated parameters was quantified with 95-percent confidence intervals. These confidence intervals indicate more uncertainty (or less reliability) in the estimates of unmonitored ground-water pumpage than estimates of pan-evaporation multipliers, because of the nature and distribution of observations used during calibration. Comparison of simulated water levels, streamflows, and net recharge with field data suggests the model is a good representation of field conditions.

Potential mechanisms of saltwater intrusion into the lower Tamiami aquifer include: (1) lateral inland movement of the freshwater-saltwater interface from the southwestern coast of Florida; (2) upward leakage from deeper saline water-bearing zones through natural upwelling and upconing, both of which could occur as diffuse upward flow through semiconfining layers, conduit flow through karst features, or pipe flow through leaky artesian wells; (3) downward leakage of saltwater from surface-water channels; and (4) movement of unflushed pockets of relict seawater. Of the many potential mechanisms of saltwater intrusion, field data and variable-density ground-water flow simulations suggest that upconing is of utmost concern, and lateral encroachment is of second-most concern. This interpretation is uncertain, however, because the predominance of saltwater intrusion through leaky artesian wells with connection to deeper, more saline, and higher pressure aquifers was difficult to establish.

Effective management of ground-water resources in southwestern Florida requires an understanding of the potential extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs. Variable-density, ground-water flow simulations suggest that when saltwater is at dynamic equilibrium with 1996 seasonal stresses, the extent of saltwater intrusion is about 100 square kilometers areally and 70,000 hectare-meters volumetrically. The volumetric extent of saltwater intrusion was most sensitive to changes in recharge, ground-water pumpage, sea level, salinity of the Gulf of Mexico, and the potentiometric surface of the sandstone aquifer, respectively.

INTRODUCTION

Urbanization is proceeding rapidly along the coast of southwestern Florida, with cities and communities springing up from Fort Myers to Naples. In fact, the coast around Bonita Springs is one of the Nation's fastest growing areas. The expanded population has resulted in increased public-supply withdrawals from the lower Tamiami aquifer that have lowered ground-water levels and reversed hydraulic gradients in the aquifer between Bonita Springs and the coastline. Long-term movement of saltwater into coastal aquifers is often attributed to declines in ground-water levels, thus limiting the future availability of potable-water supplies.

Saltwater intrusion is defined by Stewart (1999) as the mass transport of saline waters into zones previously occupied by fresher waters. This definition is broad because natural processes (such as sea level rise and drought) and anthropogenic processes (such as ground-water pumpage and construction of canals) can cause saltwater intrusion. Thus, the investigator is faced with a "classic" inverse problem because an observed distribution of saltwater could be explained equally well by one or more mechanisms of saltwater intrusion. Under these circumstances, multiple sources of information are useful to help identify the predominant mechanisms of saltwater intrusion, including ground-water levels and pumpage, geochemical data (such as chloride concentrations and strontium isotope analysis), surface and borehole geophysical data, research from previous studies, and numerical modeling tools.

Water managers need a clear understanding of the saltwater intrusion process to ensure protection of the fresh ground-water resources in southwestern Florida. In 1999, the U.S. Geological Survey (USGS), in cooperation with the South Florida Water Management District (SFWMD), initiated a study to: (1) quantify modern (stresses with the desired characteristics) and seasonal stresses; (2) help identify potential mechanisms of saltwater intrusion; and (3) estimate the potential extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs. Field data and numerical methods were used in this effort.

Purpose and Scope

The purpose of this report is to describe the results of numerical simulation procedures that represent the movement of saltwater in the lower Tamiami aquifer beneath Bonita Springs in southwestern Florida. Water-budget components were characterized and mathematically represented to help simulate ground-water flow and saltwater intrusion in the surficial aquifer system, which includes the lower Tamiami aquifer. A modular, three-dimensional, finite-difference, ground-water flow model was used to represent modern and seasonal stresses during March and September 1996 when ground-water levels are generally at their lowest and highest, respectively. Field data were collected and variable-density, ground-water flow simulations were performed to help identify mechanisms of saltwater intrusion of utmost concern and estimate the potential extent of saltwater intrusion in the lower Tamiami aquifer beneath Bonita Springs. The extent of saltwater intrusion was simulated from predevelopment distribution to dynamic equilibrium with calibrated March and September 1996 conditions.

Description of Study Area

The study area encompasses about 860 km^2 in Lee and western Collier Counties (fig. 1), and is characterized by low topographic relief and a high water table. The physiographic provinces that comprise the study area (fig. 2) are the Gulf Coastal Lowlands, Caloosahatchee Incline, Desoto Plain, Southwestern Slope, Immokalee Rise, Everglades, Okeechobee Plain, Big Cypress Spur, and the Reticulate Coastal Swamps (Fernald and Purdum, 1998). The Immokalee Rise, a sandy ridge formed during high sea-level stands, occupies the highest part of the study area to the northeast (at an elevation of about 12 m) and borders the Caloosahatchee River and Big Cypress watersheds.

The Caloosahatchee River, Estero Bay, and Big Cypress watersheds are located in the study area (fig. 2). The Caloosahatchee River watershed extends from Lake Okeechobee to San Carlos Bay and passes through parts of Charlotte, Glades, Hendry, and Lee Counties and dips slightly into Collier County. The lower reaches of the watershed are characterized by a shallow bay, extensive seagrass beds, and sand flats.

The Estero Bay watershed (fig. 2) occupies central and southern Lee County and parts of northern Collier and western Hendry Counties. The principal surface-water features are Estero River, Spring Creek, Kehl Canal, Imperial River, and Cocohatchee River. The low gradients in these channels result in sluggish and tidally induced flow that is probably much greater than freshwater flow. Channel stages fluctuate

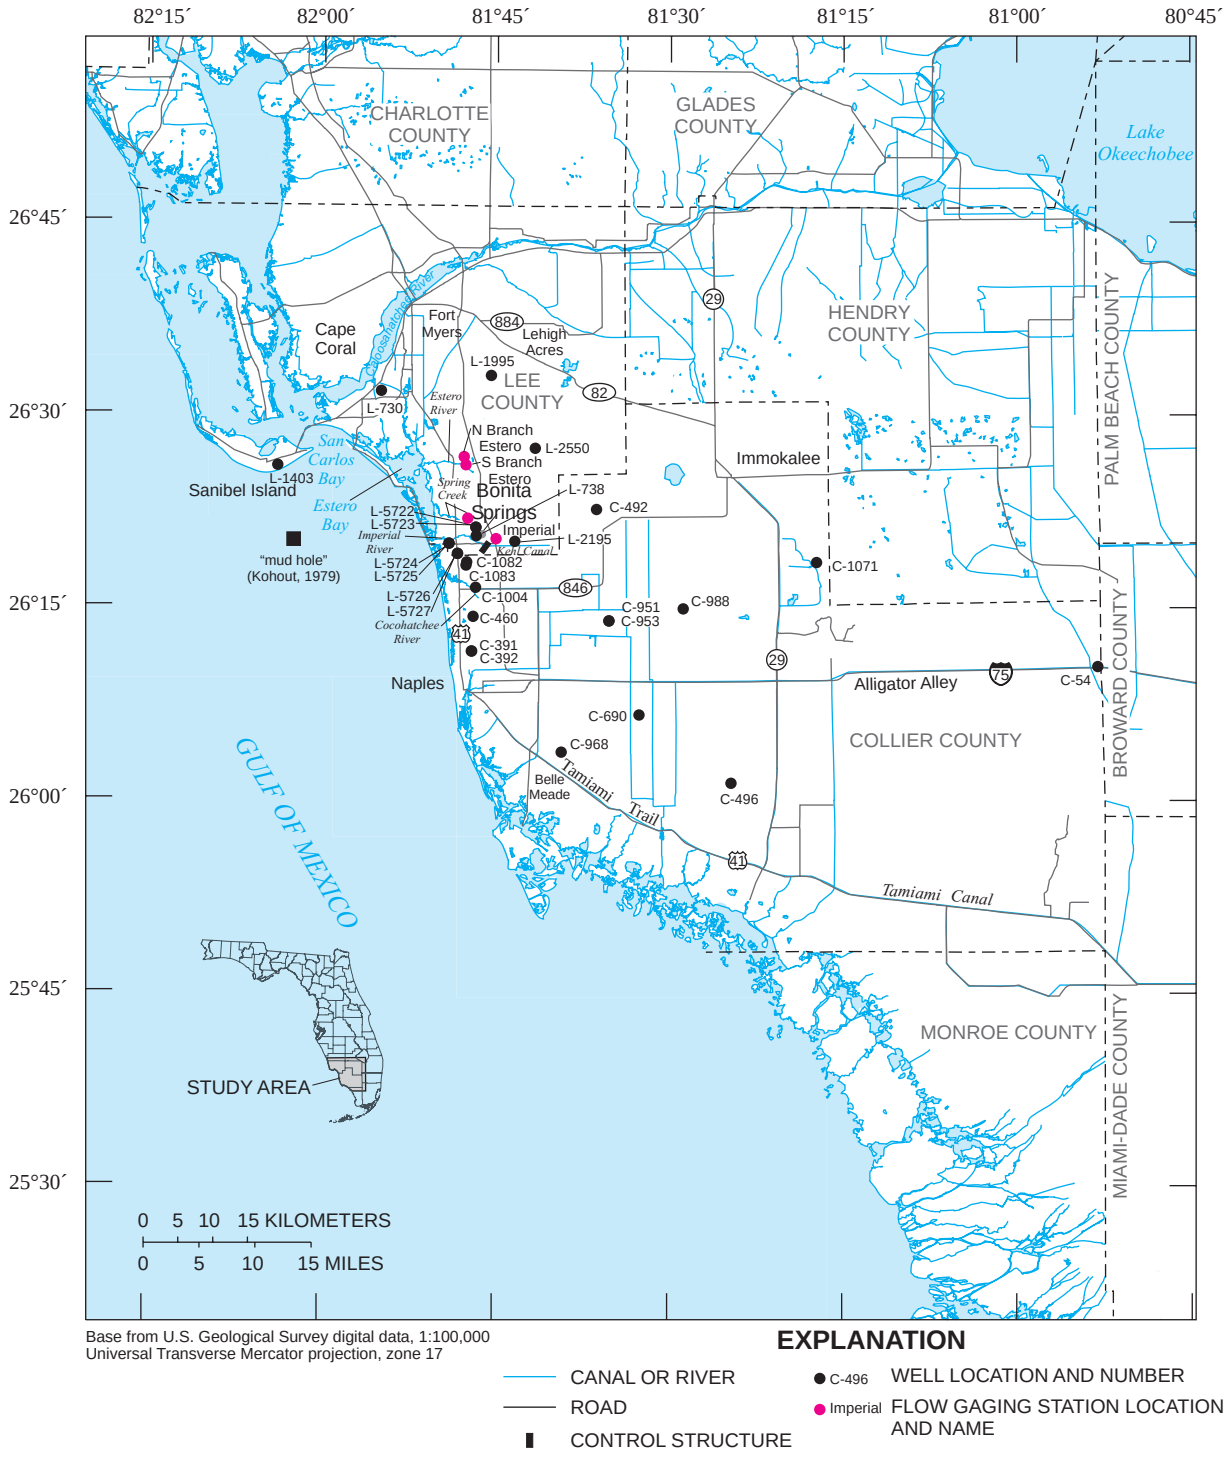

Figure 1. Location of the study area in southwestern Florida.

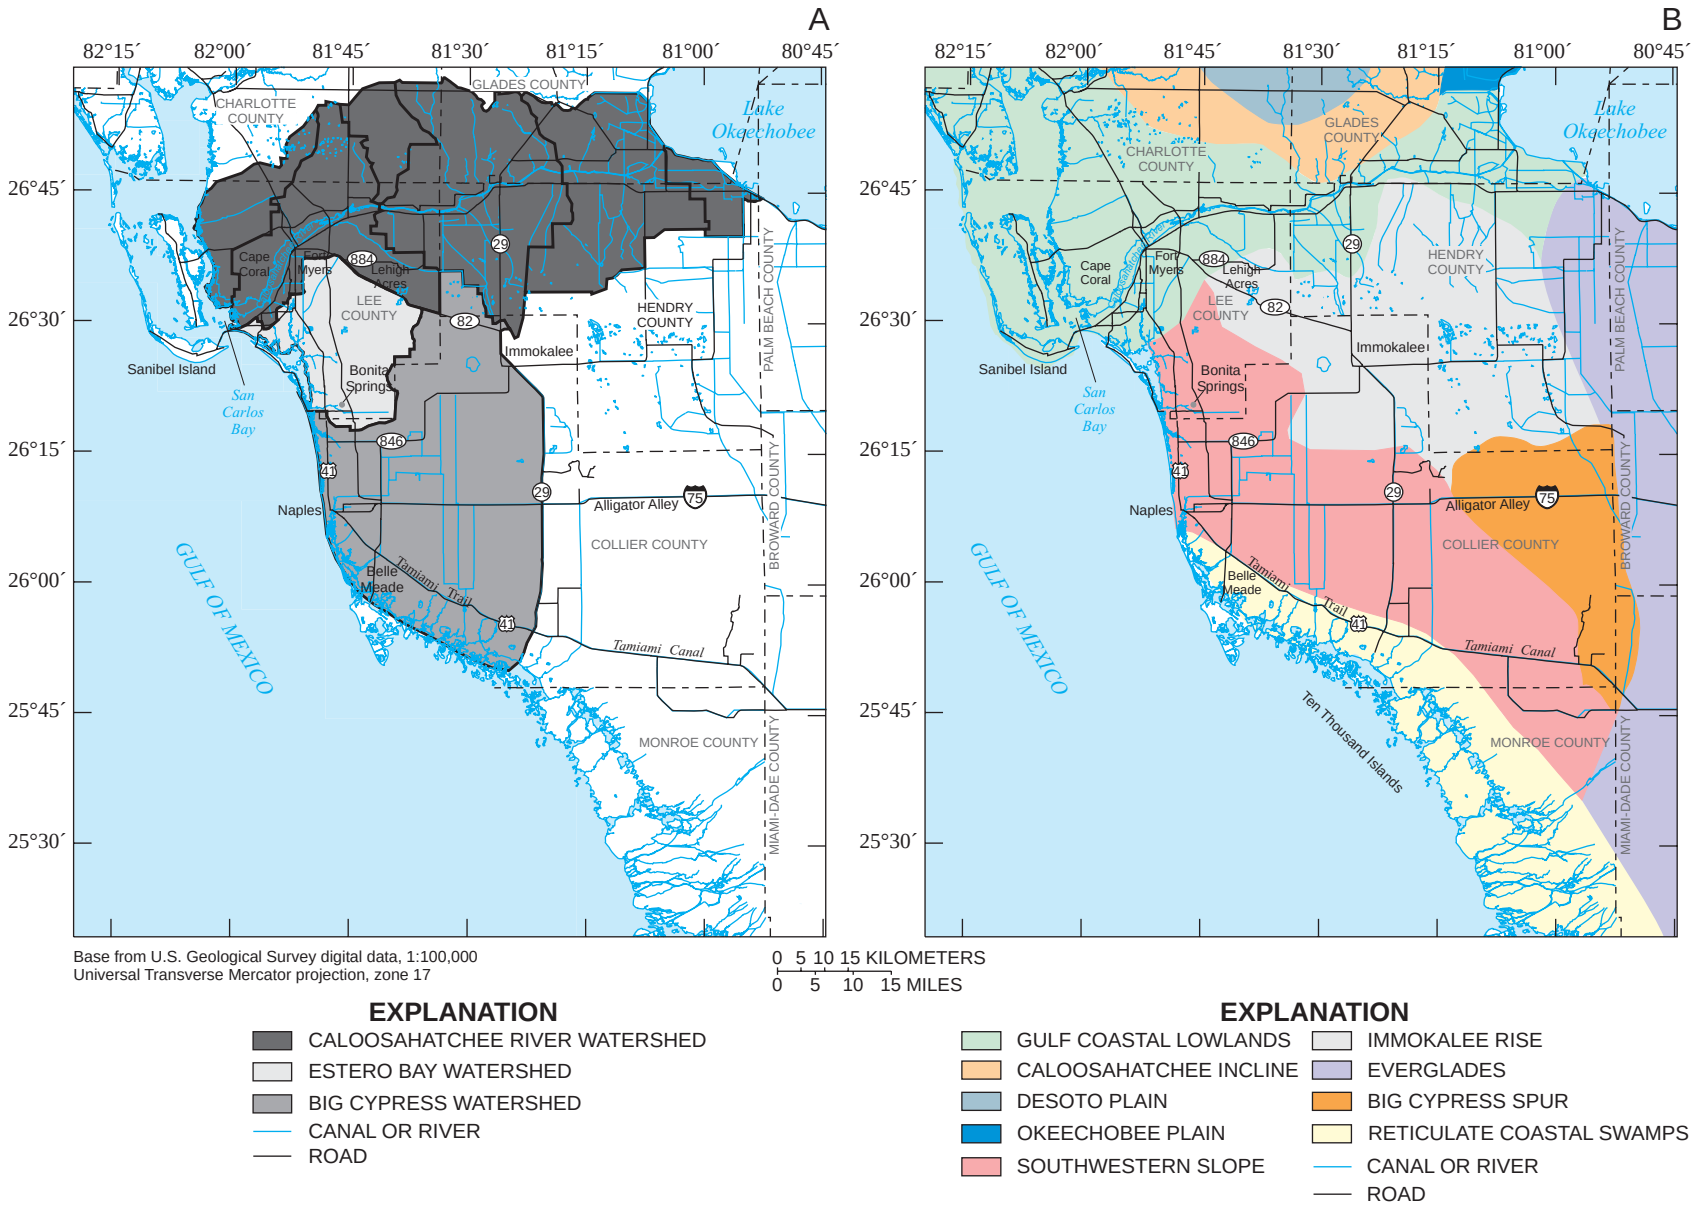

Figure 2. (A) Major watersheds (South Florida Water Management District, 1989), and (B) physiographic features (modified from Fernald and Purdum, 1998) in study area. The Big Cypress watershed includes the Corkscrew Swamp Sanctuary northeast of Naples, Florida.

seasonally with the highest and lowest levels occurring during summer and winter, respectively. The flora and fauna of the Estero Bay watershed are varied and abundant.

The Big Cypress watershed (fig. 2) drains a wide area through a large network of man-made canals and natural sloughs in southern Lee and Hendry Counties and western Collier County. A variety of grasses, shrubs, and small cypress trees dominate the Big Cypress watershed, which includes the Corkscrew Swamp Sanctuary located northeast of Naples. South of Naples, freshwater sloughs and rivers mix with Gulf of Mexico bays and tidal creeks.

Development in the study area is primarily urban and agricultural. Urban development is greatest along the coast west of I-75 (Interstate 75) in Lee and Collier Counties. Agricultural development, located between wetland systems, increases to the east and south in the study area. The undeveloped regions consist of flatwoods, sloughs, swamps, and estuaries. Predevelopment sheetflow in the study area probably was slow due to the vegetation, geomorphology, and low land-elevation gradients. Canals and roads resulting from urban and agricultural development have nearly eliminated the natural sheetflow across the land surface and altered the natural drainage patterns by concentrating stormwater runoff in canals and ditches.

Previous Studies

Many studies of saltwater intrusion have been conducted over the years, and a comprehensive record can be found in Bear and others (1999). Two "classic" studies were completed by Badon-Ghyben (1888) and Herzberg (1901) in which the depth of the saltwater interface below sea level was predicted to be 40 times the freshwater head above sea level in the aquifer of interest, given hydrostatic conditions in a homogeneous unconfined aquifer with a seaward sloping water-table surface. Kohout (1964) recorded that the saltwater front in the Biscayne aquifer in southeastern Florida is as much as 13 km seaward of the position predicted by the Ghyben-Herzberg equation due to ground-water circulation patterns near the saltwater interface. Later research of saltwater intrusion in southeastern Florida was accomplished by Hull and Meyer (1973), Klein and Waller (1985), Klein and Ratzlaff (1989), Sonenshein and Koszalka (1996), Merritt (1996), Sonenshein (1997), Konikow and Reilly (1999), and Langevin (2001). Merritt (1996) used a sensitivity analysis of numerical simulations to address the importance of properties and processes affecting the saltwater interface in Broward County along the southeastern coast of Florida.

On the southwestern coast of Florida, Klein (1954) studied saltwater intrusion in coastal areas near Naples. In the 1960's, field studies by McCoy (1962), Cooper (1964), Henry (1964), and Glover (1964) advanced the knowledge and understanding of ground-water movement near the saltwater interface in southern Florida. Sherwood and Klein (1963) mapped a salinity plume beneath the Caloosahatchee River, whose source was a leaky well with connection to the deeper, more saline, and higher pressure Floridan aquifer system. Kohout (1979) used remote sensing to map a geothermal submarine ground-water spring off the coast of Bonita Springs, informally known as the "mudhole" by local fisherman. Stewart and others (1982) used direct-current (DC) resistivity soundings to map the saltwater interface near Belle Meade south of the study area.

Acknowledgments

Technical support for this project was provided by Chris Langevin and Keith Halford of the USGS, Mark Stewart of the University of South Florida Department of Geology, and Akin Owosina and Terry Bengtsson of the SFWMD. Terry Bengtsson and Lee Worst from the SFWMD helped delineate areas near Bonita Springs where unmonitored ground-water pumpage is likely occurring. Pamela Telis helped design, distribute, and compile results from a survey designed to estimate unmonitored ground-water pumpage. Several colleagues reviewed the initial drafts of this report, including Terry Bengtsson and Rama Rani, and the following USGS employees: Barbara Howie, Eric Swain, Chris Langevin, Melinda Wolfert, Richard Krulikas, Ward Sanford, Gary Mahon, Eve Kuniansky, Michael Deacon, Roy Sonenshein and David Schmerge. Fernando Miralles-Wilhelm of the University of Miami and Eric Swain of the USGS provided useful insight into the sensitivity behavior of saltwater intrusion simulations. Rhonda Howard and Barbara Howie provided many suggestions that significantly improved the clarity and content of the report. Kimberly Swidarski prepared the illustrations. USGS employee Haymeli Castillo, is recognized for her constant support, patience, and guidance.

HYDROGEOLOGY OF SOUTHWESTERN FLORIDA

Southern Florida is underlain by rocks of Cenozoic age to a depth of about 1,525 m. These rocks principally are carbonates (limestone and dolostone), with minor amounts of evaporites (gypsum and anhydrite) in the lower part of the section and clastics (sand and clay) in the upper part. The movement of ground water from inland areas to the ocean (and the reverse) occurs primarily through the carbonate rocks (Meyer, 1989, p. G5). This section of the report describes the hydrogeologic framework of the study area including the lithology, stratigraphy, hydrogeologic units, and hydraulic characteristics. Also discussed are the water-budget components, which used in conjunction with the hydrogeologic framework, are necessary to understand the processes that affect ground-water flow. Finally, water-quality and geochemical data collected from the lower Tamiami aquifer near Bonita Springs are used to examine salinity. The locations of monitoring stations for data used in the study are presented in the appendix.

Lithology and Stratigraphy

Geologic units in southwestern Florida consist, in ascending order, of the Suwannee Limestone of Oligocene age, Hawthorn Group of Oligocene to Pliocene age, Tamiami Formation of Pliocene age, and undifferentiated sediments of Holocene to Pleistocene age (fig. 3). The Suwannee Limestone is composed of fossiliferous, calcarenitic limestone with minor amounts of quartz sand. The thickness of the limestone varies widely, but commonly is greater than 100 m in Lee and Collier Counties. The basal Suwannee Limestone generally contains fine-grained, phosphatic, clastic material with interbeds of micrite and clay (Reese, 2000).

The Hawthorn Group is divided into the Arcadia Formation and the Peace River Formation (fig. 3). The Arcadia Formation, which unconformably overlies the Suwannee Limestone, consists of fine-grained carbonate sediments as well as sandy limestone, shell beds, dolomite, phosphatic sand and carbonate, sand, silt, and clay. The predominantly clastic Peace River Formation has a highly irregular erosional, and karstic surface. The contact with the overlying Tamiami Formation appears to be unconformable in some areas,

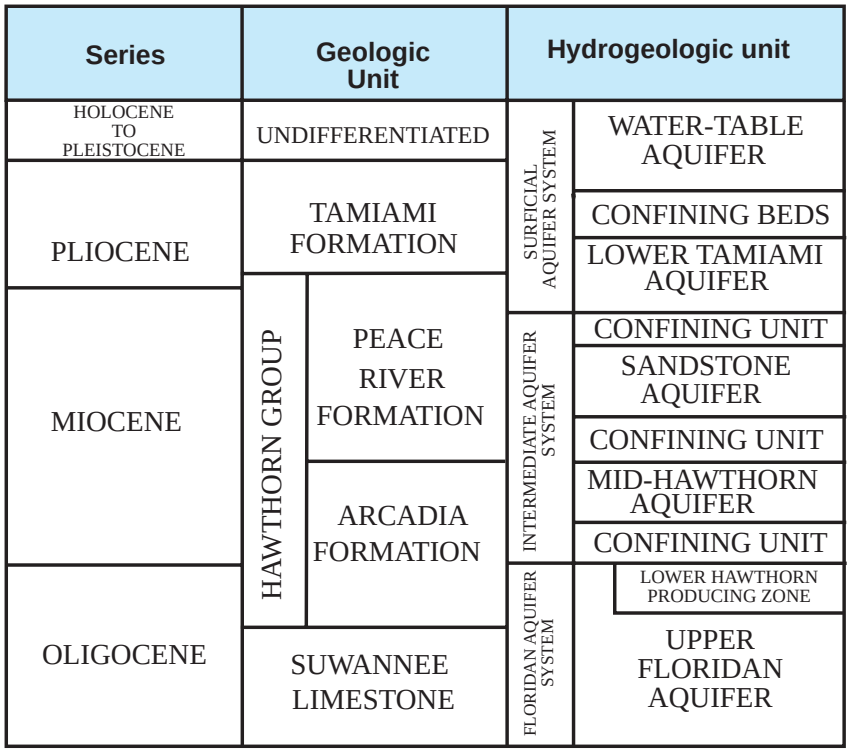

Figure 3. Generalized geologic and hydrogeologic units in the study area. Modified from Reese (2000).

but indistinct in other areas. The siliciclastic sediments of the Peace River Formation consist of interbedded, fine- to coarse-grained quartz sand, quartz silt, gravel, clay, carbonate, and phosphatic sand (Reese, 2000).

The Tamiami Formation overlies the Peace River Formation and consists of varying amounts of silt, sandy clay, micritic limestone, sandy and shelly limestone, calcareous sandstone, and quartz sand. The lithology of the Tamiami Formation varies greatly because of the complex nature of the depositional environment. The limestone is well indurated to unindurated, slightly phosphatic, variably sandy, and fossiliferous. The sand facies varies from well sorted, clean sand with abundant shells and traces of silt-size phosphate, to clayey sand with sand-size phosphate, clay-size carbonate in the matrix, and abundant well-preserved mollusk shells (Knapp and others, 1986; Reese, 2000).

The undifferentiated sediments of Holocene to Pleistocene age overlie the Tamiami Formation at land surface (Reese, 2000). These deposits mainly consist of quartz sand with minor amounts of shell and clay, and contain interfingering limestones, sandstones, and shell beds. With increasing elevation inland, the sand becomes thicker and less calcareous. The sand facies varies from fine to coarse grained, nonindurated to poorly indurated, and nonclayey to slightly clayey. Included in this group are marine terrace sediments, aeolian sand dunes, fluvial deposits, freshwater carbonates, peats, and clay beds.

Hydrogeologic Units and Hydraulic Characteristics

The principal aquifer systems in southwestern Florida are, in descending order, the surficial, intermediate, and Floridan aquifer systems (fig. 3). The focus of this report is the water-table and lower Tamiami aquifers of the surficial aquifer system and the sandstone aquifer of the upper part of the intermediate aquifer system. The confining beds of the Tamiami Formation and the upper confining unit of the Peace River Formation also are considered because they vertically "straddle" the lower Tamiami aquifer. For simplicity, these semiconfining units are called the Tamiami confining beds and the upper Hawthorn confining unit (Wedderburn and others, 1982) in this report. More detailed information on the water-bearing and confining units in southwestern Florida is presented in Reese (2000).

Maps are used in this section to show estimated hydraulic conductivities and depict the lines of equal thickness of the rock units that comprise the water-table, lower Tamiami, and sandstone aquifers. Maps showing lines of equal thicknesses were constructed by the South Florida Water Management District (1994). Histograms (fig. 4) and maps showing estimated hydraulic conductivities were developed using well construction reports and previous aquifer performance test data (Knapp and others, 1986; Montgomery, 1988). Many previously conducted aquifer performance tests were reanalyzed to assess reliability and to "fill in data gaps" (K.M. Edwards, U.S. Geological Survey, written commun., 2000). Horizontal hydraulic conductivity values (in meters per day) were computed by dividing transmissivity estimates by the thickness of the aquifer at the location of the aquifer performance test. Numerous estimates of hydraulic characteristics were compiled from various sources. Hydraulic conductivity was assumed to be log-normally distributed when computing permeability averages and standard deviations (fig. 4).

In southwestern Florida, the water-table aquifer is present in the undifferentiated deposits of Holocene to Pleistocene age and the upper part of the Tamiami Formation (fig. 3). The lines of equal thickness of the rock units that comprise the water-table aquifer range from 6 m (about 20 ft) in Hendry County south of the Caloosahatchee River to 30 m (about 100 ft) in northern Collier County along the border with Lee and Hendry Counties (fig. 5). The spatial distribution of estimated horizontal hydraulic conductivity in the water-table aquifer (fig. 6) reflects the complex heterogeneity of this characteristic in the study area. In log space (fig. 4A), the mean and standard deviation of 244 log estimates of horizontal hydraulic conductivity in the water-table aquifer were 2.16 and 0.6, respectively. In parameter space, this translates to a range of about 40 to 600 m/d, which is one standard deviation from the mean.

The water-table aquifer is underlain by rocks and sediments that form the confining beds of the Tamiami Formation (fig. 3). The thickness of these Tamiami confining beds ranges from 0 to about 15 m (about 0 to 50 ft) in Lee, Collier, and Hendry Counties (South Florida Water Management District, 1994). The beds, which pinch out in the central and northern parts of Lee County and northwestern Hendry County, are thickest in localized areas near Bonita Springs in northern and eastern Collier County, and in central and

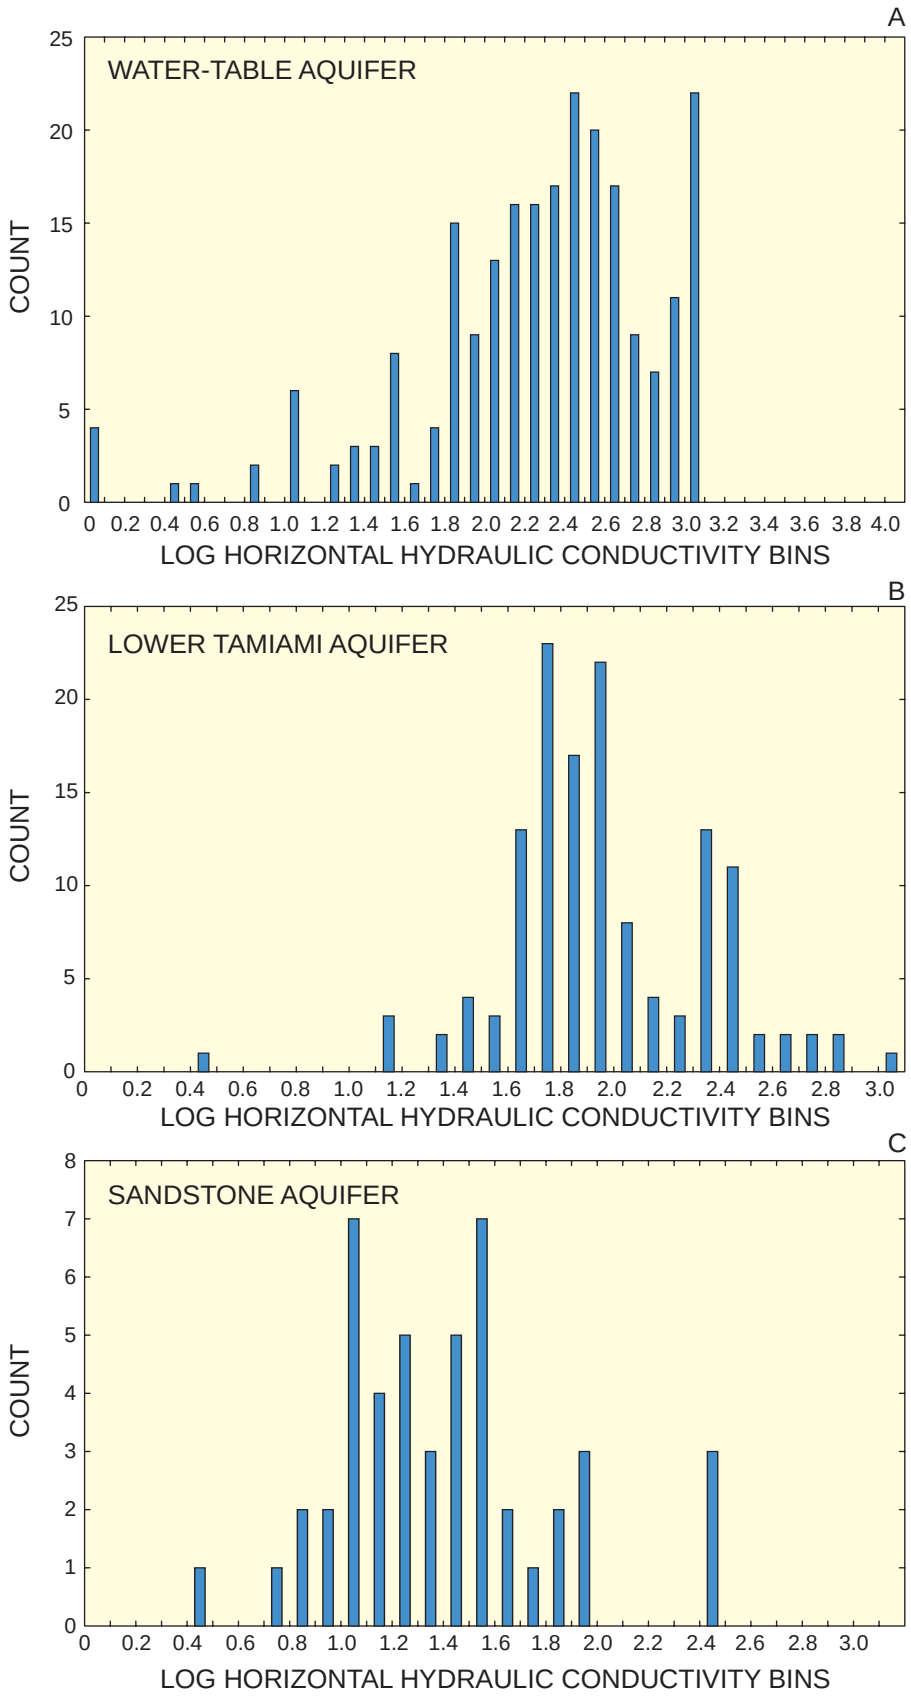

Figure 4. Estimated horizontal hydraulic conductivity values of the (A) water-table, (B) lower Tamiami, and (C) sandstone aquifers. The values of hydraulic conductivity are in meters per day.

southern Hendry County. Sparse data are available to describe the distribution of vertical hydraulic conductivity in the Tamiami confining beds. Montgomery (1988) reports a value of 0.004 m/d for vertical hydraulic conductivity based on aquifer performance tests. In a reanalysis of aquifer performance tests (K.M. Edwards, U.S. Geological Survey, written commun., 2000), four reliable values of the vertical hydraulic conductivity of the Tamiami confining beds each equaled about 0.004 m/d.

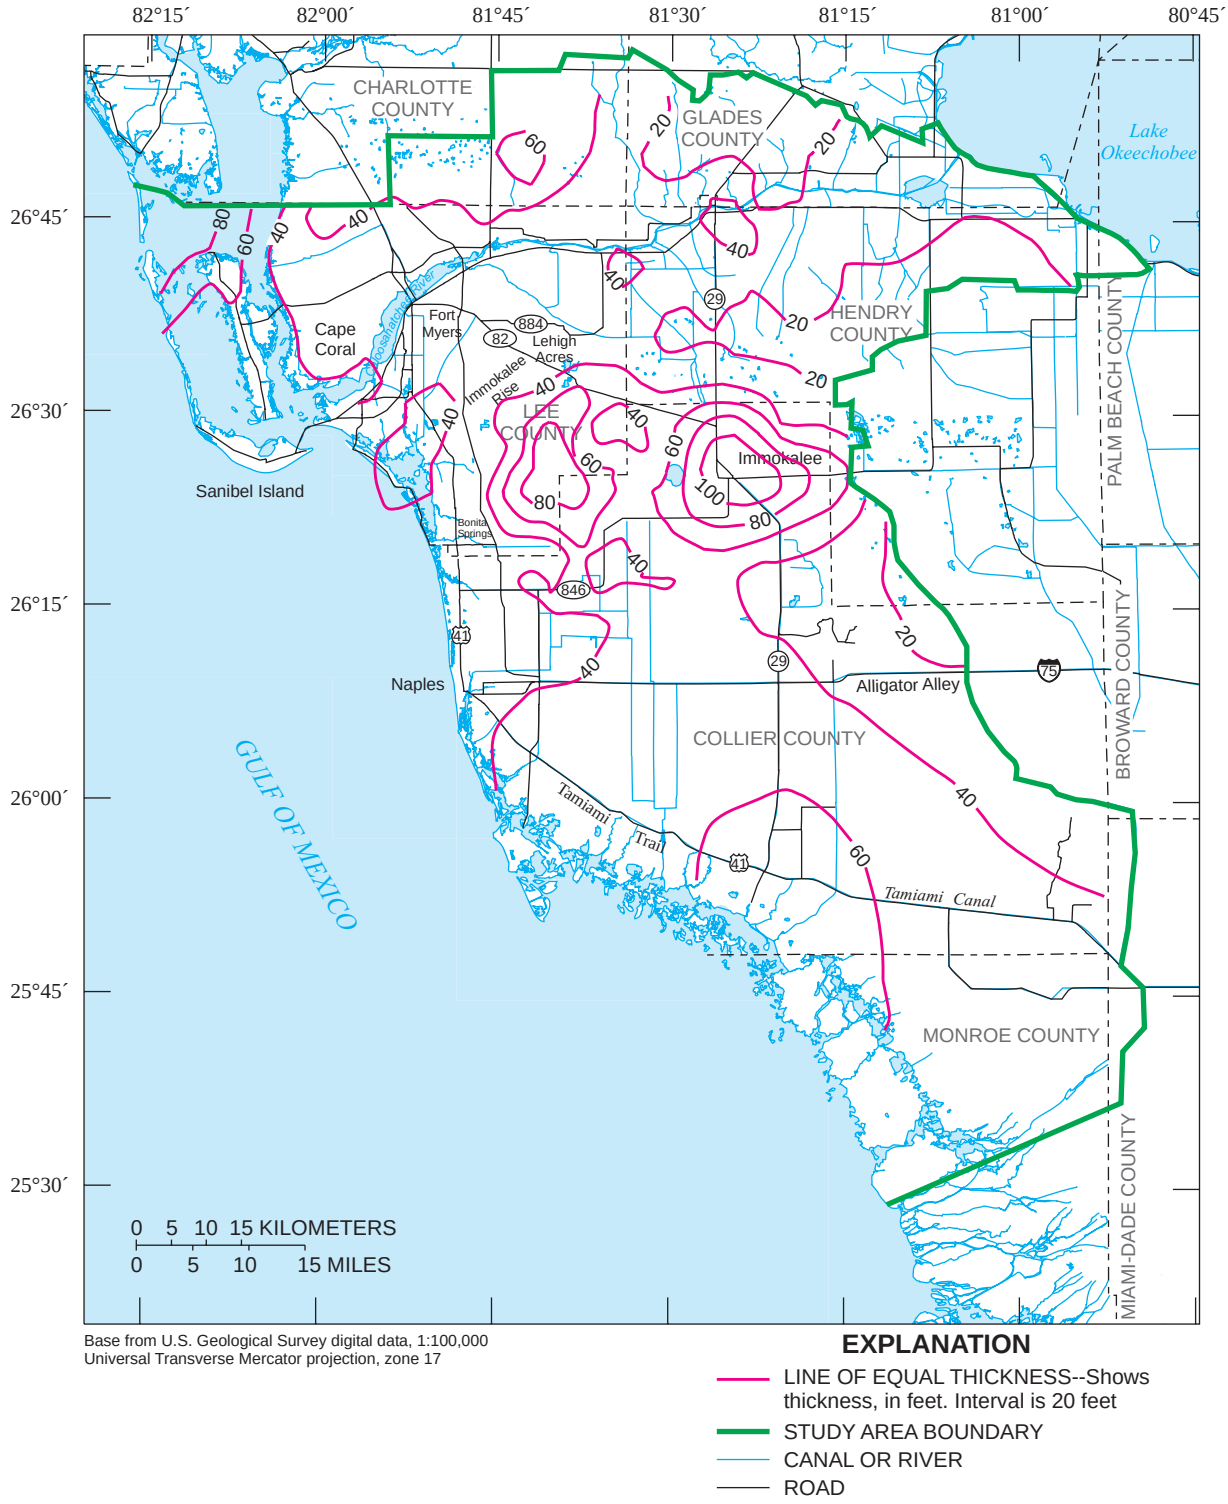

Figure 5. Lines of equal thickness of the rock units that comprise the water-table aquifer. From the South Florida Water Management District (1994).

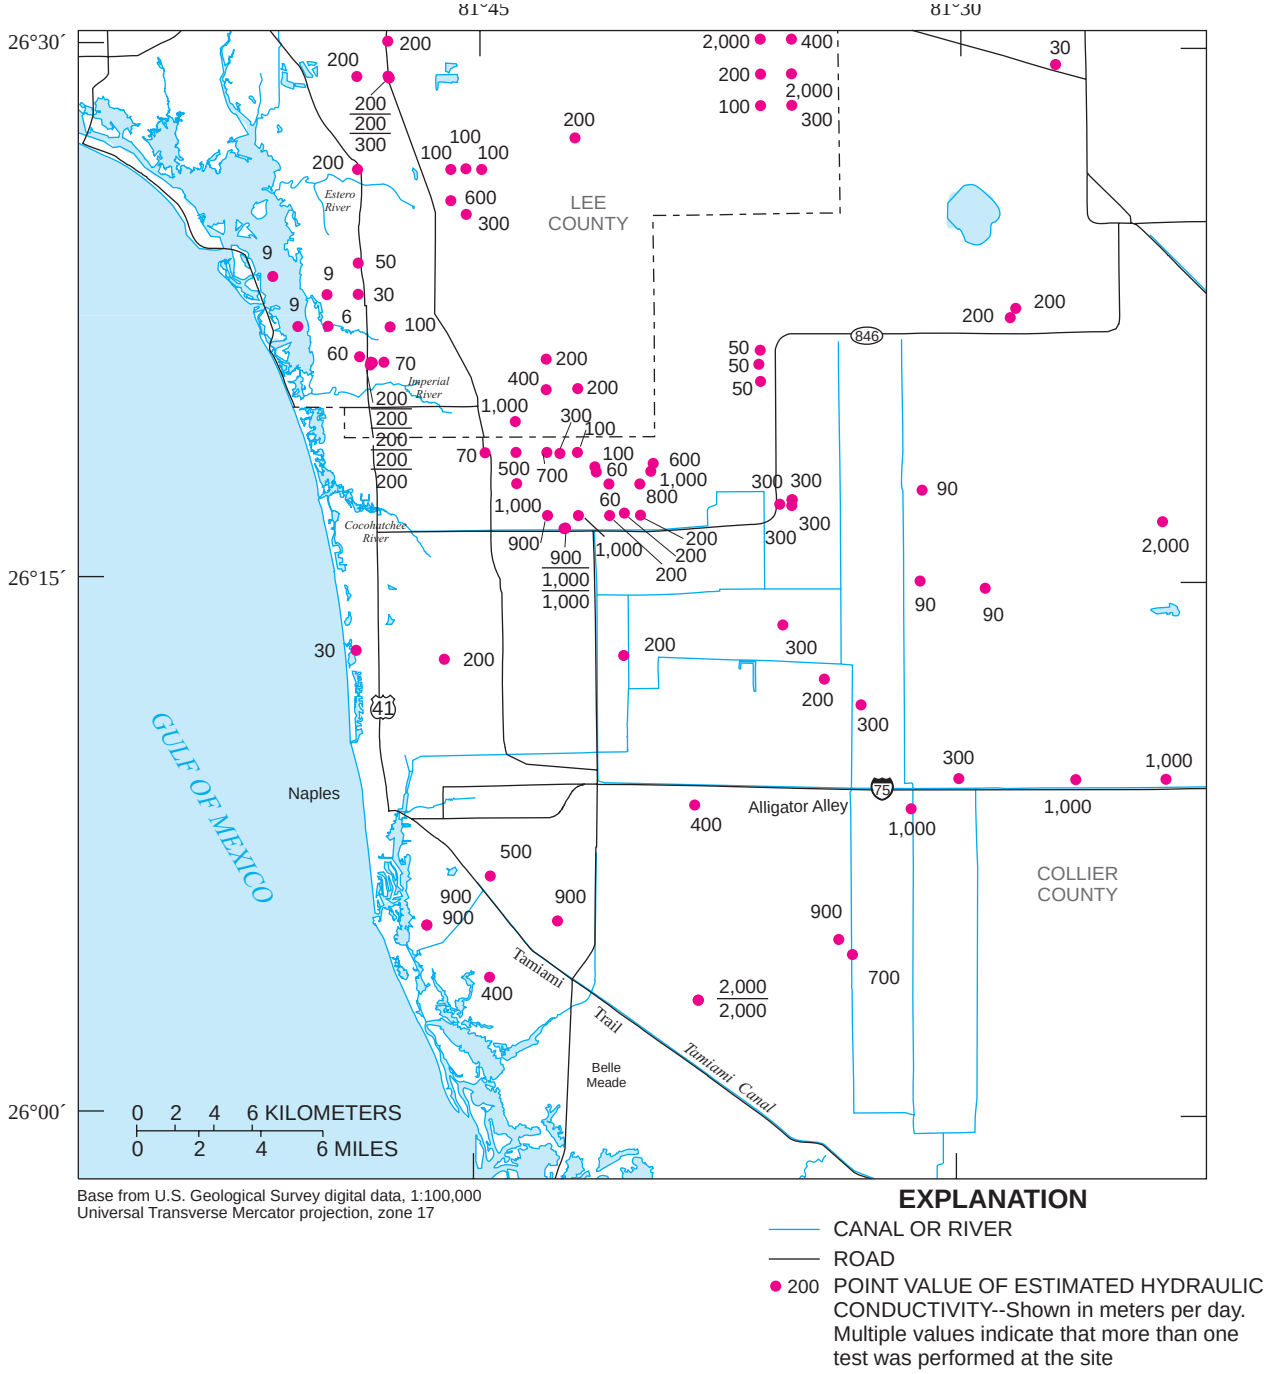

Figure 6. Spatial distribution of horizontal hydraulic conductivity in the water-table aquifer estimated from analyses of aquifer performance tests.

Underlying the confining beds, the lower Tamiami aquifer, a major water-producing unit within much of the study area, generally lies within the lower part of the Tamiami Formation of Pliocene age (fig. 3). In some places, the lower Tamiami aquifer includes unconsolidated quartz sand of late Miocene age (Knapp and others, 1986; Weedman and others, 1997; Edwards and others, 1998). The lines of equal thickness of the rock units that comprise the lower Tamiami aquifer ranges from 0 to 55 m (about 0 to 180 ft) in Lee, Henry, and Collier Counties (fig. 7). The aquifer, which is not present in the central and northern parts of Lee County and in northwestern Hendry County, is thickest in localized areas southeast of Bonita Springs (fig. 7).

Estimates of horizontal hydraulic conductivity in the lower Tamiami aquifer seem to have a bimodal log K distribution (fig. 4B). Results from this and previous research (Meeder, 1979) suggest that the lower Tamiami aquifer is highly permeable where coral reef facies are present (fig. 8). In the coral reef facies mapped by Meeder (1979), the mean and standard deviation of eight log estimates of horizontal hydraulic conductivity (fig 4B) were 2.11 and 0.4, respectively. In parameter space, this translates to a range of about 50 to 300 m/d, which is one standard deviation from the mean. In places within the lower Tamiami aquifer

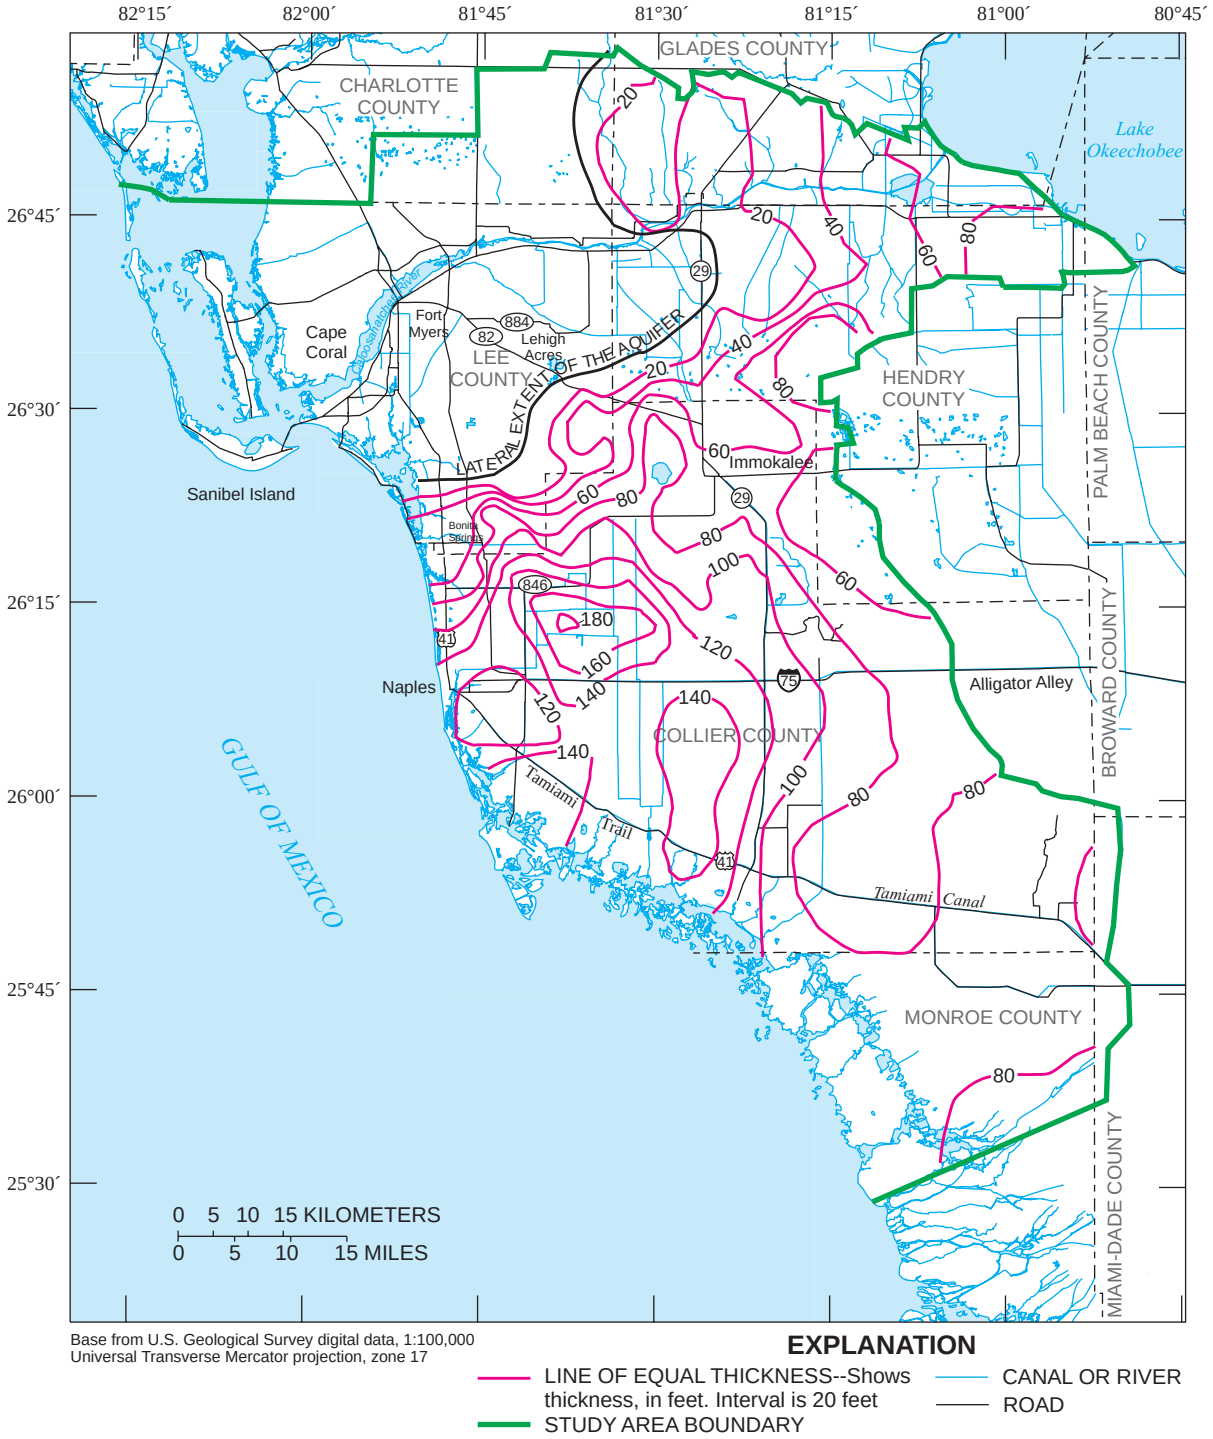

Figure 7. Lines of equal thickness of the rock units that comprise the lower Tamiami aquifer. From the South Florida Water Management District (1994).

where coral reef facies are not present, the mean and standard deviation of 136 log estimates of horizontal hydraulic conductivity (fig. 4B) were 1.8 and 0.4, respectively. In parameter space, this translates to a range of about 30 to 200 m/d, which is one standard deviation from the mean.

The lower Tamiami aquifer is underlain by rocks and sediments that form the upper confining unit of the Hawthorn Group (fig. 3). This unit, called the upper Hawthorn confining unit in this report, thins and may be absent near Bonita Springs (Wedderburn and others, 1982). Limited data are available to describe the

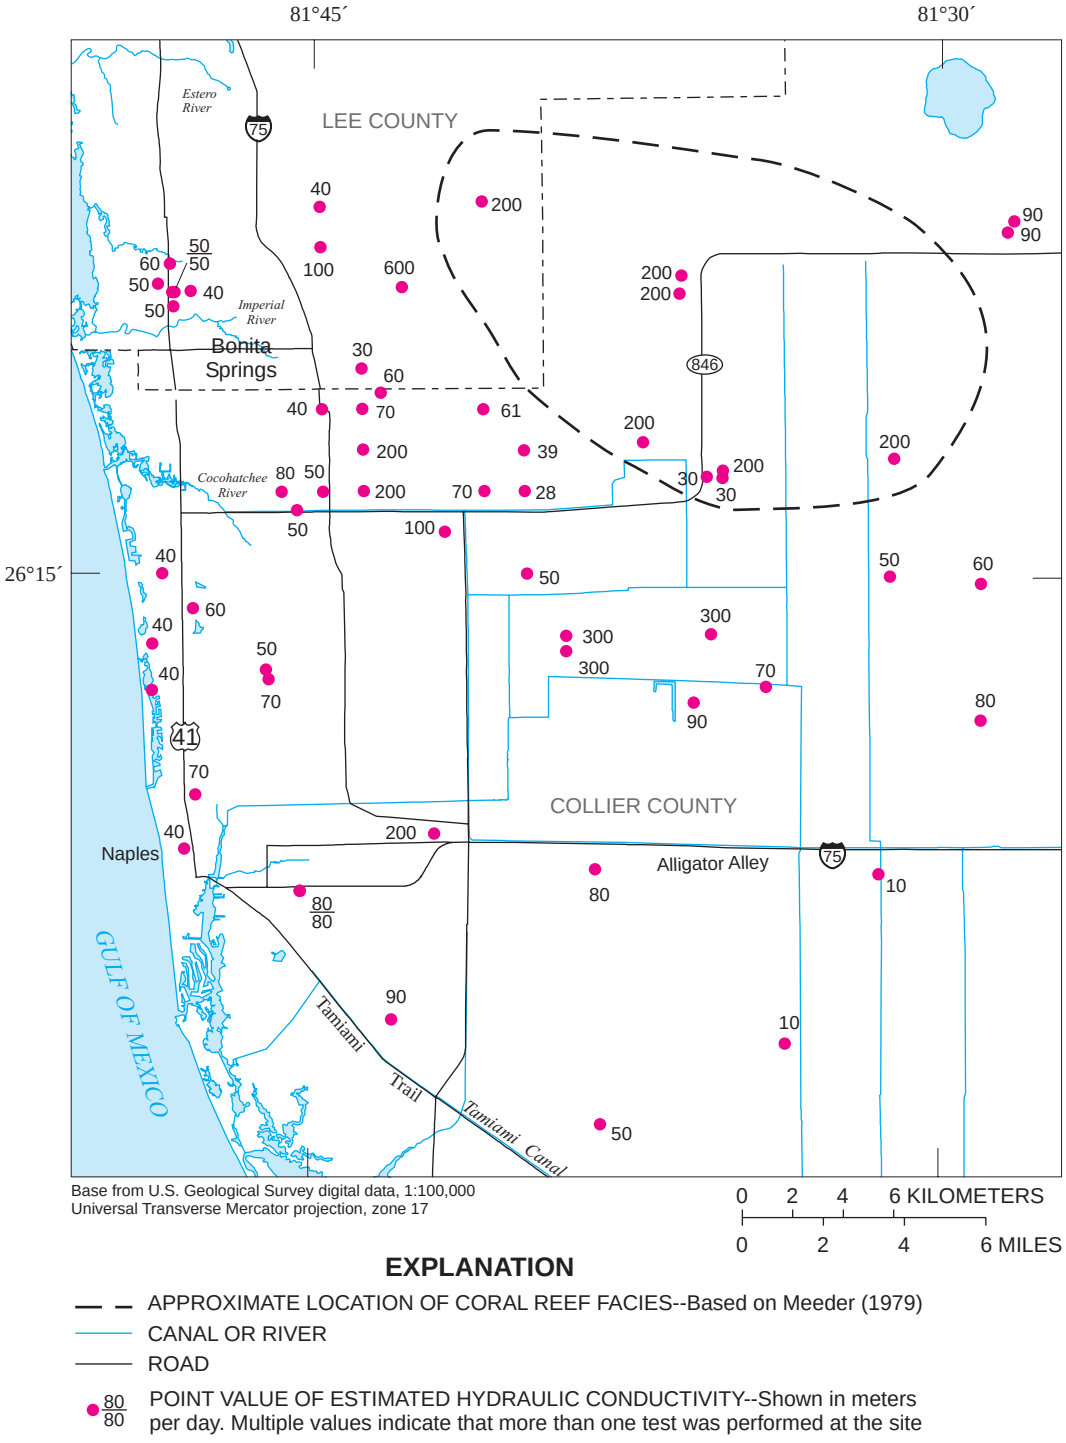

Figure 8. Spatial distribution of horizontal hydraulic conductivity in the lower Tamiami aquifer estimated from analyses of aquifer performance tests.

distribution of vertical hydraulic conductivity in the upper Hawthorn confining unit. Montgomery (1988) reports a value of 0.003 m/d for vertical hydraulic conductivity based on aquifer performance tests. This value was used by Bower and others (1990) and Bennett (1992) in numerical models for parts of the study area.

The sandstone aquifer underlies the upper Hawthorn confining unit in the intermediate aquifer system (fig. 3). The lines of equal thickness of the rock units that comprise the sandstone aquifer range from 0 to 33 m (0 to about 110 ft) in Lee, Henry, and Collier Counties (fig. 9). The sandstone aquifer seems to be

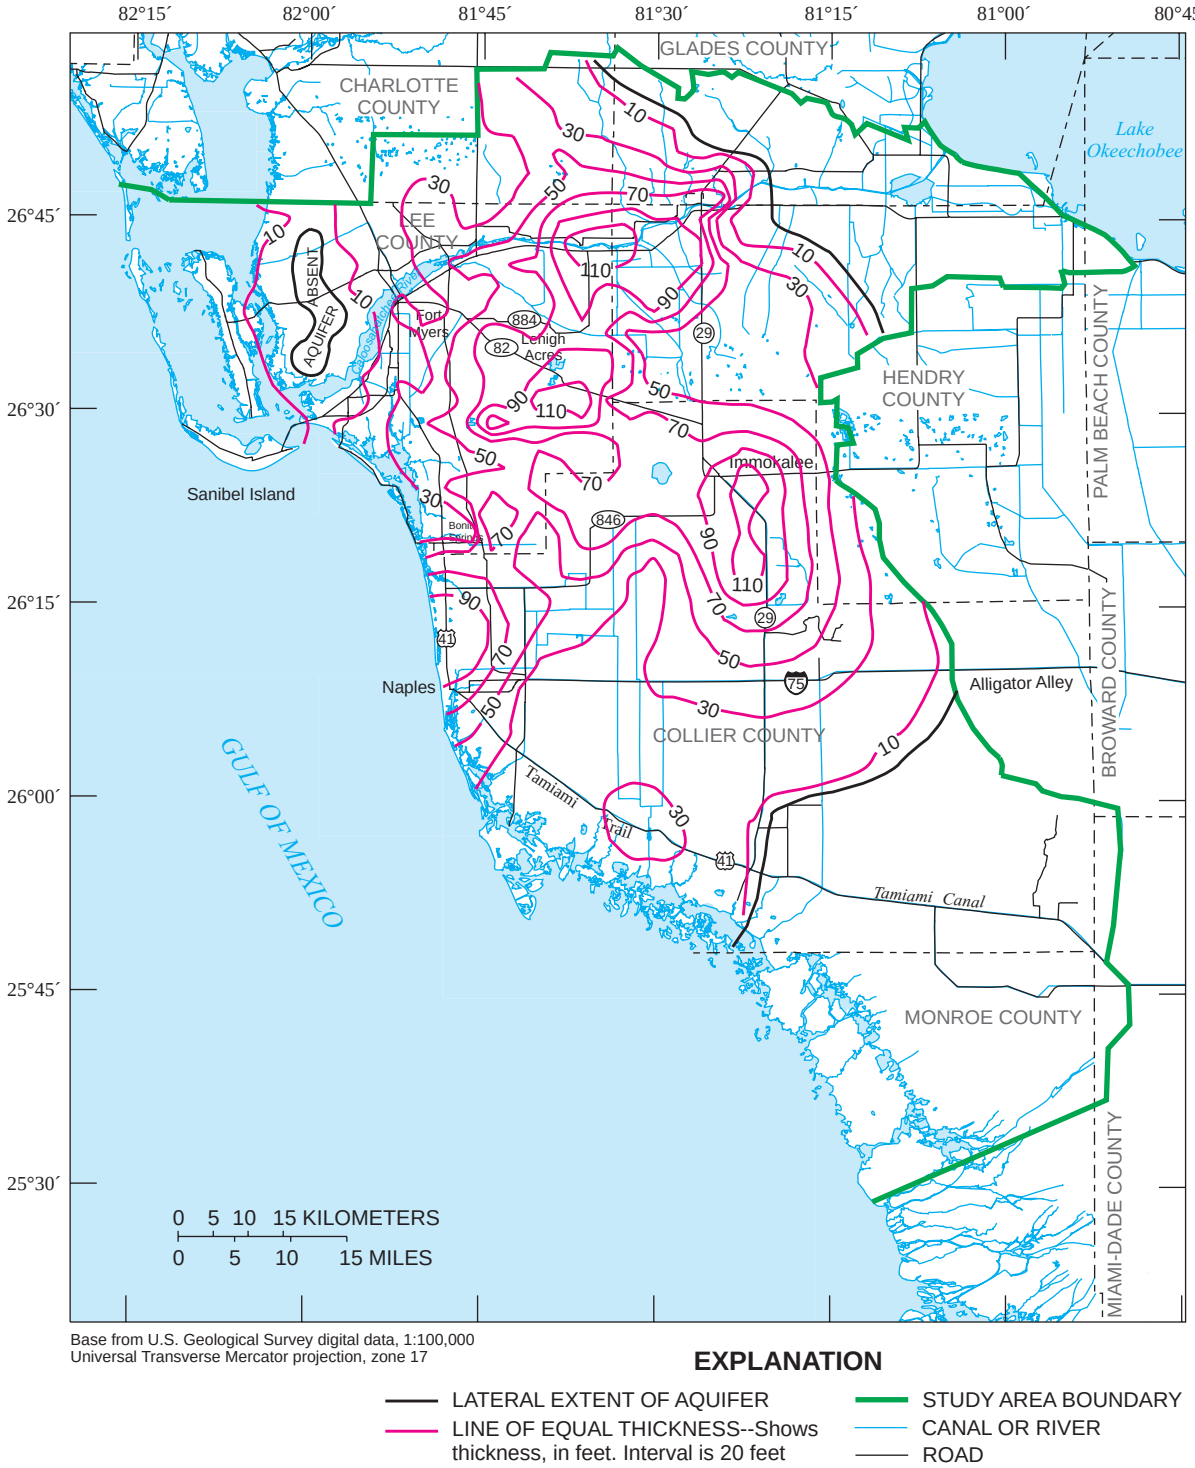

Figure 9. Lines of equal thickness of the rock units that comprise the sandstone aquifer. From the South Florida Water Management District (1994).

thickest in localized areas in northern Collier County, southeastern Lee County, and northeastern Lee County and is absent in southeastern Collier County, northeastern Hendry County, and in parts of northwestern Lee County (fig. 9). The spatial distribution of estimated horizontal hydraulic conductivity in the sandstone aquifer (fig. 10) reflects the complex heterogeneity of this characteristic in the study area. In log space (fig. 4C), the mean and standard deviation of 25 log estimates of horizontal hydraulic conductivity in the sandstone aquifer were 1.26 and 0.4, respectively. In parameter space, this translates to a range of about 10 to 50 m/d, which is one standard deviation from the mean.

Water Budget

This section describes components of the water budget that may be affecting saltwater movement in the water-table and lower Tamiami aquifers near Bonita Springs (fig. 11). Equation 1 provides a qualitative understanding of how these components interact. The terms are not summed together in this analysis; therefore, the units of each component are sometimes reported differently depending upon the source of information.

$$P + I - ET - D - Q_S - Q_P - Q - Q_{uk} = \Delta S \cong 0, \quad (1)$$

where

P is precipitation;

I is irrigation;

ET is evapotranspiration;

D is net deep leakage between the sandstone aquifer and the lower Tamiami aquifer;

Q_S is submarine ground-water discharge to the Gulf of Mexico,

Q_P is pumpage from the water-table and lower Tamiami aquifers;

Q is stream discharge, which is composed of surface runoff, Q_{ro}, and baseflow, Q_B;

Q_{uk} is other or unknown components of the water budget that may be affecting saltwater movement; and

ΔS is change in storage, which is assumed to be negligible over the long term.

Precipitation (P) and irrigation (I) that exceed evapotranspiration (ET) and runoff (Q_{ro}) can recharge the water table if it infiltrates land surface and overcomes capillary forces in the unsaturated zone. This recharge is generally called net recharge. Krulikas and Giese (1995) estimate net recharge in the study area to range from 1.5 to 22.9 cm/yr, using chloride concentration ratios and flow-tube analysis methods. They further indicate that net recharge rates greater than 22.9 cm/yr could be induced by lowering the water table through ground-water withdrawals or seepage to canals.

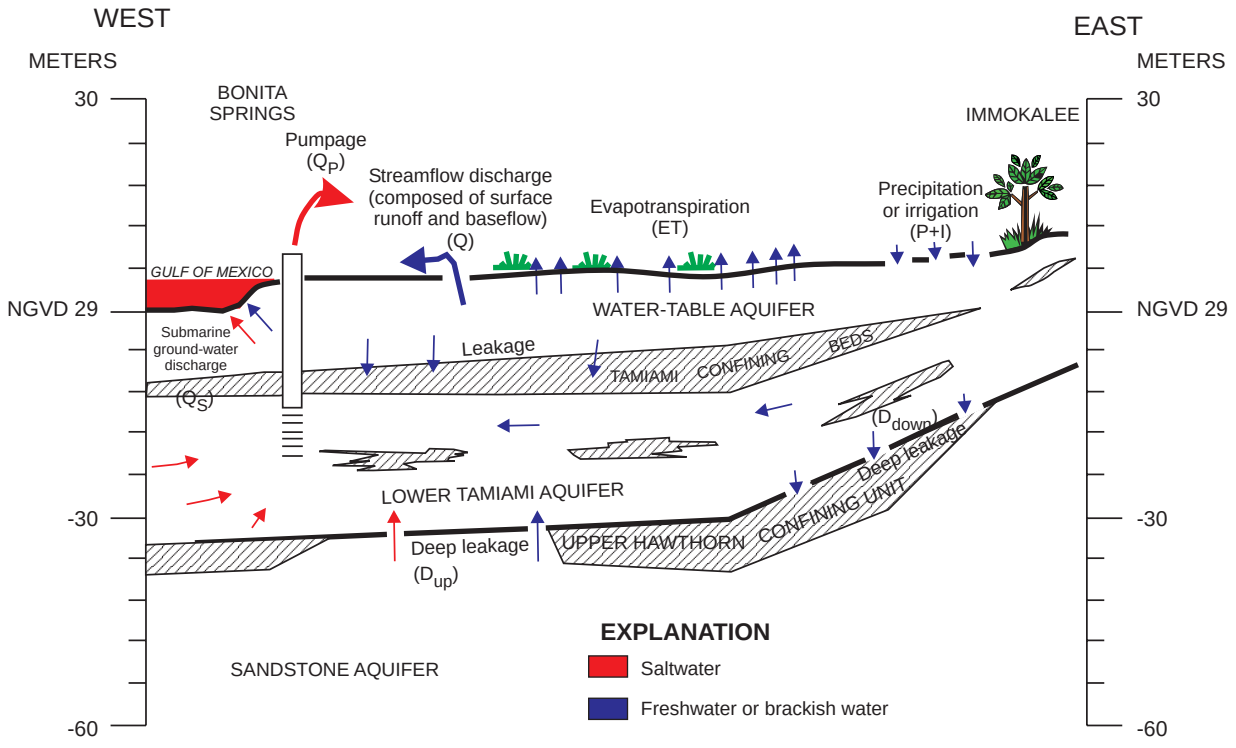

Figure 11. Hypothetical control volume and selected water-budget components within the study area. D_{up} is deep upward leakage and D_{down} is deep downward leakage. NGVD 29 is National Geodetic Vertical Datum of 1929.

Net deep leakage, D, represents the difference between upward, $D_{up,}$ and downward leakage, D_{down}, that occurs naturally between the lower Tamiami and sandstone aquifers. This leakage results from the semiconfining nature of the upper Hawthorn confining unit and the difference in head between the aquifers (fig. 11). Deep leakage was inferred between the lower Tamiami and sandstone aquifers using a map of the head difference between these two units. Average 1996 water levels were computed from water levels measured in 45 USGS monitoring wells in the lower Tamiami aquifer, and from 30 USGS monitoring wells in the sandstone aquifer (table 1). Average water levels were plotted and contoured and spatially interpolated to a common grid. The difference in interpolated head between the lower Tamiami and sandstone aquifers was then computed. This approach has many assumptions including: (1) water-level contours in the lower Tamiami aquifer are vertical; (2) water-level contours in the sandstone aquifer are vertical; and (3) the head difference, as calculated from the water-level contours, occurs directly within the upper Hawthorn confining unit.

In 1996, head differences between the lower Tamiami and sandstone aquifers ranged from -2.0 to 2.6 m (fig. 12). A negative sign suggests leakage is upward into the lower Tamiami aquifer, whereas a positive sign suggests leakage is downward into the sandstone aquifer. Areas where relatively large amounts of deep leakage occur are indicated by large positive or negative head-difference values. For example, Bonita Springs may have the largest amount of deep leakage occurring into the lower Tamiami aquifer because this area has the largest negative head-difference values (about -2.0 to -0.5 m). The assumption is that the upper Hawthorn confining unit is continuous with a constant vertical hydraulic conductivity.

Submarine ground-water discharge to the Gulf of Mexico, Q_S, occurs as ground water flowing toward the Gulf of Mexico moves upward and over more saline ground water. Fresher ground water discharges to the bottom of the Gulf of Mexico or Estero Bay. Estimates of submarine ground-water discharge are difficult to find in the study area. However, a recent study of submarine ground-water discharge from the Biscayne aquifer to Biscayne Bay in coastal southeastern Florida was completed by Langevin (2001). The average rate of submarine ground-water discharge to Biscayne Bay over a 10-year period was 200,000 m^3/d along 100 km of coastline. The Biscayne aquifer is more permeable and receives more recharge than the water-table aquifer near Bonita Springs, which suggests submarine ground-water discharge near this area would be less than that in Biscayne Bay.

Ground-water pumpage, Q_P, from the water-table and lower Tamiami aquifers in the study area (fig. 11) is monitored by the SFWMD. According to R.L. Marella (U.S. Geological Survey, written commun., 1999), ground-water withdrawals by municipal supply facilities in Lee and Collier Counties nearly doubled from 1985 to 1998 (fig. 13). Withdrawals generally are greater during the dry season (October to May) when rainfall is scarce than during the wet season (June to September) when rainfall is abundant (fig. 14). A water-use survey suggests a large volume of unmonitored ground-water pumpage from the lower Tamiami aquifer occurred for irrigation and agricultural uses (P.A. Telis, U.S. Geological Survey, written communication, 2000). This survey, however, was restricted to a small sample size with an even smaller number of responses. Unmonitored ground-water pumpage could exceed monitored ground-water pumpage in the lower Tamiami aquifer because the deepest areas of potentiometric drawdown exist at locations where no monitored ground-water pumpage is occurring (K.J. Halford, U.S. Geological Survey, written communication, 1999).

Streamflow discharge, Q, is composed of surface runoff, Q_{ro}, and baseflow, Q_B (fig. 11). In 1996, the average annual streamflow (including runoff and baseflow) at four gaging stations was about 2 m^3/s (fig. 1, Spring Creek, Imperial River, and northern and southern branches of Estero River). The area of the Imperial River basin is about 2.2 x 10^8 m^2 (Johnson Engineering, Inc., and others, 1999). By dividing the average annual streamflow by the area of the Imperial River basin, the average rate of streamflow in the basin equates to about 29 cm/yr in 1996. The rainfall rate in the Imperial River basin was about 1.3 m/yr in 1996, as estimated from a rainfall monitoring station near Bonita Springs. Land use in the Imperial River basin is predominantly nonurban where runoff coefficients averaged from Bennett (1992) are about 0.1. Using this runoff coefficient to assume a 13-cm/yr average runoff rate from the 1.3-m/yr rainfall rate, the average rate of baseflow, B_f, in the basin equates to about 16 cm/yr. Higher (wet season) water levels from the water-table aquifer can force more baseflow to surface-water features, creating rates greater than 16 cm/yr. Conversely, lower (dry season) water levels can induce baseflow rates less than 16 cm/yr.

Water Quality and Geochemistry

Water-quality and geochemical data collected from the lower Tamiami aquifer near Bonita Springs were used to examine historical trends in salinity and to identify potential sources of saltwater. Numerous water samples were collected and analyzed for chloride concentration and strontium isotopes (Schmerge, 2001). Chloride concentration is a common surrogate for salinity, and strontium isotopes have proven to be a useful tracer for determining ground-water movement and the origin of salinity (Clark and Fritz, 1997). Further explanation of methods and data analysis of strontium isotopes can be found in Schmerge (2001).

Historical trends in salinity were examined for nine USGS monitoring wells open to the lower Tamiami aquifer near Bonita Springs; chloride concentrations ranged from about 10 to 1,300 mg/L (fig. 15). Monitoring well L-738 is the only well examined with a record that pre-dates 1985. Chloride concentrations in well L-738 have increased steadily from about 100 mg/L in 1968 to about 350 mg/L in 1998. A statistical analysis conducted by Prinos and others (2002) detected a significant upward trend in chloride concentration at monitoring well L-738. Chloride concentrations in this well have increased at a rate of about 6.6 mg/L annually from 1974 through 1998 (Prinos and others, 2002). Several possible explanations for this increasing chloride concentration are presented later in the discussion of ground-water flow and mechanisms of saltwater intrusion. In the other eight wells, chloride concentrations remained relatively stable or decreased over time.

Salinity also was examined historically by comparing areal maps of chloride concentration in the lower Tamiami aquifer. In a study by Knapp and others (1986), lines of equal chloride concentration reached a maximum value of 500 mg/L near Bonita Springs (fig. 16A). In a study by Schmerge (2001), lines of equal chloride concentration reached a maximum value of 1,000 mg/L near Bonita Springs (fig. 16B). Additionally, the 300-mg/L line of equal chloride concentration extended farther inland in the latter study. This comparison suggests saltwater occurs farther eastward than in 1986 in the lower Tamiami aquifer near Bonita Springs. Differences in the locations of lines of equal chloride concentrations, however, could be explained by differences in the amount and location of data available for contouring in Knapp and others (1986) and Schmerge (2001). With this in mind, the historical comparison of lines of equal chloride concentration does not conclusively determine if saltwater has moved since 1986.

Water samples were collected from the lower Tamiami aquifer near Bonita Springs for strontium isotope analyses (Schmerge, 2001). Strontium isotope data can be used in conjunction with the hydrogeologic framework to provide evidence of the source of strontium in ground water (Sacks and Tihansky, 1996). Results suggest that the source of strontium in ground water sampled in the lower Tamiami aquifer near Bonita Springs is the underlying Floridan aquifer system (Schmerge, 2001).

GROUND-WATER FLOW AND MECHANISMS OF SALTWATER INTRUSION

Ground-water flow patterns and potential mechanisms of saltwater intrusion in the study area are described in this section. Lateral ground-water flow in the lower Tamiami aquifer occurs in a southwesterly direction and becomes radially convergent near Bonita Springs. Vertical ground-water flow can be inferred from a map of the head difference between the lower Tamiami and sandstone aquifers (fig. 12). This map suggests that the greatest rates of vertical ground-water flow from the sandstone aquifer to the lower Tamiami aquifer are occurring beneath Bonita Springs, assuming that the upper Hawthorn confining unit is continuous and uniform in thickness and hydraulic conductivity. Approaching the saltwater interface, fresher ground water flowing toward the Gulf of Mexico moves upward and over more saline ground water that is flowing toward inland areas in lower parts of the lower Tamiami aquifer. This circulation process in the saltwater interface was observed in the Biscayne aquifer by Kohout (1964) and can only be inferred from the current monitoring well network established near Bonita Springs.

The distribution of saltwater in the lower Tamiami aquifer is likely not at equilibrium with current hydrologic conditions near Bonita Springs because of rapidly increasing rates of ground-water pumpage, rising sea level, and the lag in response time for saltwater to move to equilibrium when hydrologic conditions change. In fact, four potential mechanisms could move saltwater into zones of the lower Tamiami aquifer previously occupied by fresher waters. These mechanisms are: (1) lateral movement of the

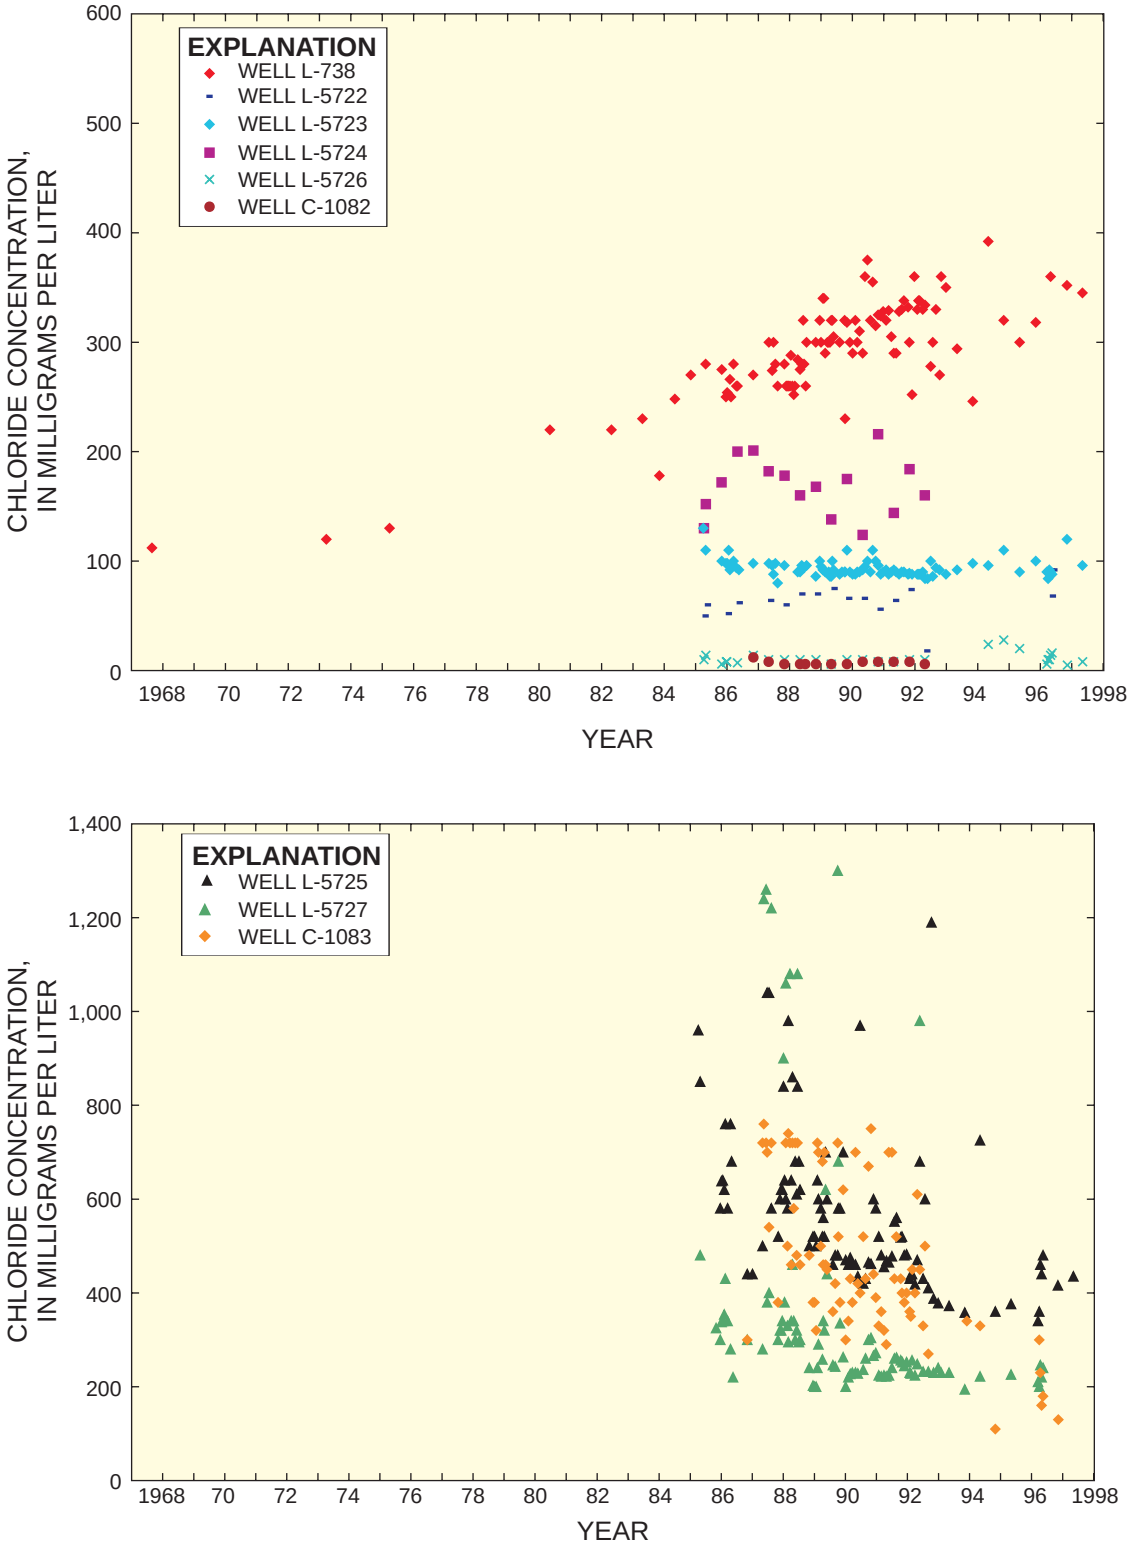

Figure 15. Historical trends in chloride concentration for selected monitoring wells near Bonita Springs, 1968-98. Well locations are shown in figure 1.

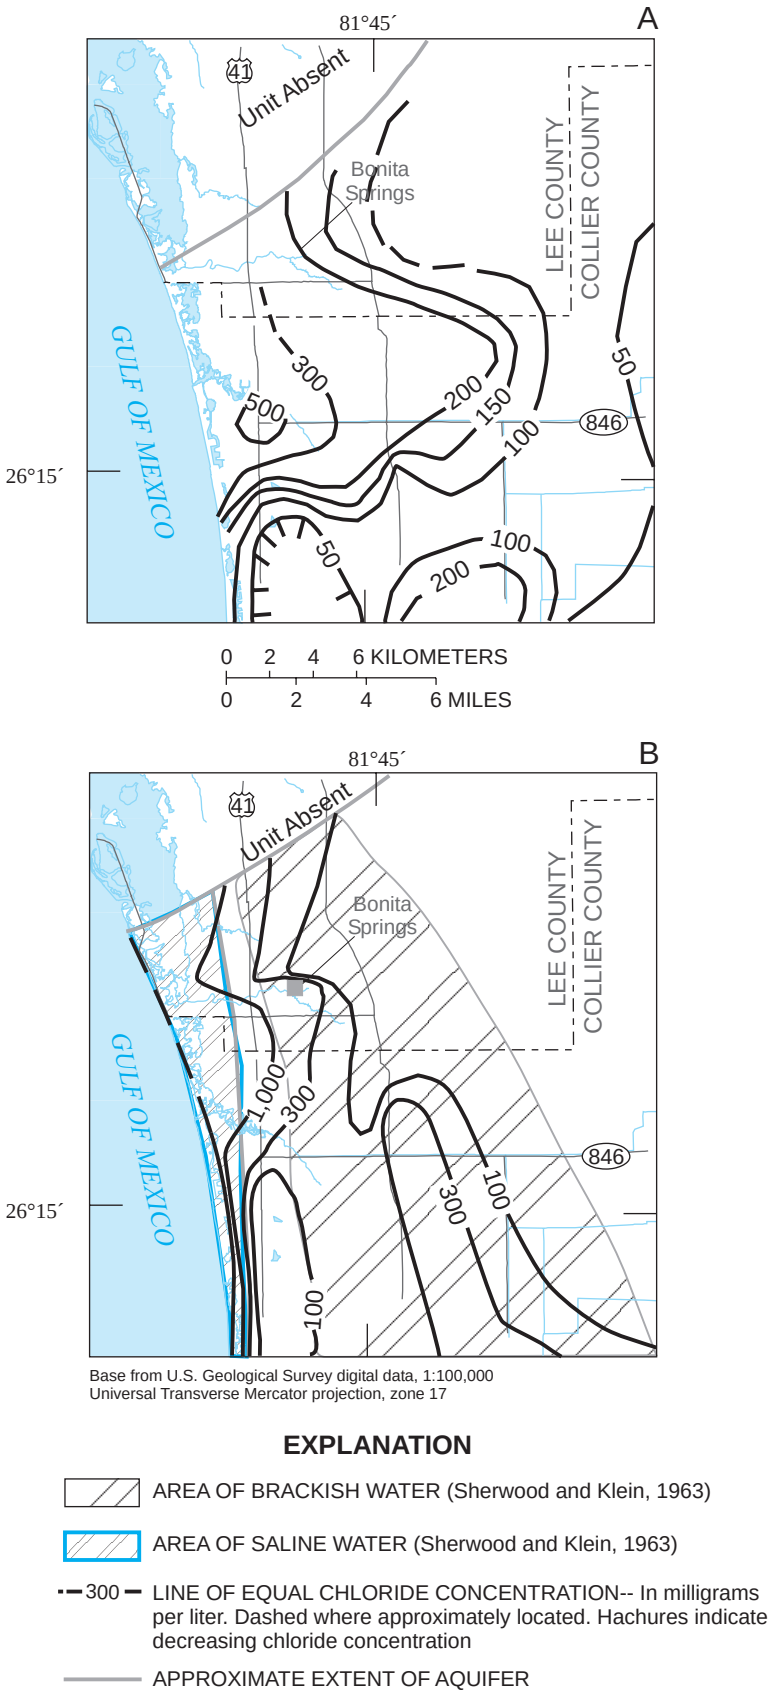

Figure 16. Lines of equal chloride concentration in the lower Tamiami aquifer near Bonita Springs over time. Map A modified from Knapp and others (1986), and map B modified from Schmerge (2001).

freshwater-saltwater interface inland from the southwestern coast of Florida; (2) upward leakage from deeper, saline water-bearing zones through natural upwelling and upconing; (3) downward leakage of saltwater from surface-water channels; and (4) movement of unflushed pockets of relict seawater in the lower Tamiami and water-table aquifers (fig. 17).

Lateral Encroachment

Lateral encroachment of recent seawater into the lower Tamiami aquifer may be possible in southwestern Florida. Saline ground water beneath the Gulf of Mexico could move through the permeable rock comprising the lower Tamiami aquifer to come into equilibrium with modern natural and anthropogenic stresses, such as withdrawals, sea level, and drought (fig. 17). Some evidence indirectly suggests the occurrence of lateral encroachment in the lower Tamiami aquifer near Bonita Springs. For instance, the average annual potentiometric surface of the lower Tamiami aquifer in 1996 is below sea level in some areas beneath Bonita Springs adjacent to the Gulf of Mexico; however, the predominance of lateral encroachment is uncertain.

Upward Leakage

A plausible mechanism for the movement of saline ground water into the freshwater zones of the lower Tamiami aquifer near Bonita Springs is upward leakage (fig. 17) either through natural upwelling or upconing. Natural upwelling is defined here as the upward movement of ground water within or into the lower Tamiami aquifer due to head differences caused by natural stress-producing processes. Natural upwelling can cause saltwater intrusion where salinity is higher in deeper locations of higher head. Upconing is defined here as the upward movement of saline ground water within or into the lower Tamiami aquifer due to head differences caused by anthropogenic stress. The primary difference between these two processes is the source of stress, either natural or anthropogenic.

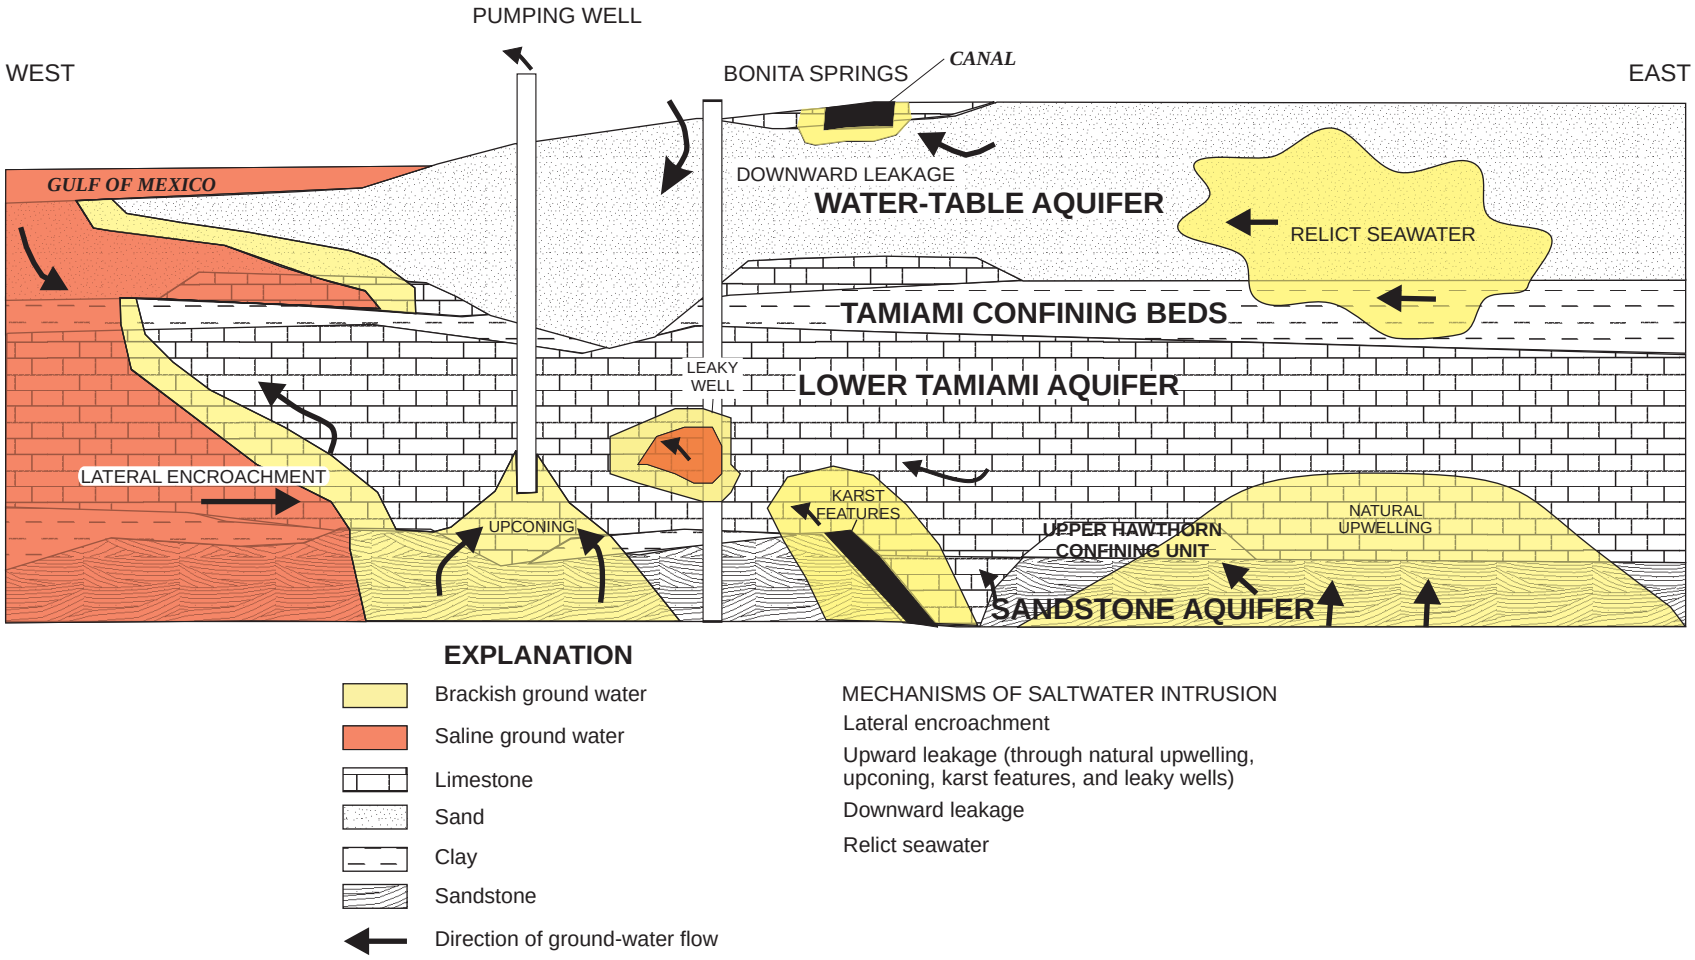

Figure 17. Potential mechanisms of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs.

Diffuse natural upwelling of brackish ground water from the sandstone aquifer to the lower Tamiami aquifer probably is occurring in some parts of the study area. There is evidence of upward leakage to the base of the lower Tamiami aquifer in southwestern Collier County several kilometers north and south of I-75 and north of U.S. Highway 41 (fig. 12). These areas can be isolated as natural upwelling rather than upconing because they are characterized by sloughs, swamps, cypress domes, pine and/or oak islands, and mangrove estuaries where little anthropogenic stress, such as ground-water withdrawal, occurs. Upward leakage through natural upwelling is not apparent in the lower Tamiami aquifer beneath Bonita Springs because the potentiometric surface of the aquifer has been drawn down as a result of ground-water pumpage. This drawdown means natural upwelling probably is secondary to upconing.

Upconing of saltwater probably can be considered of utmost concern in the lower Tamiami aquifer beneath Bonita Springs. Upward leakage to the base of the lower Tamiami aquifer was inferred to be occurring at maximum rates beneath Bonita Springs in 1996 (fig. 12), assuming the upper Hawthorn confining unit is continuous and uniform. However, Wedderburn and others (1982) report that the upper confining unit thins and is absent in southernmost Lee County near Bonita Springs. Thus, saltwater upconing can occur more easily in this area because of less resistance to vertical flow. Other evidence shows that water in this area of the lower Tamiami aquifer was less saline in the past (Prinos and others, 2002) and originated from deeper discharging aquifers (Schmerge, 2001). This latter evidence also suggests that upconing may be occurring in the lower Tamiami aquifer beneath Bonita Springs.

As previously discussed, diffuse natural upwelling probably is not important in the lower Tamiami aquifer near Bonita Springs. Earlier studies had suggested that non-diffuse natural upwelling and upconing of saltwater through karst features could be occurring. Kohout (1979) identified the “mudhole” (fig. 1) discharging warm water to the Gulf of Mexico about 26 km northwest of Bonita Springs. Additionally, heads in the Floridan aquifer system are about 10 m higher than heads in the lower Tamiami aquifer near Bonita Springs. Thus, ground water would naturally tend to flow from deeper, more saline, and more pressurized aquifer systems to the lower Tamiami aquifer along preferential karstic flow paths. Although karst features exist in the study area, this mechanism of saltwater intrusion probably is not predominant in the lower Tamiami aquifer near Bonita Springs based on historical chloride concentration trends (Prinos and others, 2002). Water in the lower Tamiami aquifer would have chloride concentrations similar to the Floridan aquifer system (about 1,200 to 1,600 mg/L) if karst features were naturally transporting large quantities of saltwater from deeper aquifers for thousands of years.

According to previous investigators (Sherwood and Klein, 1963; Burns, 1983; Schmerge, 2001), natural upwelling and upconing of saltwater through leaky wells could be occurring in the lower Tamiami aquifer near Bonita Springs. Additionally, a poorly sealed annulus of well L-2310 (not shown) was hypothesized as the source of saltwater intrusion in well L-738 (fig. 15) by Schmerge (2001). Well L-2310 tapped the Upper Floridan aquifer and may have provided a pathway for upward leakage to the lower Tamiami aquifer near well L-738. The existence of other leaky wells (or potential leaky wells) is unknown; therefore, the predominance of leaky wells as a mechanism of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs remains uncertain.

Downward Leakage

Downward leakage could occur as saline water from surface-water channels moves through the water-table aquifer and underlying Tamiami confining beds to come into equilibrium with modern natural and anthropogenic stresses. Downward leakage of saltwater from rivers and canals has been documented in the water-table aquifer near Naples (McCoy, 1962) and near boat basins in Naples (Klein, 1954). Downward leakage, however, seems an unlikely mechanism of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs. Gaging stations on the northern and southern branches of the Estero River, Spring Creek, and the Imperial River record flow during the dry season, suggesting ground water flows from the water-table aquifer to these rivers and creeks even in times of drought. Additionally, flow from the water-table aquifer to the base of the Imperial River was observed during field reconnaissance in July 2000. Given these observations, it seems unlikely that saltwater moving upstream along Spring Creek and the Estero, Imperial, and Cocohatchee Rivers (fig. 1) would infiltrate through the water-table aquifer and underlying Tamiami confining beds and result in the distribution of saltwater mapped by Knapp and others (1986) and Schmerge (2001).

Relict Seawater

Relict seawater from former high sea-level stands could move through the permeable rock comprising the lower Tamiami aquifer to come into equilibrium with modern natural and anthropogenic stresses (fig. 17). The presence of unflushed relict seawater has been hypothesized as a source of brackish ground water in the shallow surficial aquifer system in parts of southwestern Florida (Sherwood and Klein, 1963; Schmerge, 2001). Evidence suggests, however, that relict seawater is not present in the lower Tamiami aquifer near Bonita Springs. For example, strontium isotope data indicate ground water in the area is from deeper discharging aquifers (Schmerge, 2001). Additionally, McCoy (1962) reports that flushing of most seawater in the shallow aquifers would have occurred since the Pleistocene based on ambient ground-water flow and recharge rates. According to Knapp and others (1986), the regional presence of unflushed water from sea inundations during Pleistocene interglacial stages is minimal.

SIMULATION OF SALTWATER INTRUSION NEAR BONITA SPRINGS

Numerical simulation is used to quantify modern and seasonal stresses, help identify mechanisms of saltwater intrusion, and estimate the potential extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs. Numerical codes were selected to (1) solve the constant-density ground-water flow equation, (2) solve the variable-density ground-water flow and solute transport equations, and (3) facilitate model calibration and sensitivity analysis in three dimensions (table 2). Model discretization, assignment of aquifer properties, and assignment of boundary conditions provided the spatial and temporal framework necessary for solving the finite-difference equations. A predevelopment distribution of saltwater was simulated, and the model was calibrated to typical and modern stresses. The potential movement of saltwater from predevelopment distribution to dynamic equilibrium with calibrated typical, modern, and seasonal stresses was then simulated. Modern stresses are represented as stresses with the desired characteristics.

Table 2. Description and primary use of modeling tasks

Task	Spatial discretization	Temporal discretization	Code[1]	Initial conditions	Primary use
1	105 rows, 80 columns, 17 layers[2]	One steady-state flow stress period, representing predevelopment (1930) conditions. Transient transport time steps	SEAWAT	Freshwater equivalent heads equal to zero, a wall of saltwater at coast	Estimate predevelopment salinity conditions and establish initial head and salinity conditions for predictive simulations of saltwater movement
2	Same as above	Two steady-state flow stress periods, representing March and September 1996 conditions. Transient transport time steps	MODFLOW-88	Heads at land surface	Obtain an accurate representation of March and September 1996 head and flow conditions
3	Same as above	1,200 alternating steady-state flow stress periods, representing March and September 1996.[3] Transient transport time steps.	SEAWAT	Final predevelopment distribution of freshwater equivalent head and salinity	Help identify mechanisms of saltwater intrusion and estimate the extent of saltwater intrusion in the lower Tamiami aquifer beneath Bonita Springs

Modeling Approach

The modeling approach for this study can be summarized by three tasks (table 2):

1. Variable-density simulation of predevelopment conditions,
2. Calibration of a constant-density flow model to typical, modern and seasonal stresses, and
3. Variable-density predictive simulations of saltwater movement to equilibrium with the typical, modern, and seasonal stresses.

The rationale and limitations for each modeling task, and solely simulating advective solute transport while neglecting the effects of dispersion, were considered.

The first task of simulating a predevelopment distribution of saltwater was performed so a comparison could be made between the distribution of saltwater under predevelopment conditions and the distribution of saltwater at equilibrium with typical, modern, and seasonal stresses. This comparison was made to determine the potential occurrence of saltwater intrusion. Additionally, the predevelopment simulation provided a no-flow boundary condition at the saltwater interface for model calibration in task 2. Another reason for simulating a predevelopment distribution of saltwater was to develop initial conditions of freshwater equivalent head and ground-water salinity that were internally self-consistent for predictive simulations of saltwater movement (task 3). While performing variable-density flow simulations, consistent initial conditions of equivalent freshwater head and salinity will result in a model that responds to the imposed hydrologic stresses rather than to disequilibrium of the initial conditions.

The second task in the modeling approach is model calibration. A constant-density ground-water flow simulator was chosen for this task for two reasons:

1. Matching observed heads and flows in the study area was not highly dependent upon simulating saltwater movement. Chloride concentrations in observation wells were about 100 to 1,300 mg/L (fig. 15), suggesting the bulk of the saltwater transition zone remains either offshore, between the monitoring wells and the coastline, or within deeper hydrogeologic units. Thus, the difference between hydraulic-head observations and their simulated equivalents (when modeling) was more likely attributable to uncertainties in aquifer properties and boundary conditions, rather than saltwater or saltwater movement.
2. Computer run times for constant-density ground-water flow simulations are much shorter than computer run times for variable-density flow simulations. Therefore, more time is available to test different conceptual models and parameter estimates while calibrating with a constant-density flow simulator. A limitation of this approach, however, was that the information contained in salinity observation could not be used to better estimate values of transport parameters, such as effective porosity and dispersivity. These parameters are important to solute transport, and thus saltwater movement.

The model was calibrated to typical, modern, and seasonal stresses with certain attributes. A year with "typical" stresses was selected to prevent approximations of saltwater movement from being biased toward wet or dry years. A year with "modern" stresses was selected to determine whether natural and anthropogenic stresses such as recharge, ground-water withdrawal, canal drainage, and sea level would move saltwater to areas previously occupied by fresher waters. "Seasonal" stresses were represented to test theories that alternating wet- and dry-season water levels move saltwater into and out of the lower Tamiami aquifer, respectively, but result in no net saltwater intrusion over a typical water year.

Typical, modern, and seasonal stresses were observed during 1996, so this year was chosen for model calibration. The year 1996 (which had about 1.3 m of rainfall) was selected as "typical" after plotting average annual rainfall values at Bonita Springs Utility rainfall monitoring station (fig. 18). The rainfall data indicate that 1995 represents a wet year (with about 2.1 m of rainfall) and 1950 represents a dry year (with about 1.1 m of rainfall). The average of annual rainfall values in figure 18 is about 1.4 m. The 1996 year also was selected because: (1) pumpage data obtained from the SFWMD began that year, and (2) numerous water-level and flow measurements were taken near Bonita Springs that year relative to other years. Perhaps the flooding of Bonita Springs during the heavy rains of 1995 (Johnson Engineering, Inc., and others, 1999) prompted increased awareness about the importance of data collection during 1996.

During model calibration, seasonal fluctuations in water levels were approximated by designing two steady-state flow stress periods, representing time periods in 1996 when water levels were high (wet

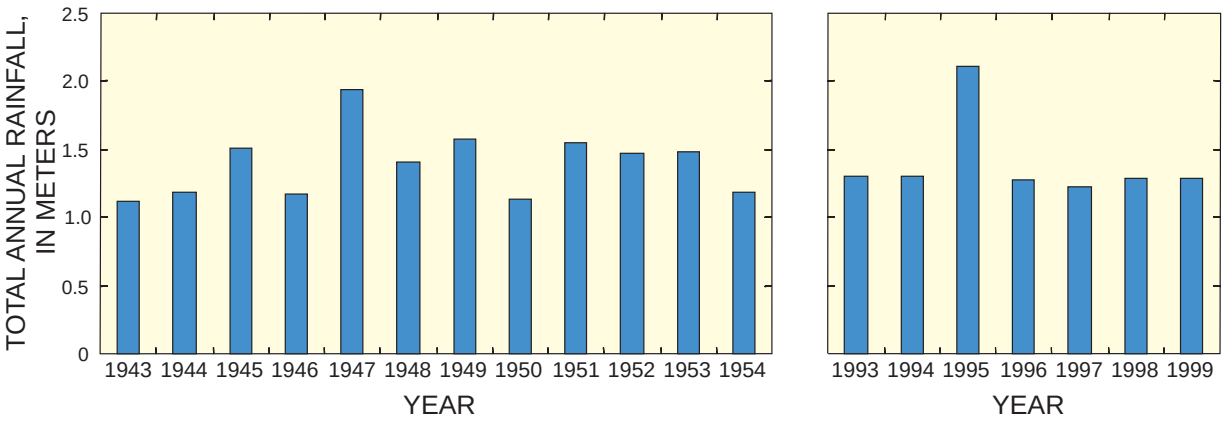

Figure 18. Historical record of annual rainfall at Bonita Springs Utility rainfall monitoring station, 1943-54 and 1993-99.

season) and low (dry season) (table 2). By simulating periods with high and low water levels, the seasonal movement of the saltwater interface can be approximated. Additionally, a steady-state approach can be employed when the selected time periods show relatively stable water levels, suggesting the ground-water flow system is as close to steady state as realistically possible. There are two advantages to using the steady-state approach. First, a steady-state model does not require aquifer storage values. This eliminates the need to specify an additional parameter, which may be highly uncertain. Second, steady-state models tend to run faster than transient models because there are fewer input requirements and fewer solutions to the flow equation. Shorter computer run times allow more time for calibration and sensitivity analysis. A disadvantage of the steady-state approach is the possibility of developing a model that may fail to represent transient particularities important to the true nature of ground-water flow and saltwater movement near Bonita Springs.

March and September 1996 were selected to represent typical, modern, and seasonal stresses because ground-water levels in the water table and lower Tamiami aquifers generally were at or near seasonal lows and highs and also were relatively stable (fig. 19), justifying the steady-state assumption. Given these data and the above considerations, developing a model with two steady-state stress periods calibrated to average March and September 1996 conditions seemed to be a reasonable representation of typical, modern, and seasonal stresses.

Most ground-water models are calibrated by adjusting hydraulic conductivity until simulation results match with observed field conditions. The model documented here was calibrated by assuming hydraulic conductivity parameters were accurate, and estimating unmonitored ground-water pumpage and pan evaporation multipliers using UCODE. Unmonitored ground-water pumpage was estimated because unknown pumpage parameters caused the largest discrepancies between observed and simulated heads near the coast in the lower Tamiami aquifer beneath Bonita Springs. Accurately simulated heads in this location are most important for accurately simulating saltwater movement in this location, which was a primary objective of this study. Pan evaporation multipliers were estimated simultaneously with unmonitored pumpage because pan evaporation parameters were the most sensitive model parameters that were not correlated with unknown pumpage. Correlated parameter values cannot be simultaneously estimated by parameter estimation codes, such as UCODE. This is because coordinated linear changes in correlated parameter values produce the same simulated heads and flows at observation locations (Poeter and Hill, 1997).

The third task in the modeling approach was to simulate the movement of saltwater to equilibrium with the typical, modern, and seasonal stresses. This task was accomplished using the predevelopment distribution of saltwater and calibrated March and September 1996 steady-state flow stress periods. The calibrated steady-state flow stress periods were run in continual succession with a variable density ground-water flow simulator until the total salt mass in the simulation approached “dynamic equilibrium.” At dynamic equilibrium, the average annual total salt mass in the simulation is a constant value, even though some seasonal fluctuation in total salt mass may occur between stress periods.

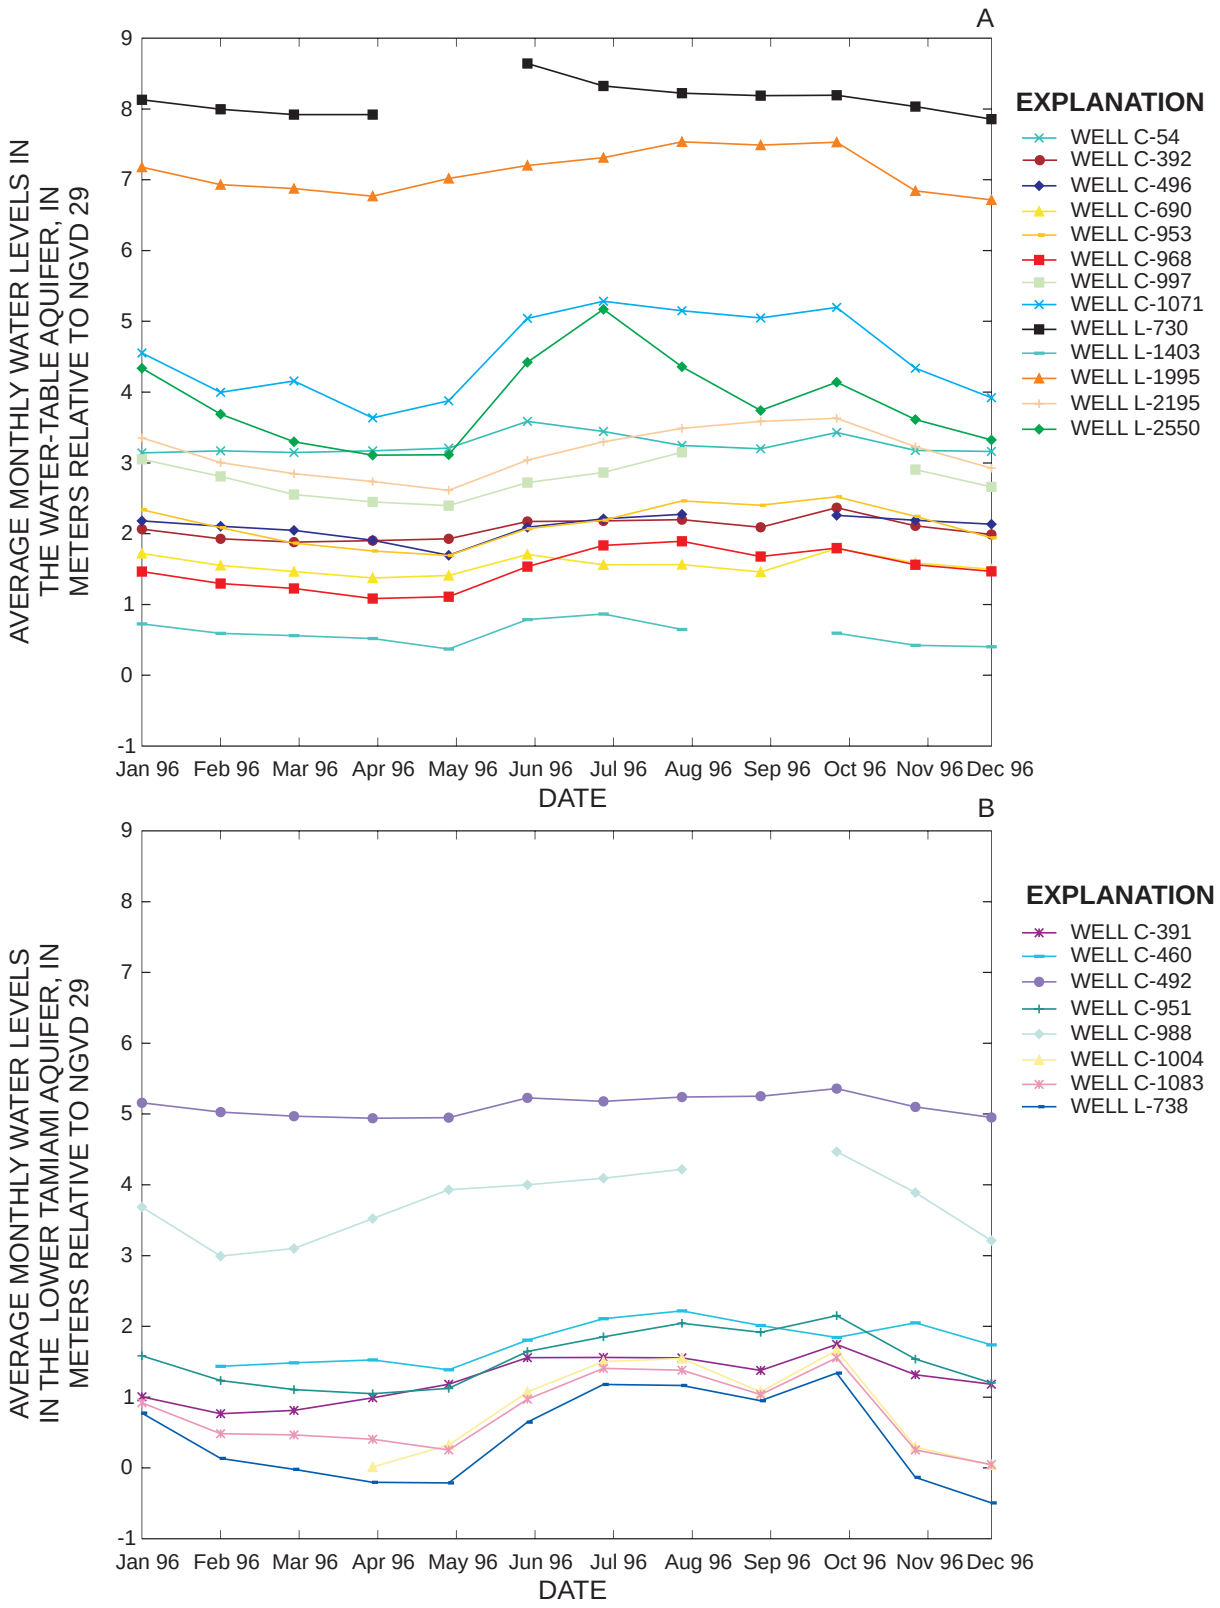

Figure 19. Average monthly water levels from selected monitoring wells in the (A) water-table and (B) lower Tamiami aquifers near Bonita Springs. Well locations are shown in figure 1. NGVD 29 is National Geodetic Vertical Datum of 1929.

Steady-state flow conditions were used for task 3 by assigning a small value (1×10^{-8}) for aquifer storage properties. This means that within each transport step, heads respond instantaneously (or nearly instantaneously) to changes in salinity. Thus, heads and flows for a particular transport step are always of steady state with salinity for that transport step. This approach is a simpler alternative than trying to determine appropriate storage values and run a fully transient model.

Advective solute transport was simulated while solving for the predevelopment distribution of saltwater and solving for the potential movement of saltwater from predevelopment distribution. Dispersive solute transport was not simulated. According to traditional advection-dispersion theory, hydrodynamic dispersion is the tendency for a solute to spread from the path it would be expected to follow according to advective hydraulics (Freeze and Cherry, 1979). Hydrodynamic dispersion results from molecular diffusion and mechanical dispersion. Molecular diffusion, the process by which a plume spreads due to concentration gradients, is small enough in magnitude to be ignored in ground-water flow systems with velocities as high as the system near Bonita Springs. Mechanical dispersion, another process by which a plume spreads, is caused by small-scale velocity variations.

Rather than assign dispersivity values, which would contain a high level of uncertainty, the numerical dispersion caused by the model was assumed to be similar in magnitude to the actual dispersion in the aquifer. Although there was no way to evaluate this assumption, it seemed justified by a lack of field data that could be used to calibrate dispersivity values and considerably long computer run times for simulations that directly represented dispersion. Neglecting dispersion may cause the potential extent of saltwater intrusion to be overestimated. This limitation is discussed in more detail in the model limitation section of the report. If field data are available, the effects of dispersion could be evaluated with future simulations of saltwater intrusion.

Code Selection

Two modular, three-dimensional, finite-difference models were used to simulate ground-water flow and salinity transport in this study (table 2). MODFLOW (McDonald and Harbaugh, 1988) was chosen as the constant-density ground-water flow simulator, and SEAWAT (Guo and Langevin, 2002) was chosen as the variable-density ground-water flow simulator.

Constant-Density Ground-Water Flow Simulator

MODFLOW (McDonald and Harbaugh, 1988), widely accepted by the modeling community as a reliable tool, was chosen as the constant-density ground-water flow simulator. This program was used to solve the following steady-state ground-water flow equation:

$$\frac{\partial}{\partial x}\left(K_{xx}\frac{\partial h}{\partial x}\right)+\frac{\partial}{\partial y}\left(K_{yy}\frac{\partial h}{\partial y}\right)+\frac{\partial}{\partial z}\left(K_{zz}\frac{\partial h}{\partial z}\right)-W=0\ , \quad (2)$$

where K_{xx}, K_{yy}, and K_{zz} are values of hydraulic conductivity along the x-, y-, and z-coordinate axes, which are assumed to be parallel to the major axes of hydraulic conductivity [LT^{-1}]; h is the potentiometric head [L], and W is a volumetric flux per unit volume and represents sources and/or sinks of water [T^{-1}].

Variable-Density Ground-Water Flow Simulator

SEAWAT (Guo and Langevin, 2002), capable of solving for variable-density ground-water flow patterns in three dimensions, was chosen as the variable-density ground-water flow simulator. The SEAWAT program explicitly or implicitly couples a variable-density form of the ground-water flow equation solved with MODFLOW-88 (McDonald and Harbaugh, 1988) to the solute transport equation solved with MT3Dms (Zheng and Wang, 1998). Because MT3Dms is used, solute concentrations or salinities are approximated with transient, three-dimensional, variable-density, ground-water flow patterns. Several methods are available to solve the advection and dispersion terms of the transport equation using MT3Dms (Zheng and Wang, 1998). Thus, the user can experiment to find a solution with acceptable levels of numerical dispersion and/or artificial oscillation while attempting to maintain a reasonable computer run time.

SEAWAT reformulates the ground-water flow equation to solve for freshwater equivalent head as follows:

$$\frac{\partial}{\partial x}\left(\rho K_{fx}\left[\frac{\partial h_f}{\partial x}+\frac{\rho-\rho_f}{\rho_f}\frac{\partial Z}{\partial x}\right]\right)+$$
$$\frac{\partial}{\partial y}\left(\rho K_{fy}\left[\frac{\partial h_f}{\partial y}+\frac{\rho-\rho_f}{\rho_f}\frac{\partial Z}{\partial y}\right]\right)+$$
$$\frac{\partial}{\partial z}\left(\rho K_{fz}\left[\frac{\partial h_f}{\partial z}+\frac{\rho-\rho_f}{\rho_f}\frac{\partial Z}{\partial z}\right]\right)=$$
$$\rho S_f\frac{\partial h_f}{\partial t}+\theta\frac{\partial \rho}{\partial C}\frac{\partial C}{\partial t}-\bar{\rho}q_s \quad , \quad (3)$$

where x, y, and z are the principal directions of permeability,

ρ is fluid density [M/L^3],

K_f is the freshwater hydraulic conductivity [L/T],

h_f is the freshwater equivalent head [L],

ρ_f is the density of freshwater [M/L^3],

Z is the vertical direction or elevation of the center of the model cell [L],

S_f is the freshwater equivalent storage coefficient [L^{-1}],

t is time [T],

θ is effective porosity [dimensionless],

C is the solute concentration [M/L^3],

$\bar{\rho}$ is the density of water from the source or sink [M/L^3], and

q_s is the volumetric flux of water representing sources and sinks per unit volume of aquifer [T^{-1}].

The reformulated ground-water flow equation is coupled to the following solute-transport equation:

$$\nabla(D\nabla C)-\nabla\bullet(\hat{v}C)-\frac{q_s}{\theta}C_s+\sum_{k=1}^{n}R_k=\frac{\partial C}{\partial t}, \quad (4)$$

where

D is the hydrodynamic dispersion coefficient [L^2/T],

∇ is the spatial gradient operator,

$\hat{v}$ is the fluid velocity vector [L/T],

C_s is the solute concentration of the source or sink [M/L^3], and

R_k is the rate of solute production or decay in reaction k of n different reactions [M/L^{3}T].

Equations 3 and 4 are sequentially solved by first solving the variable-density ground-water flow equation and then solving the solute-transport equation. After new concentrations are calculated, a linear equation of state is used to relate solute concentrations to fluid density. The linear equation of state is:

$$\rho = \rho_f + EC \quad , \quad (5)$$

where E is an empirical, dimensionless constant with an approximate value of 0.7143 for salts commonly found in seawater.

Spatial Discretization and Assignment of Aquifer Properties

Finite-difference methods require the discretization of space into a grid consisting of rows, columns, and layers of model cells. Additionally, ground-water flow is proportional to the horizontal and vertical permeability properties of the aquifer matrix, and advective and dispersive solute transport is dependent upon the effective porosity of the aquifer matrix. Thus, in a three-dimensional, finite-difference SEAWAT model using the robust layer type 3 option (LAYCON 3), information describing the grid discretization, horizontal hydraulic conductivity, vertical conductance (VCONT) (McDonald and Harbaugh, 1988), and effective porosity must be written to model input files. The aquifer property information must be assigned to model cells in a way that reflects the bulk occurrence of these properties within the entire volume of the model cell.

The study area was spatially discretized into a grid with 105 rows, 80 columns, and 17 layers of square cells. Seventeen layers were used to obtain sufficient vertical resolution of the saltwater interface. Each model cell is 600 by 600 m and 5 m thick, except for layer 1 where the cell top varies to match land surface, and the cell bottom is 5 m below National Geodetic Vertical Datum (NGVD) of 1929. Uniform cell volumes were used, except for layer 1, to minimize mass-balance errors that could occur if a mixed Eulerian-Lagrangian method was needed to solve the advection term of the transport equation. Examples of such a method with MT3Dms are the method of characteristics (MOC), modified method of characteristics (MMOC), or hybrid method of characteristics (HMOC). Eulerian-Lagrangian methods do not guarantee local mass conservation at a particular time step because of the discrete nature of particle tracking used in these techniques (Zheng and Wang, 1998).

Mass-balance errors can be exacerbated by nonuniform cell volumes.

Bulk values of horizontal hydraulic conductivity and VCONT were assigned to model cells using a three-dimensional conceptual permeability model, the configuration of the model grid, and weighted arithmetic or harmonic averaging. The three-dimensional conceptual permeability model was developed by assigning the values of horizontal and vertical hydraulic conductivity, shown in table 3, to the framework of the water-table aquifer, Tamiami confining beds, lower Tamiami aquifer, upper Hawthorn confining unit, and sandstone aquifer. Because hydraulic conductivity typically is considered to be log-normally distributed, permeability values were assigned (as described below) using the log K histograms of aquifer horizontal hydraulic conductivity (fig. 4) compiled from: (1) previous literature (Bower and others, 1990), and (2) reanalysis of previous aquifer performance tests (K.M. Edwards, U.S. Geological Survey, written commun., 2000).

Table 3. Hydraulic conductivities used in the conceptual permeability model

Hydrogeologic unit	Hydraulic conductivity (meters per day)	
	Horizontal	Vertical
Water-table aquifer	300	15
Tamiami confining beds	.04	.004
Lower Tamiami aquifer	70	3.5
Lower Tamiami aquifer, coral reef facies	130	6.5
Upper Hawthorn confining unit	.03	.003
Sandstone aquifer	20	2

The water-table aquifer was assigned a horizontal hydraulic conductivity of 300 m/d (table 3). The horizontal hydraulic conductivity was based on the inverse log of the midpoint of the first mode in the distribution of 244 measurements (fig. 4A). A vertical hydraulic conductivity of 15 m/d was assigned to the water-table aquifer (table 3) because reanalysis of aquifer performance tests in the study area by K.M. Edwards (U.S. Geological Survey, written commun., 2000) suggests that the anisotropy ratio of horizontal to vertical hydraulic conductivity is about 20:1 in the water-table aquifer.

The Tamiami confining beds and the upper Hawthorn confining unit were assigned horizontal hydraulic conductivities of 0.04 and 0.03 m/d, respectively, and vertical hydraulic conductivities of 0.004 and 0.003 m/d, respectively (table 3). The same vertical hydraulic conductivities (0.004 and 0.003 m/d) were measured by Montgomery (1988). Little published information was available to constrain values of horizontal hydraulic conductivity for both confining units. In modeling applications, the ratio of horizontal hydraulic conductivity to vertical hydraulic conductivity is often assumed to range from 1 to 1,000 (Anderson and Woessner, 1992). Thus, the horizontal hydraulic conductivities of the Tamiami confining beds and the upper Hawthorn confining unit were set to 0.04 and 0.03 m/d, respectively, or 10 times the measured vertical hydraulic conductivity found by Montgomery (1988). This may seem somewhat arbitrary, but the results of ground-water flow models typically are insensitive to values of horizontal hydraulic conductivity in confining units. Because of the low permeability of these units, horizontal flow within them is essentially negligible.

In the lower Tamiami aquifer, horizontal hydraulic conductivity appears to have a bimodal log K distribution (fig. 4B). Results from aquifer performance tests compiled for this study (figs. 4B and 8) and for previous research (Meeder, 1979) suggest that permeabilities in the lower Tamiami aquifer are much greater in areas where coral reef facies are present. The lower Tamiami aquifer was assigned a horizontal hydraulic conductivity value of 130 m/d in areas where the coral reef facies are known to exist (table 3). This value was the inverse log of the arithmetic average log K value computed from eight aquifer performance tests completed in coral reef facies (fig. 8). Elsewhere, the lower Tamiami aquifer was assigned a horizontal hydraulic conductivity of 70 m/d (table 3) –the inverse log of the arithmetic average log K value computed from 136 measurements (fig. 4B). A vertical hydraulic conductivity value of 6.5 m/d was assigned in areas of the lower Tamiami aquifer where coral reef facies are present and 3.5 m/d elsewhere because reanalysis of aquifer performance tests suggests the anisotropy ratio of horizontal to vertical hydraulic conductivity is about 20:1 in the aquifer.

The sandstone aquifer was assigned a horizontal hydraulic conductivity of 20 m/d and a vertical hydraulic conductivity of 2 m/d (table 3). The horizontal hydraulic conductivity was based on the inverse log of the arithmetic average log K value computed from the distribution of 25 measurements (fig. 4C). Little published information was available to constrain values of vertical hydraulic conductivity for the sandstone aquifer. The vertical hydraulic conductivity was based on the 1 to 1,000 range of vertical to horizontal conductivity ratios. Thus, the vertical hydraulic conductivity of the sandstone aquifer was set to 2 m/d, or one-tenth the horizontal hydraulic conductivity. Again, this may seem somewhat arbitrary, but model results are expected to be insensitive to the vertical hydraulic conductivity of the sandstone aquifer. Because the focus of this study is the lower Tamiami aquifer, flow into or out of the aquifer will be controlled more by the vertical hydraulic conductivity of the underlying upper Hawthorn confining unit than the vertical hydraulic conductivity of the sandstone aquifer.

Because the hydrogeologic units do not coincide with model layers, bulk values of horizontal hydraulic conductivity (fig. 20) were computed as the weighted arithmetic mean of the hydraulic conductivities (table 3) that lie within the model cell (fig. 21). The weighted arithmetic mean is expressed as:

$$Kxy_{i,\ j,\ k} = \sum_{u=1}^{n} W_u Kxy_u \quad , \qquad (6)$$

where $Kxy_{i,j,k}$ is the bulk horizontal hydraulic conductivity of the model cell i,j,k [L/T], u is a counter ranging from 1 to n, in which n is the number of hydrogeologic units within the model cell [dimensionless], W_u is weight representing the fraction of the model cell's thickness occupied by the hydrogeologic unit (the sum of the weights for each model cell must equal 1 [dimensionless]), and Kxy_u is the horizontal hydraulic conductivity of the hydrogeologic unit [L/T].

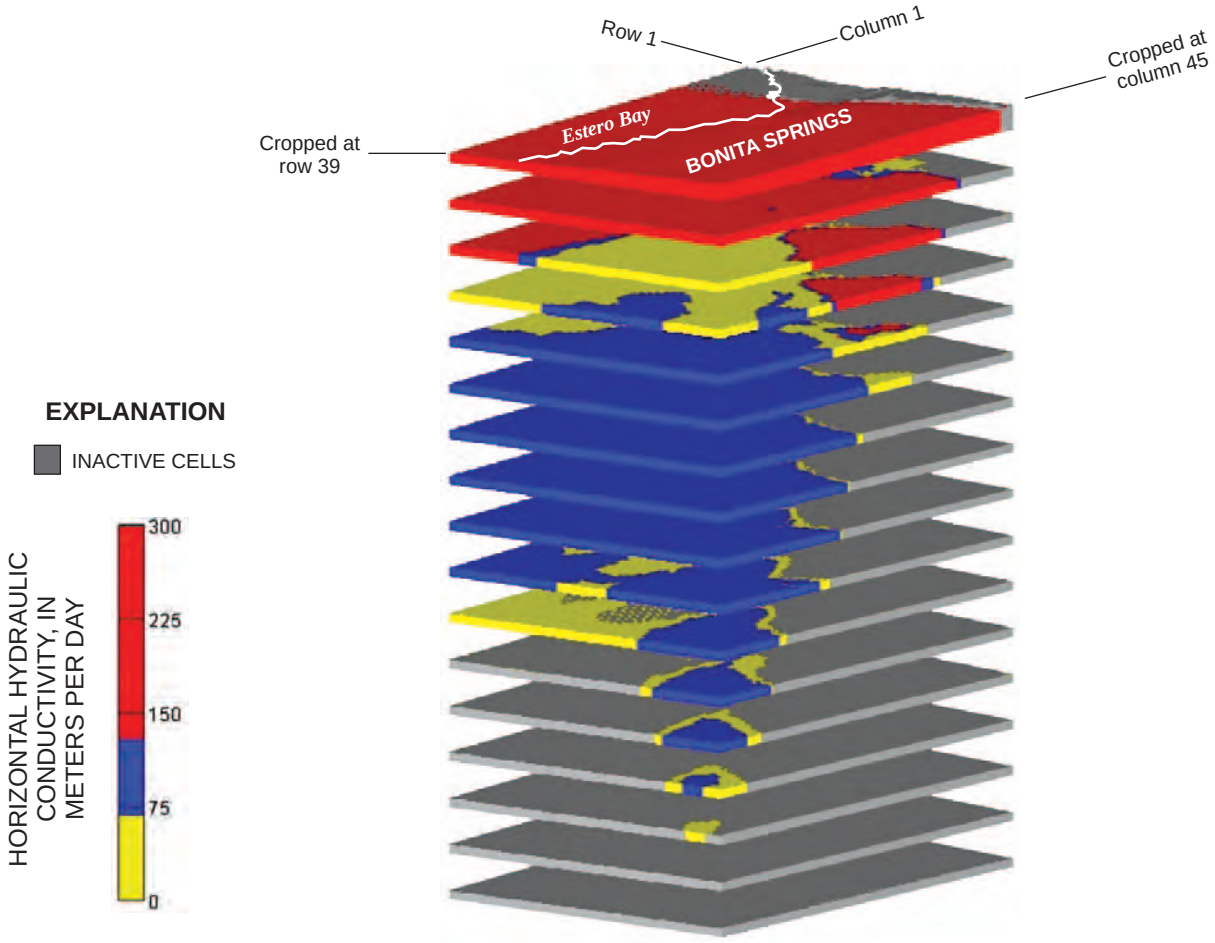

Figure 20. Distribution of bulk horizontal hydraulic conductivity in selected model cells.

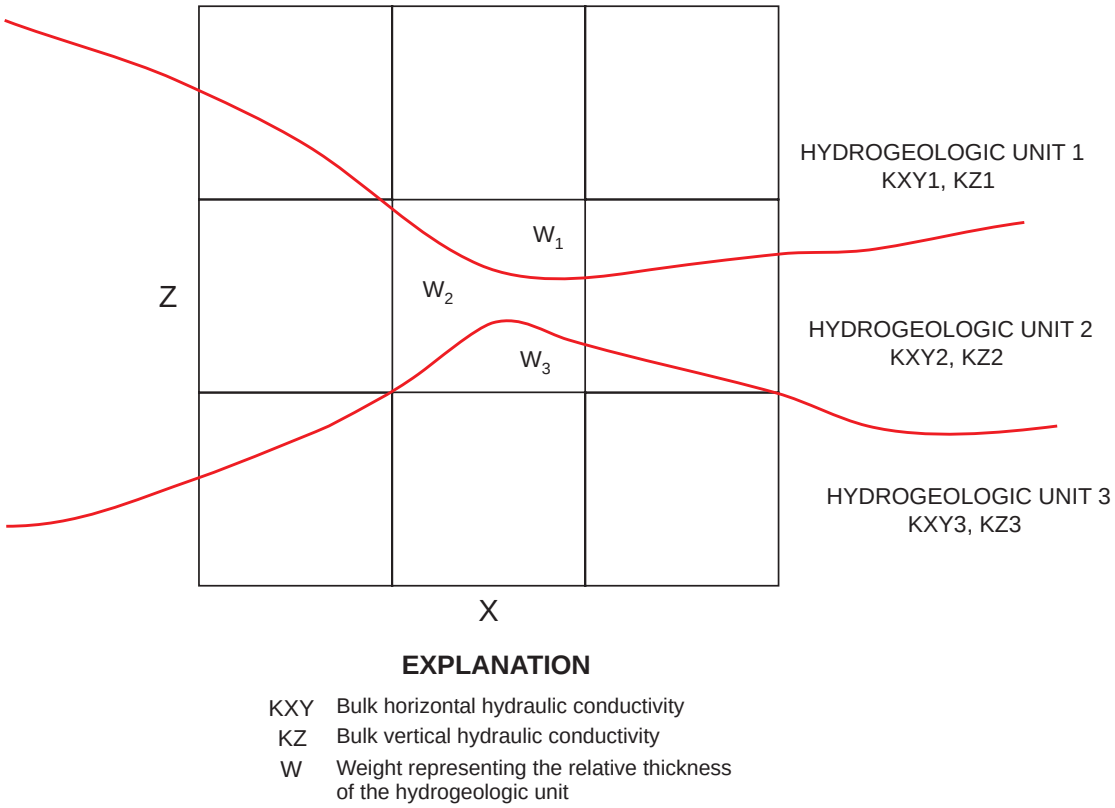

Figure 21. Approach used to compute bulk hydraulic conductivities for each model cell using weighted arithmetic and harmonic averaging.

Bulk values of vertical hydraulic conductivity for model cells were computed as the weighted harmonic mean of hydraulic conductivities (table 3) that lie within the model cell (fig. 21). A three-dimensional diagram of bulk values of vertical hydraulic conductivity would look similar to the three-dimensional diagram of bulk values of horizontal hydraulic conductivity (fig. 20), except values would range would from 15 to 0.003 m/d. The weighted harmonic mean is expressed as:

$$Kz_{i,\ j,\ k} = \frac{1}{\sum_{u=1}^{n} W_u \frac{1}{Kz_u}}, \qquad (7)$$

where $Kz_{i,j,k}$ is the bulk vertical hydraulic conductivity of the model cell [L/T], and Kz_u is the vertical hydraulic conductivity of the hydrogeologic unit [L/T].

Except for the bottom layer (layer 17), a VCONT term is required input for each model cell in a MODFLOW or SEAWAT simulation. Bulk values of VCONT were computed as:

$$VCONT_{i,\ j,\ k} = \frac{2(Kz_{i,\ j,\ k})(Kz_{i,\ j,\ k+1})}{\Delta b_{i,\ j,\ k}(Kz_{i,\ j,\ k}) + \Delta b_{i,\ j,\ k+1}(Kz_{i,\ j,\ k+1})}, \qquad (8)$$

where $VCONT_{i,j,k,}$ is the required VCONT term [1/T], and $\Delta b_{i,j,k}$ is the thickness of the model cell [L].

Estimates of effective porosity were needed for variable-density ground-water flow simulations. Effective porosity, the percentage of interconnected pore space within geologic material, was uniformly set to 30 percent. This percentage is based on analysis of exploratory cores collected from the gray limestone and lower Tamiami aquifers in the study area (Reese and Cunningham, 2000).

Simulation of Predevelopment Conditions

In the first modeling task, the SEAWAT program was used to simulate the location of the interface prior to development. The year 1930 was selected to represent predevelopment conditions primarily because the network of canals had not yet been constructed (Ananta Nath, Big Cypress Basin, oral commun., 2001), and ground-water pumpage probably was negligible. A single steady-state stress period was used to represent conditions in 1930. The spatial discretization and aquifer properties previously described were used for the simulation. Results from the predevelopment model consist of three-dimensional distributions of head and salinity. These model results are used to help define a coastal boundary condition for model calibration (task 2). Results from the predevelopment simulation also are used as initial conditions for predictive simulations of saltwater movement (task 3).

Boundary Conditions

Boundary conditions for simulating the predevelopment distribution of saltwater include rainfall, evapotranspiration, rivers, lateral conditions of no flows, and constant heads with constant concentrations (pl. 1). Rainfall and evapotranspiration boundary conditions were used to allow the simulation to calculate the net recharge to the top of active model cells located inland from the coastline. Because rainfall and evapotranspiration are assigned to active cells in layer 1, these boundary conditions are not shaded nor labeled on plate 1. River boundary conditions were used to represent Spring Creek, and the Imperial, Cocohatchee and Estero Rivers. No-flow boundary conditions were used to represent predevelopment hydrologic divides that were assumed to exist along modern ground-water flow lines. Because each cell in layers 16 and 17 is a no-flow boundary condition, only layers 1 to 15 are plotted on plate 1. Layers 16 and 17 were kept in the model, however, in case they are needed to represent deeper hydrogeologic units in future investigations. Constant-head and constant-concentration boundary conditions were used to represent the Gulf of Mexico. The salinity of inflow from each source boundary condition was set to zero, with exception to the boundary conditions representing the Gulf of Mexico, which were assigned a salinity of seawater.

Recharge

Limited data were available that describe recharge in 1930; therefore, recharge was simulated using the approach described by Motz (1996) and Stewart and Langevin (1999). Using this approach, both rainfall and evapotranspiration are included in the model, with the maximum potential ground-water evapotranspiration rate set equal to the rainfall rate. This creates an aquifer system where water levels are controlled by land-surface topography (Motz, 1996). Using this method to simulate recharge is advantageous because spatial distributions of net recharge are generated rather than discrete zones. Disadvantages include the potential for additional uncertainty in model simulations due to the lack of data to support estimates of rainfall, maximum potential evapotranspiration rates, extinction depths, and the evapotranspiration surface.

Rainfall was entered using the Recharge package (McDonald and Harbaugh, 1988). The Recharge package requires input of an areal flux [L/T] to the top grid layer, a specified vertical distribution of layers, or the highest active cell in a vertical column of layers. The areal recharge flux was added to the highest active cell in a vertical column of layers. Average annual rainfall rates were computed from historical rainfall recorded at the Bonita Springs monitoring station from 1943 to 1999 (fig. 18). Years with no average annual rainfall rate indicate missing or insufficient data (1955-92). No trends of annual average rainfall rates are evident, thus an extrapolation relation to compute the average annual rainfall rate in 1930 was not necessary. The average of annual average rainfall rates was about 1.3 m/yr and was written as the areal flux in the Recharge package.

Evapotranspiration was entered using the Evapotranspiration package (McDonald and Harbaugh, 1988) where evapotranspiration is approximated as a linearly varying rate that is greatest at the evapotranspiration surface and decreases to zero at the extinction depth. As required by the coupled aquifer approach, the maximum evapotranspiration rate of the evapotranspiration surface was set equal to the rainfall rate. The evapotranspiration surface was set to land surface, and extinction depths were set to 5 m below land surface.

Extinction depths are uncertain in the study area. Extinction depths at about 0.3 to 2.1 m were used in previous modeling studies of southwestern Florida (Bower and others, 1990; Bennett, 1992). These depths were related to land use and based upon estimated root depths for various types of vegetation. In addition to vegetation root depth, evapotranspiration is

dependent upon other processes and properties, such as climate and soil type. For example, fine-grained soils will have deeper extinction depths than coarse-grained soils because more energy is required to lift ground water through coarse-grained soils.

A network of evapotranspiration stations maintained in southern Florida by the USGS suggests extinction depths of at least 1 m over many types of land cover (S.L. Kinnaman, U.S. Geological Survey, written commun., 2001). Tibbals (1990) estimated evapotranspiration rates of about 76 cm/yr in areas where the water table was about 4 m below land surface in east-central Florida. Merritt (1996) used extinction depths up to 6 m below land surface in a coastal ridge area of southeastern Florida. Setting extinction depths to 5 m below land surface seemed to be a reasonable compromise, given the current understanding of evapotranspiration in Florida.

Rivers

Predevelopment river boundary conditions (pl. 1) were entered using the River package (McDonald and Harbaugh, 1988). The conceptual model for the River package is based on the vertical leakage of water across river bottom sediments. The cross section of the river is conceptualized in the model code as rectangular with impermeable vertical sides. Leakage into or out of the model cell is dependent on the stage in the river (h_{riv}), the value of head in the model cell ($h_{i,j,k}$), and a conductance term. The conductance term of the river is mathematically defined as:

$$COND_{riv} = \frac{LwK_{seds}}{b_{seds}}, \qquad (9)$$

where $COND_{riv}$ is the conductance of the river bed [L^2/T],

L is the length of the river segment in the model cell [L],

w is the bottom width of the river [L],

K_{seds} is the vertical hydraulic conductivity of the river bottom sediments [L/T], and

b_{seds} is the thickness of the river bottom sediments [L].

The elevation of the base of the river bottom sediments is specified as *RBOT*, an input parameter for the River package. When $h_{i,j,k}$ is greater than *RBOT*, leakage from the aquifer to the river, Q_{riv}, is calculated as:

$$Q_{riv} = COND_{riv}(h_{riv} - h_{i,\ j,\ k}) . \qquad (10)$$

When $h_{i,j,k}$ is less than *RBOT*, the leakage rate from the river to the aquifer is calculated as:

$$Q_{riv} = COND_{riv}(h_{riv} - RBOT) . \qquad (11)$$

The Estero River, Imperial River, Cocohatchee River, and Spring Creek (fig. 1) were simulated with the River package. These surface-water features were digitized from a USGS 1:100,000-scale topographic-bathymetric map. For predevelopment conditions, an attempt was made to digitize only parts of the river and creek channels that appeared to be unaltered. Input for the River package includes the layer, row, column, h_{riv}, $COND_{riv}$, and *RBOT*. The layer, row, and column of river cells were determined by overlying the digitized river features with the model grid. The river stage, h_{riv}, was estimated at 0.5 m below the land-surface elevation of the model cell because this value seems reasonable, and no quantitative data describing river stages in 1930 exist. For each river cell, $COND_{riv}$ was computed by multiplying the area of the river or creek channel within the model cell by K_{seds} . The value of K_{seds} is assumed to be 15 m/d, which is the vertical hydraulic conductivity used for the water-table aquifer (table 3); the value of b_{seds} was set to 1 m for lack of a better value, and the value of *RBOT* was estimated at 2 m less than h_{riv}.

There may be some reason for concern about the lack of predevelopment data for assigning river parameter values. It is likely, however, that these parameters have little effect on the goal of this simulation, which is to simulate a predevelopment distribution of saltwater. River parameters control a relatively small component of the water budget in this simulation; namely, flow between the aquifer and surface-water features. Parameters that control small components of the water budget typically are less sensitive than parameters that control large components of the water budget.

No Flow

Ground-water divides observed in the water-table and lower Tamiami aquifers during March and September 1996 (fig. 22) were represented as no-flow boundary conditions in the predevelopment simulation (pl. 1). Representing a ground-water divide as a no-flow boundary is conceptually consistent with the actual behavior of the divide; ground water on each side of the divide moves away, and no flow crosses the divide (Reilly, 2001).

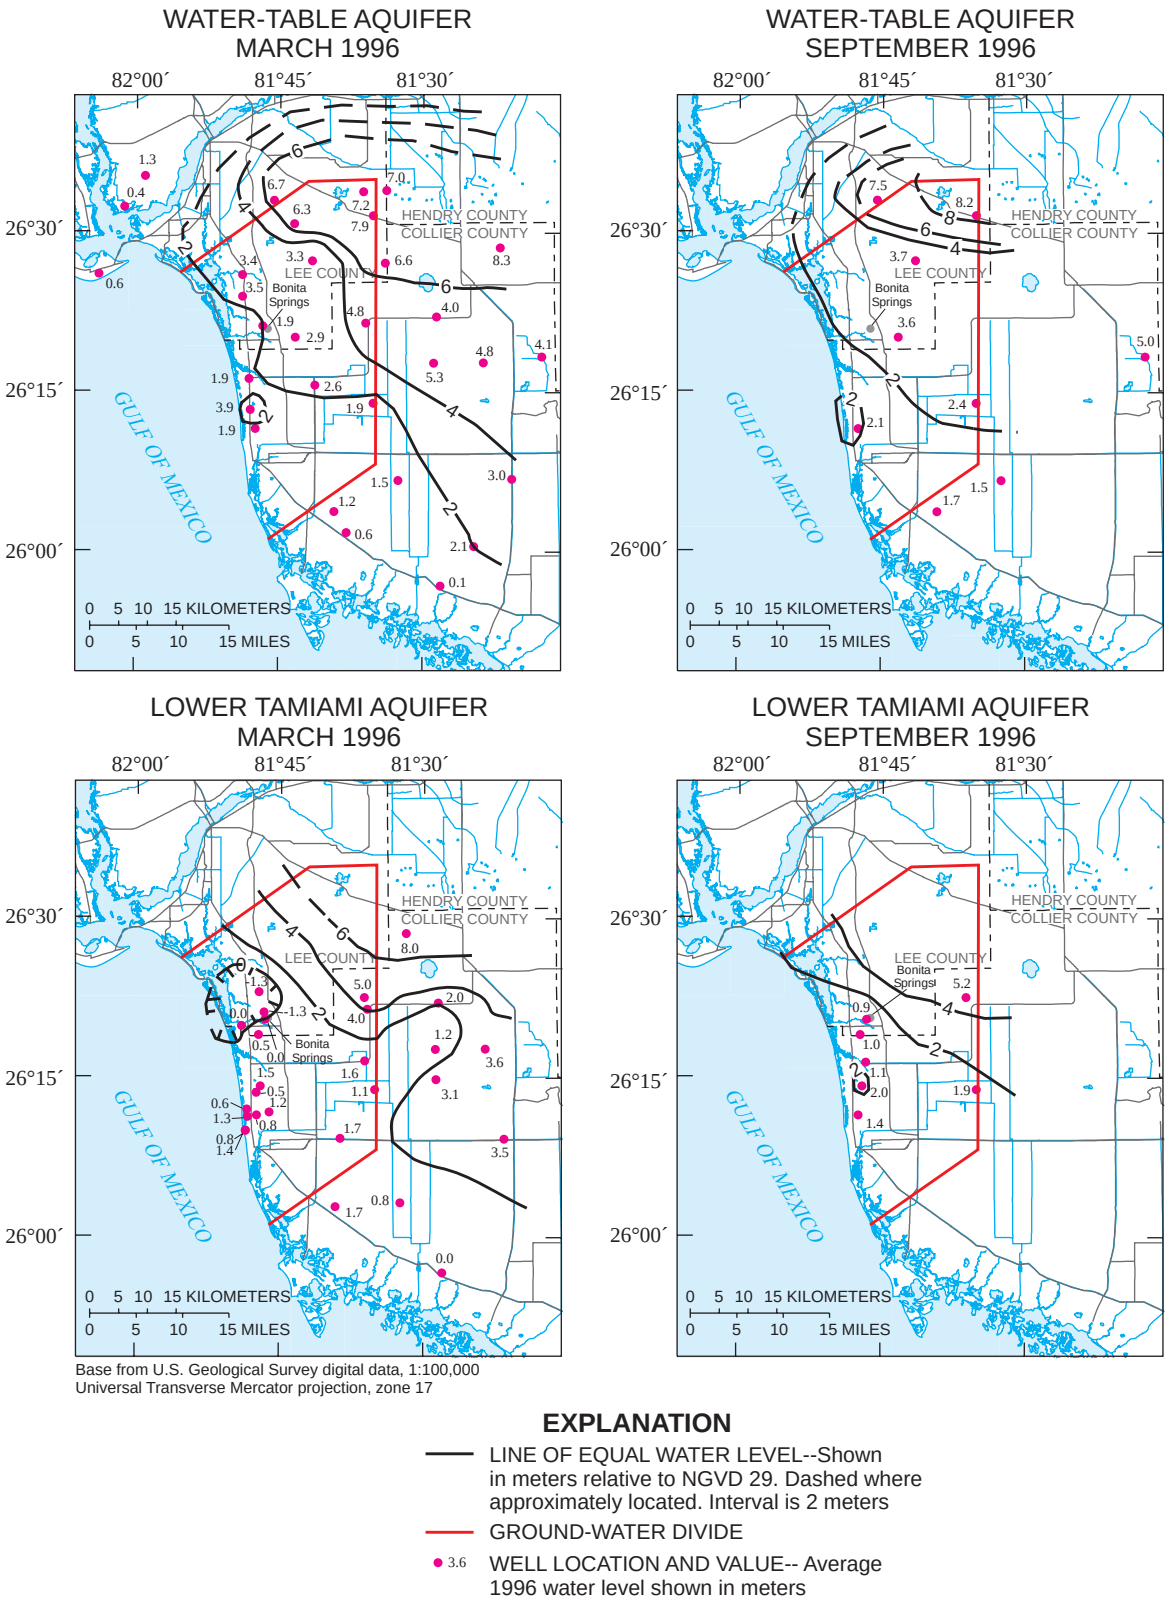

Figure 22. Average monthly water levels in the water-table and lower Tamiami aquifers during March and September 1996. NGVD 29 is National Geodetic Vertical Datum of 1929.

Ground-water divides observed in the water-table and lower Tamiami aquifers during March and September 1996 may or may not have been in the same location in 1930. It seems reasonable to expect that the northern and southern ground-water divides remain relatively stable. Recharge on the Florida Peninsula creates a mound of ground water in aquifers above sea level, resulting in flow from inland areas toward the coast. Additionally, contemporary ground-water withdrawal near these northern and southern divides is less prevalent, resulting in less opportunity for stress to move the location of these divides. The location of the eastern ground-water divide during 1930, however, is more uncertain; in fact, the divide may never have existed. This boundary condition probably is far enough away from the saltwater transition zone in the lower Tamiami aquifer to have little consequence on model results. Regardless, a better method for approximating the location of lateral predevelopment boundary conditions would reduce uncertainty in model results.

Constant Heads and Concentrations

Constant-head boundary conditions were entered into SEAWAT using the IBOUND and Shead arrays of the Basic package (McDonald and Harbaugh, 1988). An integer value less than zero in the IBOUND array of the Basic package indicates that the model cell has a constant-head throughout the simulation. The constant-head value will be equal to a real number entered in the same location of the Shead array of the Basic package. Constant-concentration boundary conditions were entered using the ICBUND array in the Basic Transport package and the Source Sink Mixing package (Zheng and Wang, 1998). An integer value less than zero in the ICBUND array of the Basic Transport package indicates the model cell has a constant concentration equal to a value specified for that model cell in the Source Sink Mixing package.

Constant-concentration boundary conditions were used for layer 1 and along the western boundary of the model in layers 2 to 15 to represent the Gulf of Mexico (pl. 1). The boundary conditions were assigned a constant salt concentration equal to 35 kg/m^3 (the salinity of seawater).

Constant-head boundary conditions were used in layer 1 and along the western boundary of the model in layers 2 to 15 to represent the Gulf of Mexico (pl. 1). Constant-head values representing the Gulf of Mexico in 1930 were assigned by: (1) computing the average value of sea level in 1996 using daily sea level measurements recorded at National Oceanic and Atmospheric Administration (NOAA) station 8725110 (not shown), (2) extrapolating sea level backward to 1930 using the average 1996 value and a 2-mm/yr rate of sea-level rise (National Research Council, 1987), and (3) converting the extrapolated 1930 sea level value to a hydrostatic freshwater equivalent sea level for input to the SEAWAT simulator. On average, sea level in 1996 was about 0.2 m above NGVD 1929. By extrapolating, sea level in 1930 was calculated to be about 0.07 m above NVGD 1929. Hydrostatic freshwater equivalent sea level (h_f) was computed using the following equation:

$$h_f = Z + \frac{\rho}{\rho_f}(h_s - Z) \quad . \tag{12}$$

Z was set to the elevation of the center of the model cell. Fluid density (ρ) was set to 1,025 kg/m^3 (density of saltwater). Extrapolated 1930 sea level (h_s) was computed as 0.07 m. Using the equation and data above, the freshwater equivalent sea level in 1930 was 0.12 m above NVGD 1929 for layer 1 and proportionately greater than 0.12 m at the western boundary of the model in layers 2 to 15 because the elevation of the center of these model cells, Z, is farther below NVGD 1929.

Simulation Results

The predevelopment simulation was run until heads and salinity reached steady state. An evaluation of simulated predevelopment heads (not shown) suggested that the model provides a reasonable representation of coastal ground-water flow. An estimate of the predevelopment distribution of saltwater is obtained by evaluating the solute concentrations simulated by the model.

A three-dimensional view of the predevelopment distribution of saltwater was prepared using Modelviewer, a visualization and animation program (Hsieh and Winston, 2002) (fig. 23). Although this view provides a more complete perspective of the predevelopment distribution of saltwater, it is difficult to visualize how ground-water salinity relates with other prominent features in the study area. Thus, a two-dimensional map showing the intersection of the predevelopment saltwater interface with the base of the lower Tamiami aquifer was prepared (fig. 24).

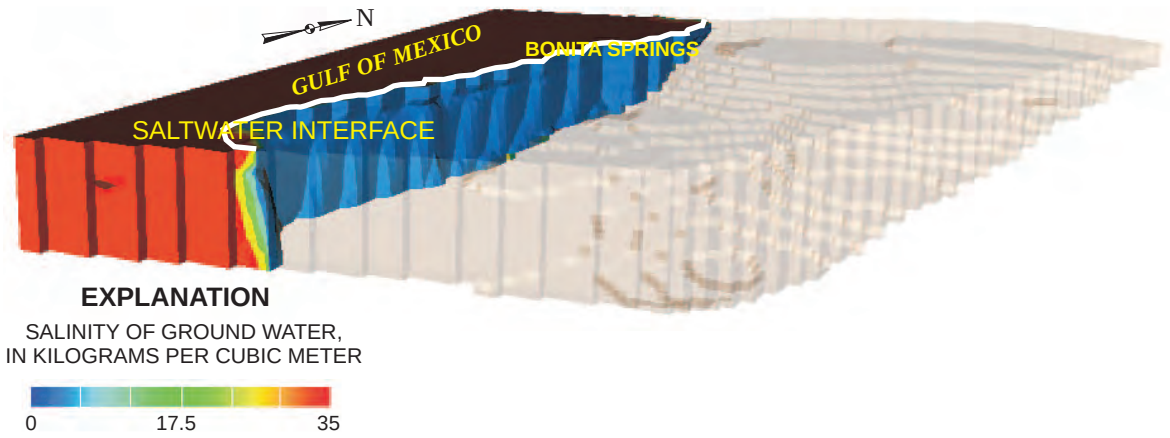

Figure 23. Three-dimensional view of the simulated predevelopment distribution of saltwater. All shaded areas represent active model cells. Blue and tan cells are equivalent in salinity; the tan shading is used to highlight the topography of the base of the lower Tamiami aquifer.

The predevelopment distribution of saltwater consists of a sharp, steep interface that roughly parallels the coast. Near Naples and central Estero Bay, the saltwater interface intersects with the base of the lower Tamiami aquifer directly beneath the coastline. In most other areas, the intersection is as much as 2 km offshore. Model results suggest the interface is directly beneath the coastline in locations where less ground water is discharging to the Gulf of Mexico. Conversely, the interface is farther from the coastline in locations where more ground water is discharging to the Gulf of Mexico. These results appear to be a reasonable estimate of salinity conditions in the water-table and lower Tamiami aquifers prior to modern stresses, such as ground-water development and canal drainage.

Model Calibration to Typical, Modern, and Seasonal Stresses

Model calibration was necessary to move the predevelopment distribution of saltwater to equilibrium with a reasonable representation of March and September 1996 conditions (table 2). The same spatial discretization and aquifer properties previously described were used for calibration. Two steady-state stress periods representing average March and September 1996 conditions were designed. The MODFLOW program was used to simulate ground-water flow.

The calibration objective of this study was to find the combination of model parameters or boundary conditions that best represent March and September 1996 conditions. Boundary conditions were assigned to closely resemble the time periods of interest. The parameter estimation routine, UCODE (Poeter and Hill, 1998), was used to "best fit" simulated heads and flows to their observed equivalents by solving for parameter estimates using a nonlinear least squares regression. The reliability or uncertainty in parameter estimates also was quantified with linear 95-percent confidence intervals.

Boundary Conditions

Boundary conditions for model calibration under March and September 1996 hydrologic conditions include no flow, constant heads, rivers, general heads, rainfall, evapotranspiration, and wells (pl. 2). No-flow boundary conditions were used to represent hydrologic divides and the saltwater interface. Layers 16 and 17 consist entirely of no-flow cells; therefore, these layers are not plotted on plate 2. Constant-head boundary conditions were used to represent the Gulf of Mexico. River boundary conditions were used to

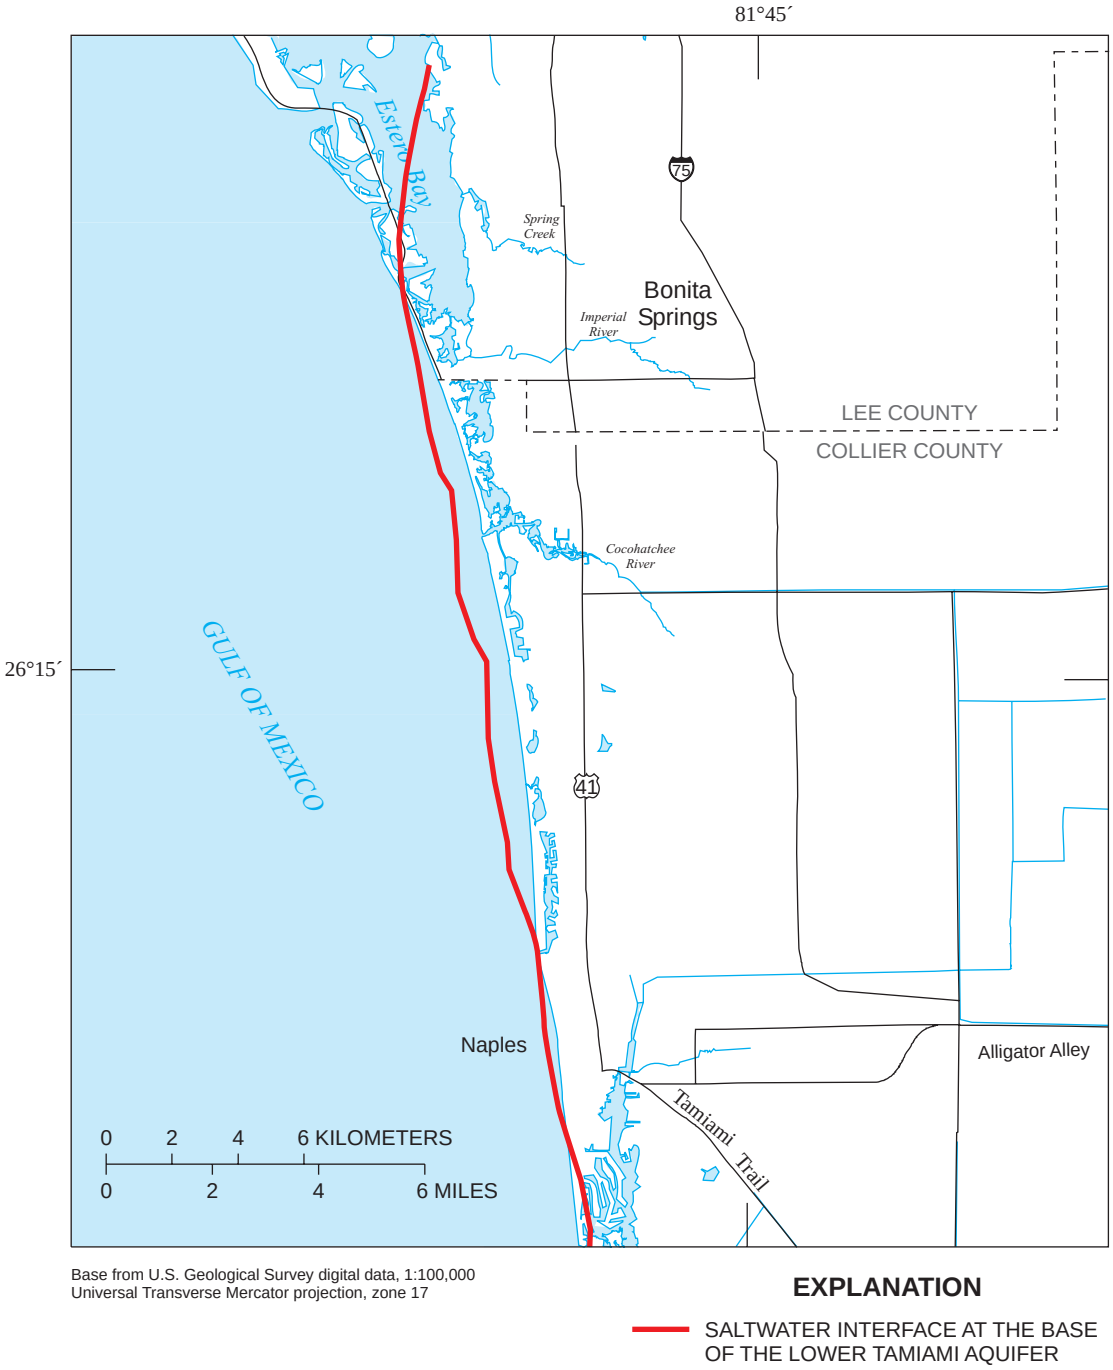

Figure 24. Approximate position of the simulated predevelopment saltwater interface at the base of the lower Tamiami aquifer.

represent local rivers and the system of canals in the southeastern part of the study area. General-head boundary conditions were used to represent deep leakage of ground water to and from the base of the lower Tamiami aquifer. Rainfall and evapotranspiration boundary conditions were used to represent net recharge; however, these boundary conditions are not plotted or labeled on plate 2 for the same reasons they are not plotted on plate 1 as previously mentioned. Well boundary conditions were used to represent ground-water pumpage from the water-table and lower Tamiami aquifers.

No Flow

The Basic package (McDonald and Harbaugh, 1988) was used to set no-flow boundary conditions that represent hydrologic divides and the saltwater interface (pl. 2). The input and mechanics of accomplishing this using the Basic package were previously described. No-flow boundary conditions representing hydrologic divides were assigned to model layers at the northern, eastern, and southern boundaries of the simulation for both steady-state stress periods. These boundary conditions were set using water-level contour maps of the water-table and lower Tamiami aquifers during March and September 1996 (fig. 22).

No-flow boundary conditions representing the saltwater interface in layers 2 to 15 beneath the Gulf of Mexico were set using the predevelopment distribution of saltwater. All model cells west of the 50-percent seawater zone in the predevelopment simulation were designated as no-flow cells in both steady-state stress periods. In systems where density changes abruptly between a freshwater zone and a more dense "salty" zone, the boundary between freshwater and saltwater can be conceptualized as a no-flow boundary condition when movement of the boundary is assumed to be of negligible importance to the problem (Reilly, 2001). Most water-level and flow observations for calibrating the model to March and September 1996 conditions are several kilometers inland with chloride concentrations less than 1,000 mg/L. This suggests the bulk of the saltwater interface has not moved through the vicinity of these observations, and the error in simulated heads and flows will more likely be attributable to uncertainty in rock properties and other boundary conditions, such as recharge, than from the position or movement of saltwater or brackish water with greater fluid density.

Constant Heads

The Constant Head Boundary (CHD) package (Leake and Prudic, 1991) was used to set constant-head boundary conditions that represent the average elevation of sea level in the Gulf of Mexico during March and September 1996. The IBOUND and Shead arrays in the Basic package could not be used because the average elevation of sea level in March 1996 (the first steady-state stress period) is different than the average elevation of sea level in September 1996 (the second steady-state stress period). The IBOUND and Shead arrays of the Basic package can apply only one constant head value entered in the Shead array for the entire length of a simulation.

The CHD package requires the input of the layer, row, column, starting head, and ending head values for the constant-head cell for each stress period. The ARC/INFO coverages of the Gulf of Mexico were overlain with ARC/INFO coverages of the model grid to identify rows and columns of model cells in layer 1 that needed to be constant heads. The starting and ending head values for the first steady-state stress period representing March 1996 were set equal to the average elevation of sea level in the Gulf of Mexico recorded at Naples station 8725110 (about 0.1 m). The starting and ending head values for the second steady-state stress period representing September 1996 were set equal to the average elevation of sea level in the Gulf of Mexico recorded by NOAA station 8725110 (about 0.3 m). By setting the starting and ending head values equal, a constant-head boundary condition was enforced with a different value for each steady-state stress period.

Rivers

The River package (McDonald and Harbaugh, 1988) was used to set river boundary conditions that represent leakage of water to and from the groundwater flow system through surface-water channels (pl. 2). The input and mechanics of the River package (McDonald and Harbaugh, 1988) were previously described. For calibrating the model to March and September 1996 conditions, the River package requires the layer, row, column, h_{riv}, $COND_{riv}$, and *RBOT* for both steady-state stress periods. The layer, row, and column of river cells were determined by overlying ARC/INFO coverages of contemporary surface-water features with the model grid. The USGS or SFWMD surface-water gaging stations, if available, were used to interpolate or extrapolate average March and September 1996 h_{riv} values for both steady-state stress periods. For each river cell, $COND_{riv}$ was computed using equation 9. The value of K_{seds} is assumed to be 15 m/d, which is the vertical hydraulic conductivity used for the water-table aquifer (table 3); the value of b_{seds} was given a reasonable value of 1 m, and the value of *RBOT* was about 2 m less than h_{riv}.

General Heads

The General-Head Boundary (GHB) package (McDonald and Harbaugh, 1988) was used to set general-head boundary conditions that represent the deep leakage of ground water to and from the base of the lower Tamiami aquifer and the sandstone aquifer during March and September 1996 (pl. 2). In MODFLOW-88, the GHB package is one of the most robust packages available for simulating a wide range of boundary conditions. General-head boundaries are head-dependent boundaries where the volumetric flux, Q_{GHB}, is proportional to the head difference between an assigned external head and the approximated head in the model cell. The form of Darcy's law used to characterize the flux is:

$$Q_{GHB} = COND_{GHB}(h_{GHB} - h_{i,\ j,\ k}) , \qquad (13)$$

where $COND_{GHB}$ is the conductance of the general-head boundary [L^2/T], and h_{GHB} is the assigned external head value of the general-head boundary [L].

The conductance value, $COND_{GHB}$, of the general-head boundary was mathematically defined as:

$$COND_{GHB} = \frac{LwK_{GHB}}{b_{GHB}} , \qquad (14)$$

where L is the length of the model cell [L], w is the width of the model cell [L], K_{GHB} is the vertical hydraulic conductivity of the upper Hawthorn confining unit [L/T], and b_{GHB} is the thickness of the upper Hawthorn confining unit [L].

Variables L and w of the model cells were assigned values of 600 m each, and a value of 0.003 m/d was used for K_{GHB} (Montgomery, 1988). A value of 9.14 m was used for b_{GHB}, the average thickness of the upper Hawthorn confining unit reported by Knapp and others (1986). The b_{GHB} could not be spatially variable because no published maps of the thickness of this unit could be found.

The h_{GHB} values were set using contour maps of the potentiometric surface of the sandstone aquifer. Sufficient water-level measurements were obtained for the March 1996 steady stress period, but not for the September 1996 period. To approximately define the potentiometric surface of the sandstone aquifer, water levels at 15 monitoring wells for March 1996 were averaged, plotted, contoured, and interpolated to the h_{GHB}. For the September 1996 period, average water levels at the same 15 monitoring wells were computed, plotted, and contoured to define the average potentiometric surface of the sandstone aquifer for the entire 1996 calendar year. This average surface then was interpolated to the h_{GHB} for the September 1996 steady-state stress period.

Recharge

The Recharge and Evapotranspiration packages (McDonald and Harbaugh, 1988) were used to represent net recharge, or the water applied to land surface through precipitation that exceeds evapotranspiration and runoff and infiltrates through the unsaturated zone to the water table. An areal flux [L/T] of rainfall minus runoff was applied to the highest active cell in a vertical column of layers using the Recharge package (McDonald and Harbaugh, 1988) for both steady-state stress periods. Average monthly rainfall rates were computed from daily rainfall totals collected in 1996 at a rainfall monitoring station near Bonita Springs. The average rainfall rate in March 1996 was about 0.3 cm/d, and the average rainfall rate in September 1996 was about 0.4 cm/d. Runoff was estimated using land-use coefficients developed during previous investigations of the study area (Bennett, 1992). These land-use coefficients suggest 10 to 30 percent of rainfall is converted to runoff during a storm event. The average of land-use coefficients (about 0.127) reported by Bennett (1992) was used to estimate the amount of rainfall lost to runoff during March and September 1996. A weighted average based on the individual area of each land-use type within the total area of the active model domain could not be computed because runoff coefficients for recent land-use maps were not available. As previously mentioned, runoff was subtracted from rainfall, and the resulting areal flux [L/T] was input for both steady-state stress periods in the Recharge package.

Evapotranspiration was simulated using the Evapotranspiration package (McDonald and Harbaugh, 1988), with the evapotranspiration surface set to land surface and an extinction depth set to 5 m at all active cells in the model domain. As previously defined, setting extinction depths to 5 m is a reasonable compromise given the current understanding of the evapotranspiration process in Florida. Maximum evapotranspiration rates were uniformly set across the model grid using free surface pan evaporation data (fig. 25) and a pan multiplier of 0.7 (Swancar and

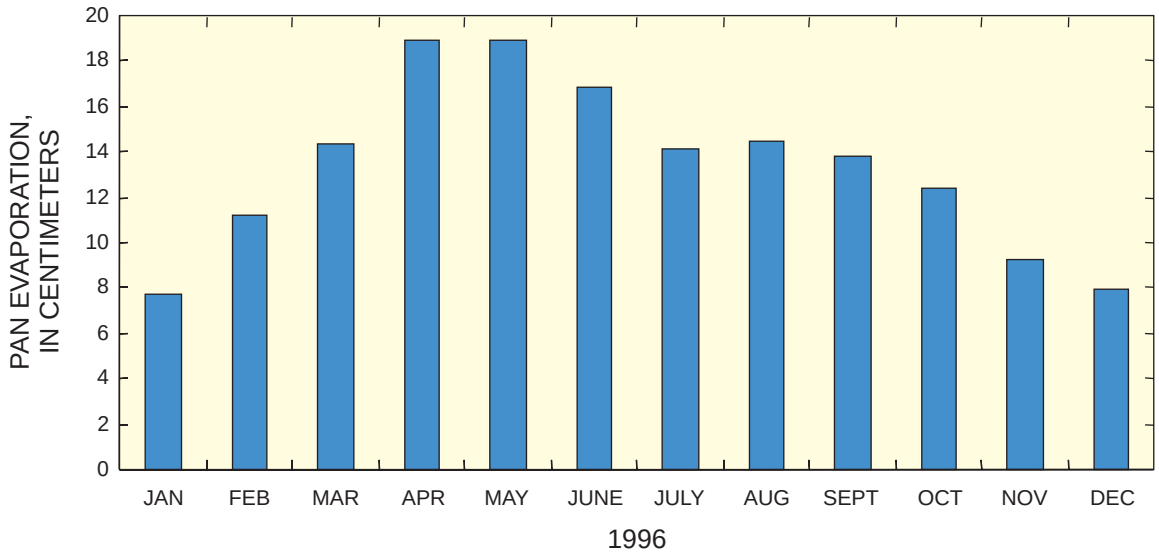

Figure 25. Total monthly pan evaporation from several monitoring stations near Bonita Springs.

others, 2000, p. 42). This means maximum ground-water evapotranspiration rates in the Evapotranspiration package were 70 percent of the average March 1996 pan evaporation rate for the first steady-state stress period and 70 percent of the average September 1996 pan evaporation rate for the second steady-state stress period.

Wells

The Well package (McDonald and Harbaugh, 1988) was used to represent the withdrawal of ground water from the water-table and lower Tamiami aquifers. Well boundaries may be used for injection or extraction wells. The layer, row, column, and injection or extraction volumetric rate are required input for the Well package. The location and volumetric rate of monitored ground-water pumpage were obtained from the SFWMD and translated to the appropriate layer, row, column, and stress period of the model simulation. Well construction information, such as depth to the top of casing and depth to the bottom of the open-hole interval, was used to determine the appropriate model layer in which to place the pumping well. Areas near Bonita Springs that are most likely to withdraw large quantities of unmonitored ground water from the lower Tamiami aquifer also were delineated (fig. 26) with the help of SFWMD personnel. Because this pumpage was unmonitored, volumetric rates and open-hole intervals were not known. The missing pumpage rates were set approximately equal to the monitored ground-water pumpage in March and September 1996. Although this may seem arbitrary, these missing pumpage rates were better estimated with UCODE during model calibration. The open-hole intervals of unmonitored pumping wells were assumed to be present at the center of the lower Tamiami aquifer (pl. 2).

Parameter Estimation

The model was calibrated with the UCODE parameter estimation routine (Poeter and Hill, 1998) to 41 average monthly head and 2 average monthly flow observations computed from USGS monitoring wells and gaging stations, respectively, in the study area (table 4). Each head observation is the average of all measurements made at the well during March or September 1996. Flow observations are the sum of the average of all flow measurements made at the northern and southern branches of the Estero River, Spring Creek, and Imperial River during March and September 1996.

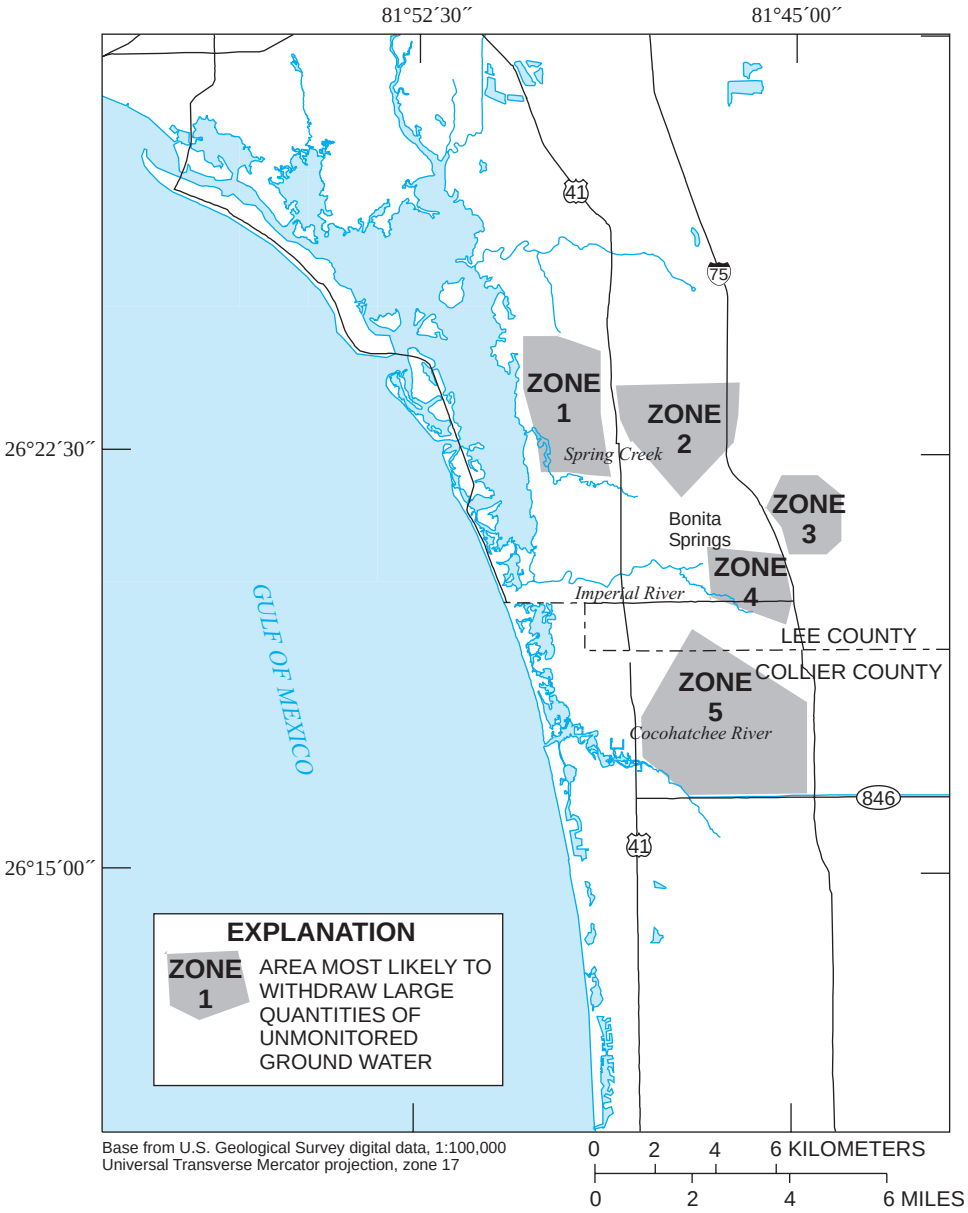

Figure 26. Areas with potentially large quantities of unmonitored ground-water pumpage.

With UCODE, head and flow observations were weighted and summed together with their simulated equivalents as the objective function, *S(b)*,

$$S(b) = \sum_{i=1}^{nh} w_i [h_i - h_i'(b)]^2 + \sum_{i=1}^{nq} w_i [q_i - q_i'(b)]^2 , \qquad (15)$$

where b is a vector containing values of each of the parameters being estimated, nh is the number of head observations, w_i is the weight for the ith observation, h_i is the ith observed water level, $h_i'(b)$ is the simulated equivalent of the ith observed water level (a function of b), nq is the number of flow observations, q_i is the ith observed flow, and $q_i'(b)$ is the simulated equivalent of the ith observed flow (a function of b). UCODE solved for parameter values, b, that minimize this objective function, *S(b)*, resulting in simulated heads and flows that most closely resemble their observed equivalents.

[1]Flow shown in meters per day.

[2]Flow observations are the sum of estimated flows at four different locations. These locations (northern and southern branches of the Estero River, Spring Creek, and Imperial River) are discussed in the text.

With UCODE, observations are weighted to: (1) maintain similar dimensions in the objective function so that head and flow residuals can be added together, and (2) emphasize observations that are more or less important to "best fit" with regression. For example, weights can be used to make an accurately measured observation more important to "best fit" and an inaccurately measured observation less important to "best fit." For this study, observations were weighted to: (1) account for the potential measurement error, such as the top-of-casing elevation, down-to-water distance, or instrumentation drift; and (2) account for the potential deviance from the true monthly average.

The variance statistic was used to compute observation weights. A variance was assigned to each observation well to account for the potential measurement errors described above. For convenience, the variance statistic was also used to account for the potential deviance from the true monthly average. This was accomplished by summing the squared differences of individual water-level measurements from the monthly average and dividing by one less than the total number of measurements. At monitoring wells where only one or two depth-to-water measurements were taken during March or September 1996, the average variance of water-level measurements at observation wells with continuous monitoring equipment was used. Using the variance statistic was convenient because variances are additive, and the final variance statistic used to calculate observation weights was the sum of the variance that accounts for measurement error and the variance that accounts for the potential deviance from the true monthly average.

A primary objective of this project was to accurately simulate saltwater movement in the lower Tamiami aquifer beneath Bonita Springs. To accomplish this objective, accurately simulated water levels in this area of the aquifer were necessary. Unmonitored ground-water pumpage created large cones of depression in the lower Tamiami aquifer beneath Bonita Springs. Large discrepancies between observed and simulated water levels initially were present in this area of the model because simulated water levels cannot be drawn down where pumpage data do not exist. For this reason, zones of unmonitored ground-water pumpage with "sufficient" sensitivity were estimated with UCODE, resulting in simulated water levels that closely match observed water levels in important areas near the coast.

Zones of unmonitored ground-water pumpage were determined to have "sufficient" sensitivity by examining composite-scaled sensitivities. Composite-scaled sensitivities (CSS) computed by UCODE are measures of the amount of information that all the observations provide for estimating a parameter (Poeter and Hill, 1998). If a parameter has large CSS, then the observations hold much information for estimating that parameter value. If a parameter has small CSS, then the observations hold little information for estimating that parameter value. Given this relation, the regression performed by UCODE can have difficulty converging on estimates of parameters with small CSS, because very little information is provided by the observations for estimating these parameter values. Thus, only parameters with large or "sufficient" CSS that are not correlated are successfully estimated with UCODE.

Parameter correlation is measured using correlation coefficients calculated as the covariance between two parameters divided by the product of their standard deviations (Hill, 1998). Correlation coefficients range from 1.0 to -1.0, with values close to 1.0 or -1.0 indicating parameters that are correlated or inversely correlated, but cannot be estimated uniquely with the observations used to calibrate a flow model. It is already well established that hydraulic conductivity parameters (K) and flow parameters (Q) representing, for example, recharge or ground-water pumpage are often highly correlated when calibrating a flow model using only hydraulic-head observations (Hill, 1998). Adding flow observations, such as streamflow gains and losses, can greatly reduce correlation of K and Q parameters and result in unique parameter estimates.

Unmonitored ground-water pumpage was correlated with the most sensitive model parameters (evapotranspiration extinction depth, canal conductance, and vertical hydraulic conductivities of the Tamiami confining beds and upper Hawthorn confining unit) as indicated by CSS (fig. 27) and correlation coefficients. This meant that while trying to estimate unmonitored ground-water pumpage with more sensitive model parameters, unique estimates could not be found. This is a disadvantage because: (1) a better regional model fit probably could be attained if the more sensitive model parameters could be estimated; and (2) some of the more sensitive model parameters, such as hydraulic conductivities and canal conductances, probably are more uncertain than the unmonitored ground-water pumpage. However, unique UCODE estimates of

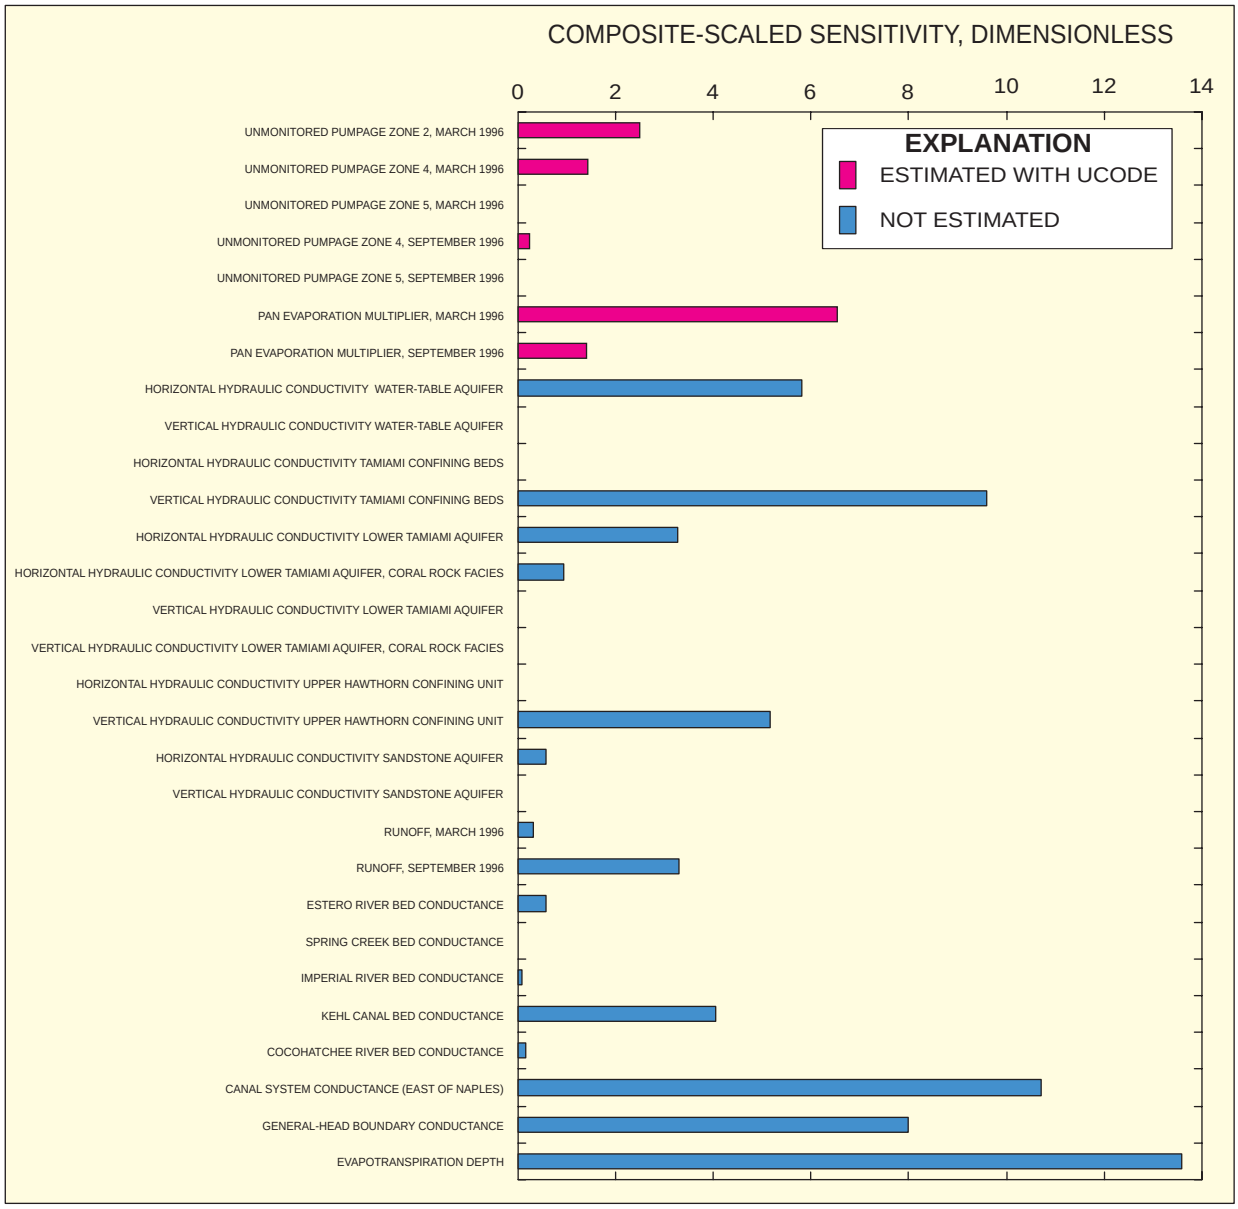

Figure 27. Composite-scaled sensitivities computed while calibrating the model to March and September 1996 conditions. Parameters with no visible bar have very small or zero sensitivity.

unmonitored ground-water pumpage zones with sufficient sensitivity and pan evaporation multipliers were found (table 5). The uniqueness is indicated by UCODE correlation coefficients (table 6) and the fact that final UCODE estimates of these parameters were not sensitive to the parameter starting values.

In the stress period representing September 1996, UCODE estimated a pan evaporation multiplier of 1.13, which means the maximum evapotranspiration rate is about 13 percent larger than the pan evaporation rate. This parameter estimate probably is unreasonable because maximum evapotranspiration rates likely are less than pan evaporation rates in most circumstances. Unreasonable parameter estimates are valuable because they suggest that either the model may not accurately represent some aspect of the physical system (most likely), or there may be an error in the observations used to calibrate the model (Poeter and Hill, 1997).

Table 5. Estimates of unmonitored ground-water pumpage and evapotranspiration multipliers with confidence intervals computed by UCODE

[Parameters are in cubic meters per day, except for evaporation multipliers, which are dimensionless]

Parameter	Parameter estimate	Linear 95-percent confidence interval
Unmonitored pumpage zone 1, March 1996	-1,080	275; -2,440
Unmonitored pumpage zone 4, March 1996	-1,180	1,650; -4,010
Unmonitored pumpage zone 5, March 1996	-6.1	4,450; -4,750

Pan evaporation multiplier, March 1996	.06	.09	.26	.00	.00	1.00	
Pan evaporation multiplier September 1996	.00	.00	.01	.20	.00	.01	1.00

In this model, rainfall may be overestimated, runoff may be underestimated, hydraulic conductivity may be underestimated, or a combination of these and other errors may exist. It is also possible that a process such as interception that prevents rainfall from reaching the water table is not represented in the model. In any of these circumstances, UCODE would estimate a larger maximum evapotranspiration to compensate for the model error, or the missing process that affects "net recharge." Because maps of "net recharge" looked reasonable and were consistent with field observations by Krulikas and Giese (1995), the model error was not resolved. Although undesirable, the unresolved error was justified because compensating errors in a model representing the various processes that affect "net recharge" can produce "net recharge" rates that are accurate.

When estimating zones of unmonitored ground-water pumpage with sufficient sensitivity and pan evaporation multipliers, the nonlinear least-squares regression performed by UCODE converged by satisfying the sum of the squares residual criteria, which was set to zero difference between parameter estimation iterations. This means the difference in the weighted objective function changed by this amount over three parameter estimation or regression iterations (Poeter and Hill, 1998). A traditional statistic for reporting calibration results is the mean absolute error (MAE), which is calculated by taking the average of the absolute values of the differences between observed and simulated heads. The MAE of the calibration was 0.73 m for the 41 average monthly water-level observations in the water-table and lower Tamiami aquifers. Graphical representations of the model

calibration are made by comparing observed and simulated water levels (fig. 28) and comparing weighted residuals and weighted simulated values (fig. 29). The comparison of weighted residuals and weighted simulated values is presented because this plot may identify model bias or trends that are obscured by the traditional comparison of observed and simulated water levels (Mary Hill, U.S. Geological Survey, written commun., 1999). No bias or trends are obvious on the plot in figure 29. The calibration plots and MAE statistic suggest that the model adequately represents the ground-water flow system in the water-table and lower Tamiami aquifers near Bonita Springs.

A component of the water budget important to water managers is unmonitored ground-water pumpage. Estimates of unmonitored ground-water pumpage zone rates per cell with confidence intervals were computed by UCODE (table 5). By calibrating to March and September 1996 water-level and flow observations, the average 1996 rate of unmonitored ground-water pumpage is bracketed because the rate of unmonitored ground-water pumpage probably is greatest during March 1995 and lowest during September 1995, as evidenced by historical ground-water withdrawals. The average 1996 rate of unmonitored ground-water pumpage can be estimated by: (1) multiplying the UCODE-estimated unmonitored ground-water pumpage rate for each zone by the number of model cells in that zone, (2) summing the total rate of unmonitored ground-water pumpage in March 1996 and September 1996, and (3) computing a weighted average. The weight was based on a 7 to 5 ratio of dry- to wet-season months, a typical southwestern Florida water year (Virogroup, Inc., 1993). Using this method, the average estimated rate of unmonitored ground-water pumpage from the lower Tamiami aquifer was

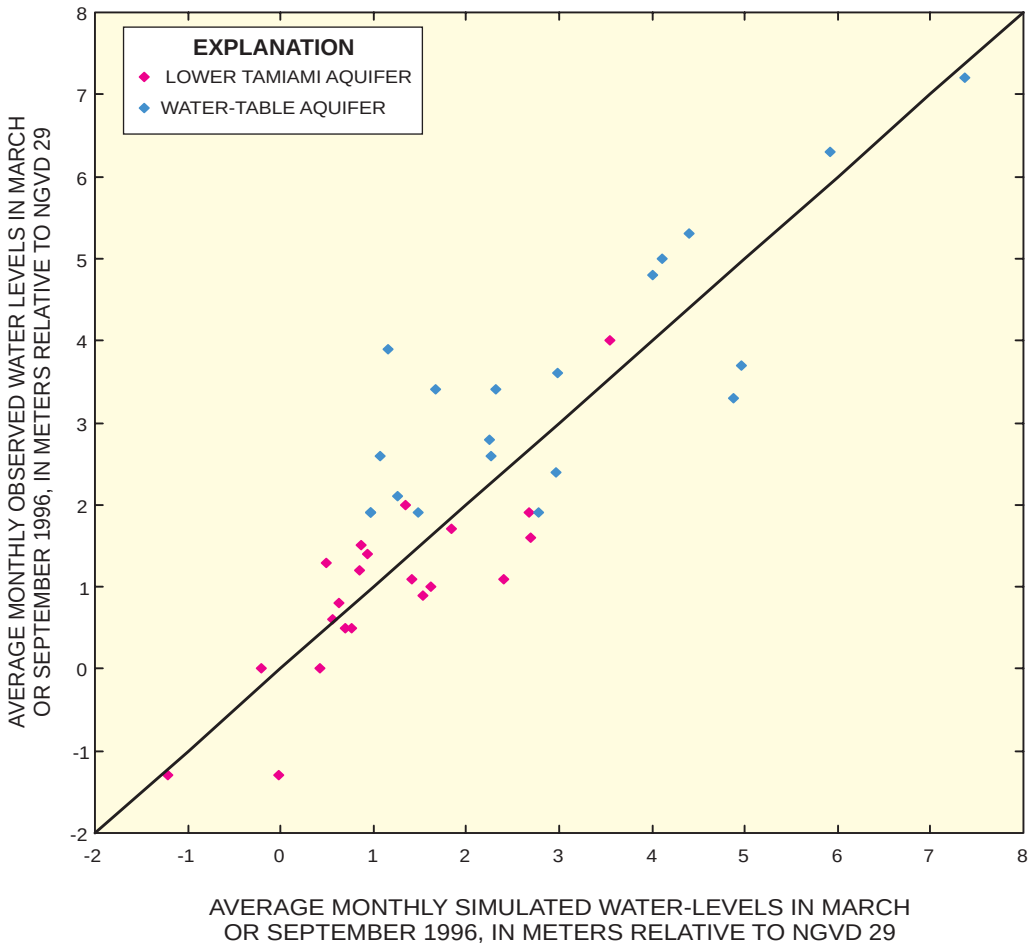

Figure 28. Comparison of observed and simulated water levels. NGVD 29 is National Geodetic Vertical Datum of 1929.

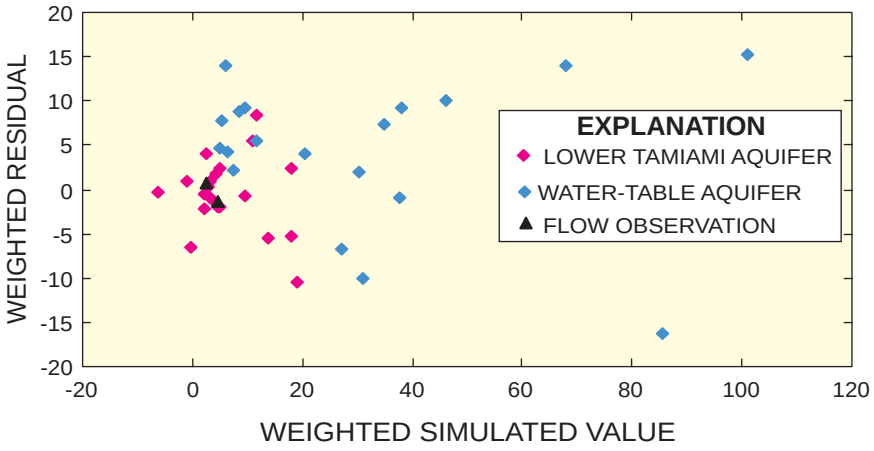

Figure 29. Comparison of weighted residuals and weighted simulated values.

about 52,000 m^3/d in 1996. The average estimated rate of monitored ground-water pumpage from the water-table and lower Tamiami aquifers in the active model domain (pl. 2) was about 59,000 m^3/d in 1996.

A good exercise to test a simulated water budget is to compare simulated net recharge with estimates of net recharge as computed by other methods. Krulikas and Giese (1995) used the chloride concentration ratio and flow-tube analysis methods to estimate net recharge, which ranged from 0 to 25 cm/yr in the study area in 1989. Net recharge maps were prepared for March and September 1996 using the cell-by-cell flow output from the MODFLOW simulations (figs. 30 and 31, respectively). Simulated values of net recharge generally ranged from 0 to 38 cm/yr. Net discharge occurred in small areas as indicated by the negative values shown in figures 30 and 31. One possible explanation for the difference in maximum net recharge rates (field-data computed compared to simulated) is that lowering the water table through pumping between 1989 and 1996 could have induced recharge rates in excess of 25 cm/yr (Krulikas and Giese, 1995).

Topography appears to influence the distribution of net recharge. In fact, simulation results suggest that there are localized areas in the water-table aquifer where net discharge occurs because of the close proximity of the water table to land surface and the effects of evapotranspiration (figs. 30 and 31). These net discharge areas constitute about 5 percent of the active model domain. Net recharge is greater in areas where land surface is relatively higher, such as Bonita Springs and areas south of the Caloosahatchee River along the Immokalee Rise (figs. 1 and 2), because the water table is deeper below land surface and the effects of evapotranspiration are less. The resulting net recharge maps (figs. 30 and 31) reflect the local topography.

Simulated water levels, streamflows, and net recharge rates adequately represent the empirical data describing these hydrologic processes in the study area. However, adequate representation of selected parameters does not ensure the accuracy of predictive simulations (Konikow and Bredehoft, 1992). Nevertheless, calibration or history matching is necessary to reduce errors in the conceptual model and to obtain more representative parameter values, given the scale of simulation.

Confidence Intervals

Linear 95-percent confidence intervals are one of the many useful statistics computed by UCODE during model calibration. Linear 95-percent confidence intervals were calculated for each UCODE estimated parameter, and represent a range that has a 95-percent probability of containing the true value if the model correctly represents the true ground-water flow system (Hill, 1998). The width of a confidence interval can be thought of as a measure of the likely precision of the parameter estimate. Wide intervals indicate less precision or more uncertainty, and narrow intervals indicate more precision or less uncertainty.

The linear 95-percent confidence intervals are wide for estimates of unmonitored ground-water pumpage and narrow for estimates of pan evapotranspiration multipliers (table 5). This suggests unmonitored ground-water pumpage rates are estimated with

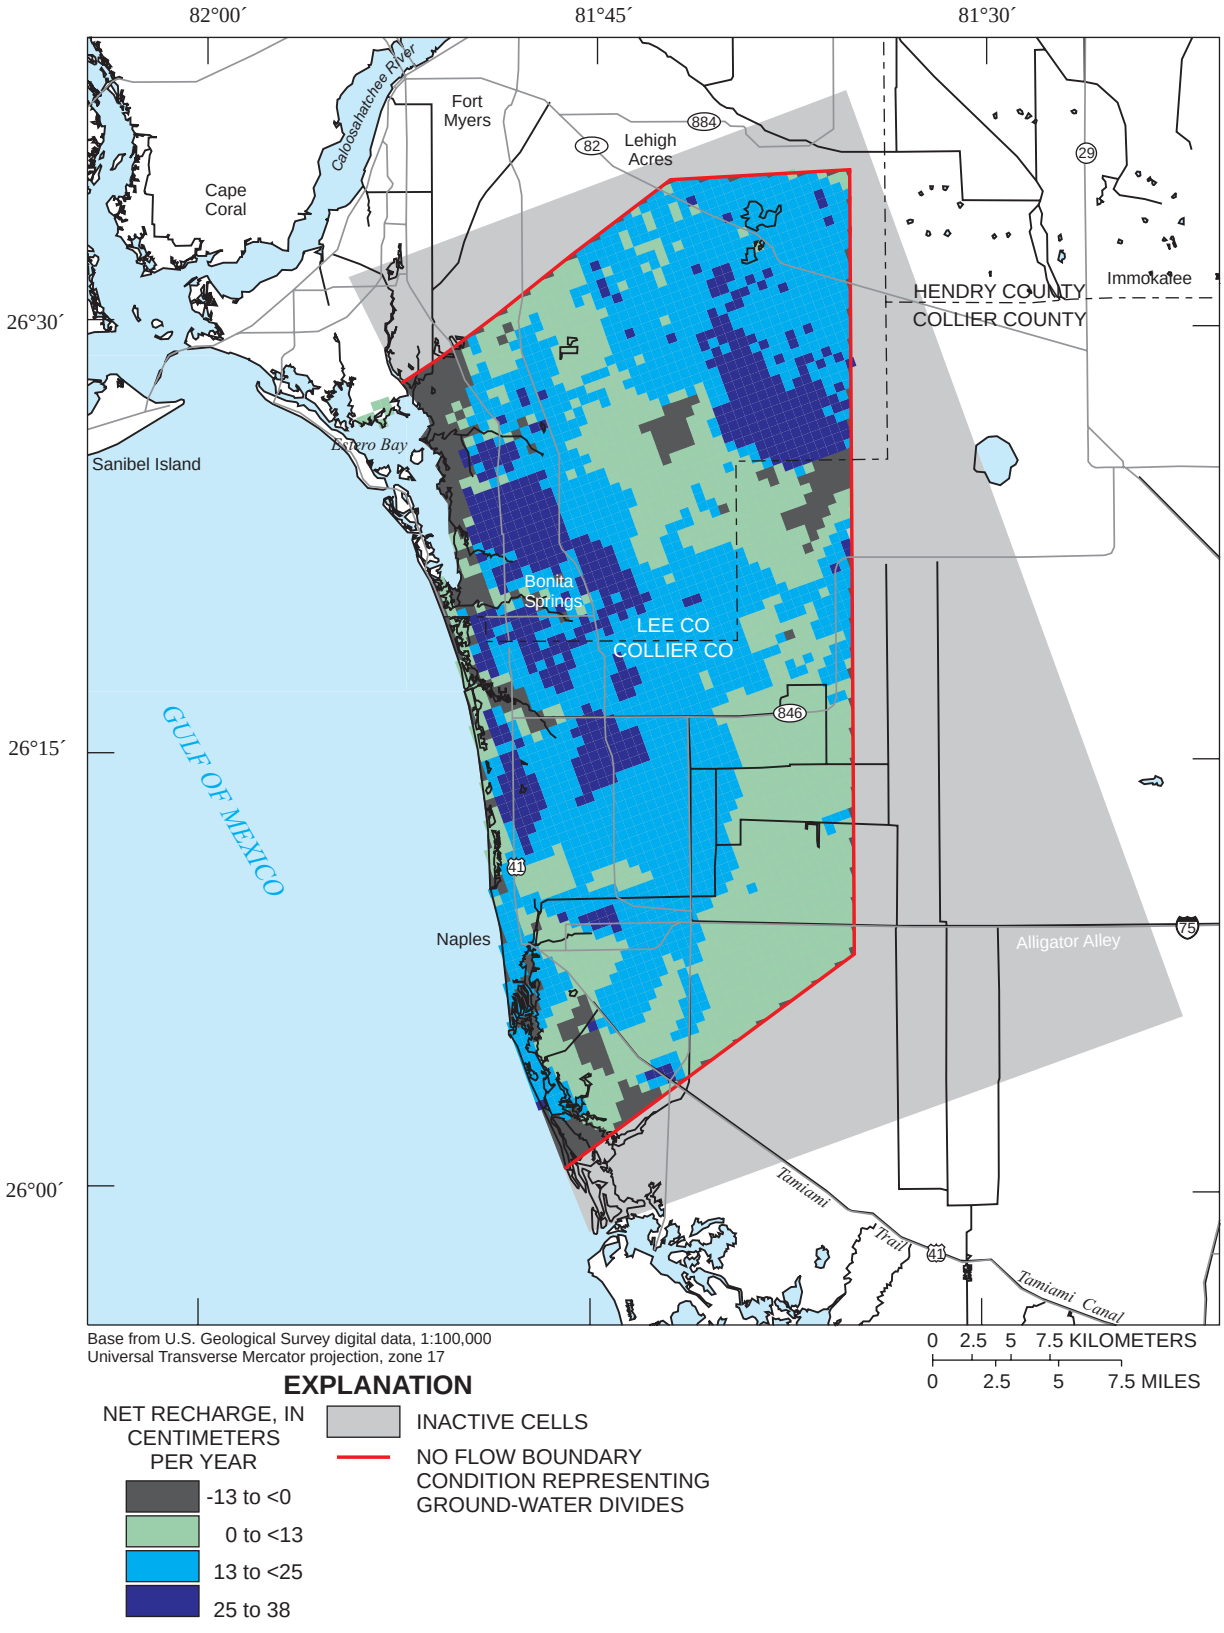

Figure 30. Simulated net recharge to the water-table aquifer during March 1996.

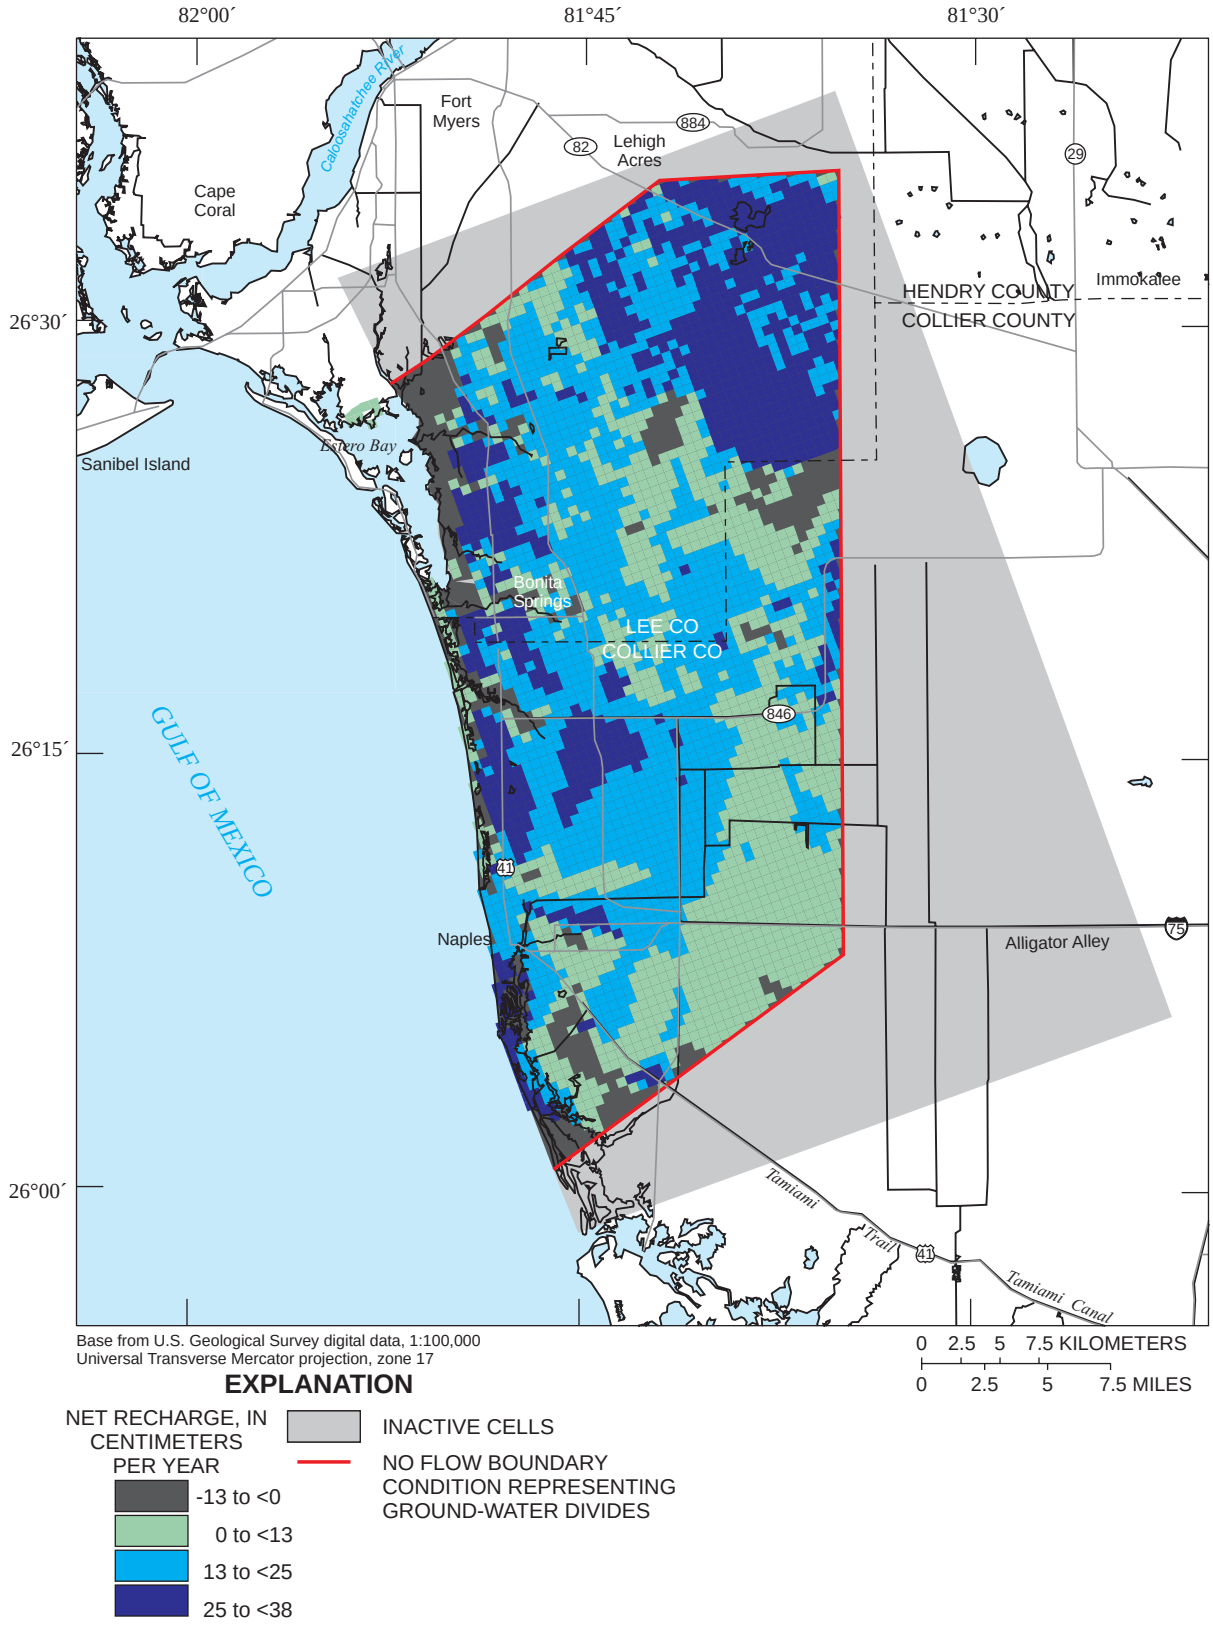

Figure 31. Simulated net recharge to the water-table aquifer during September 1996.

less precision or more uncertainty than pan evaporation multipliers. The design of the USGS network of monitoring wells and streamgaging stations in the study area apparently provides more information on estimating pan evaporation multipliers than estimating unmonitored ground-water pumpage rates. Conversely, one could also say that the pan evaporation parameters explain more of the water-level and discharge data monitored by the network than does the unmonitored ground-water pumpage.

Potential Movement of Saltwater to Equilibrium with Typical, Modern, and Seasonal Stresses

The predevelopment distribution of saltwater was moved to dynamic equilibrium with calibrated March and September 1996 steady-state stress periods (table 2). The same spatial discretization and aquifer properties previously described were used. Calibrated March and September 1996 steady-state stress periods were run successively until saltwater entering and leaving the simulation was about equal, which took about 600 years, or 1,200 steady-state stress periods. The SEAWAT program (Guo and Langevin, 2002) was used with initial conditions that consisted of the final distribution of freshwater equivalent head and salinity in the predevelopment simulation. The primary use of this simulation was to provide a baseline scenario to help identify potential mechanisms of saltwater intrusion and to estimate the potential extent of saltwater intrusion at dynamic equilibrium with modern stresses. Sensitivity analyses were performed for each of these primary objectives using the baseline scenario results.

In general, boundary conditions for this simulation are the same as boundary conditions used while calibrating the model to March and September 1996 conditions (pl. 2). The UCODE estimates of unmonitored ground-water pumpage and pan evaporation multipliers (table 5) were used. Some minor modifications to boundary conditions were necessary.

- Conversion of constant-head boundary conditions (pl. 2) to freshwater equivalent constant-head boundary conditions in the Gulf of Mexico, and conversion of the external heads of general-head boundary conditions (pl. 2) to freshwater equivalent external heads at the base of the lower Tamiami aquifer. These conversions were accomplished using chloride concentrations measured in the field, where data were available.
- Assignment of a constant concentration boundary equal to 35 kg/m^3 (salinity of seawater) in layer 1 at the Gulf of Mexico (pl. 2).
- Assignment of a constant-concentration boundary equal to 35 kg/m^3 (salinity of seawater) in layers 2 to 15 at the westernmost column (column 1) in and beneath the Gulf of Mexico (pl. 1).
- Removal of the no-flow boundary condition used in layers 2 to 15 to represent the saltwater interface (pl. 2).
- Assignment of a salinity value of 0.3 kg/m^3 to water entering the model from the general-head boundary condition at the base of the lower Tamiami aquifer. This was based on limited water-quality data from the sandstone aquifer (pl. 2).

Baseline Scenario

The final distribution of saltwater in the baseline scenario (fig. 32) supports two mechanisms of

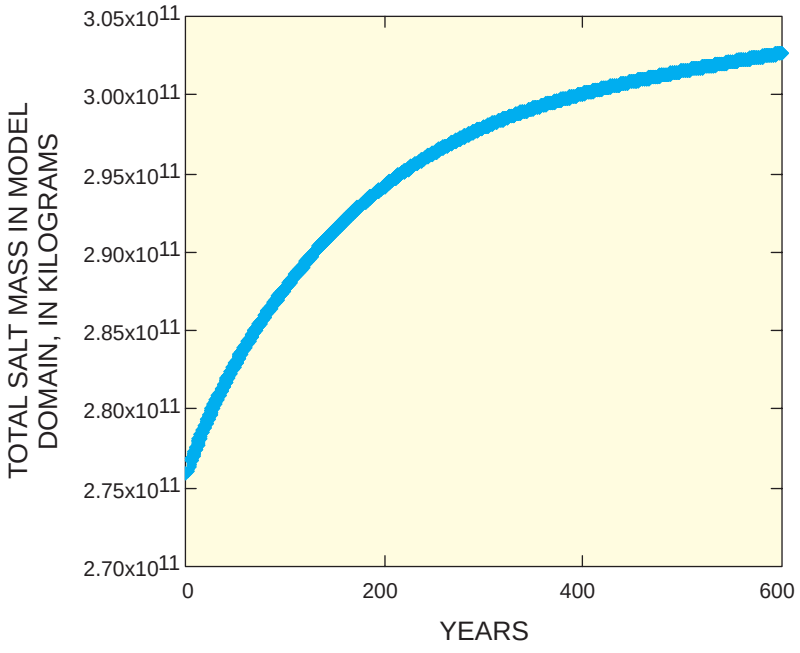

Figure 32. Total salt mass in the model while moving the simulated predevelopment distribution of saltwater to equilibrium with calibrated March and September 1996 conditions.

saltwater intrusion in the lower Tamiami aquifer near Bonita Springs—upconing and lateral saltwater intrusion. Results from the baseline scenario were used to estimate the potential extent of saltwater intrusion in the lower Tamiami aquifer beneath Bonita Springs.

Mechanisms of Saltwater Intrusion

The baseline scenario suggests that upconing of saltwater is the most predominant saltwater intrusion mechanism in the lower Tamiami aquifer beneath Bonita Springs (figs. 33 and 34). Predominance was

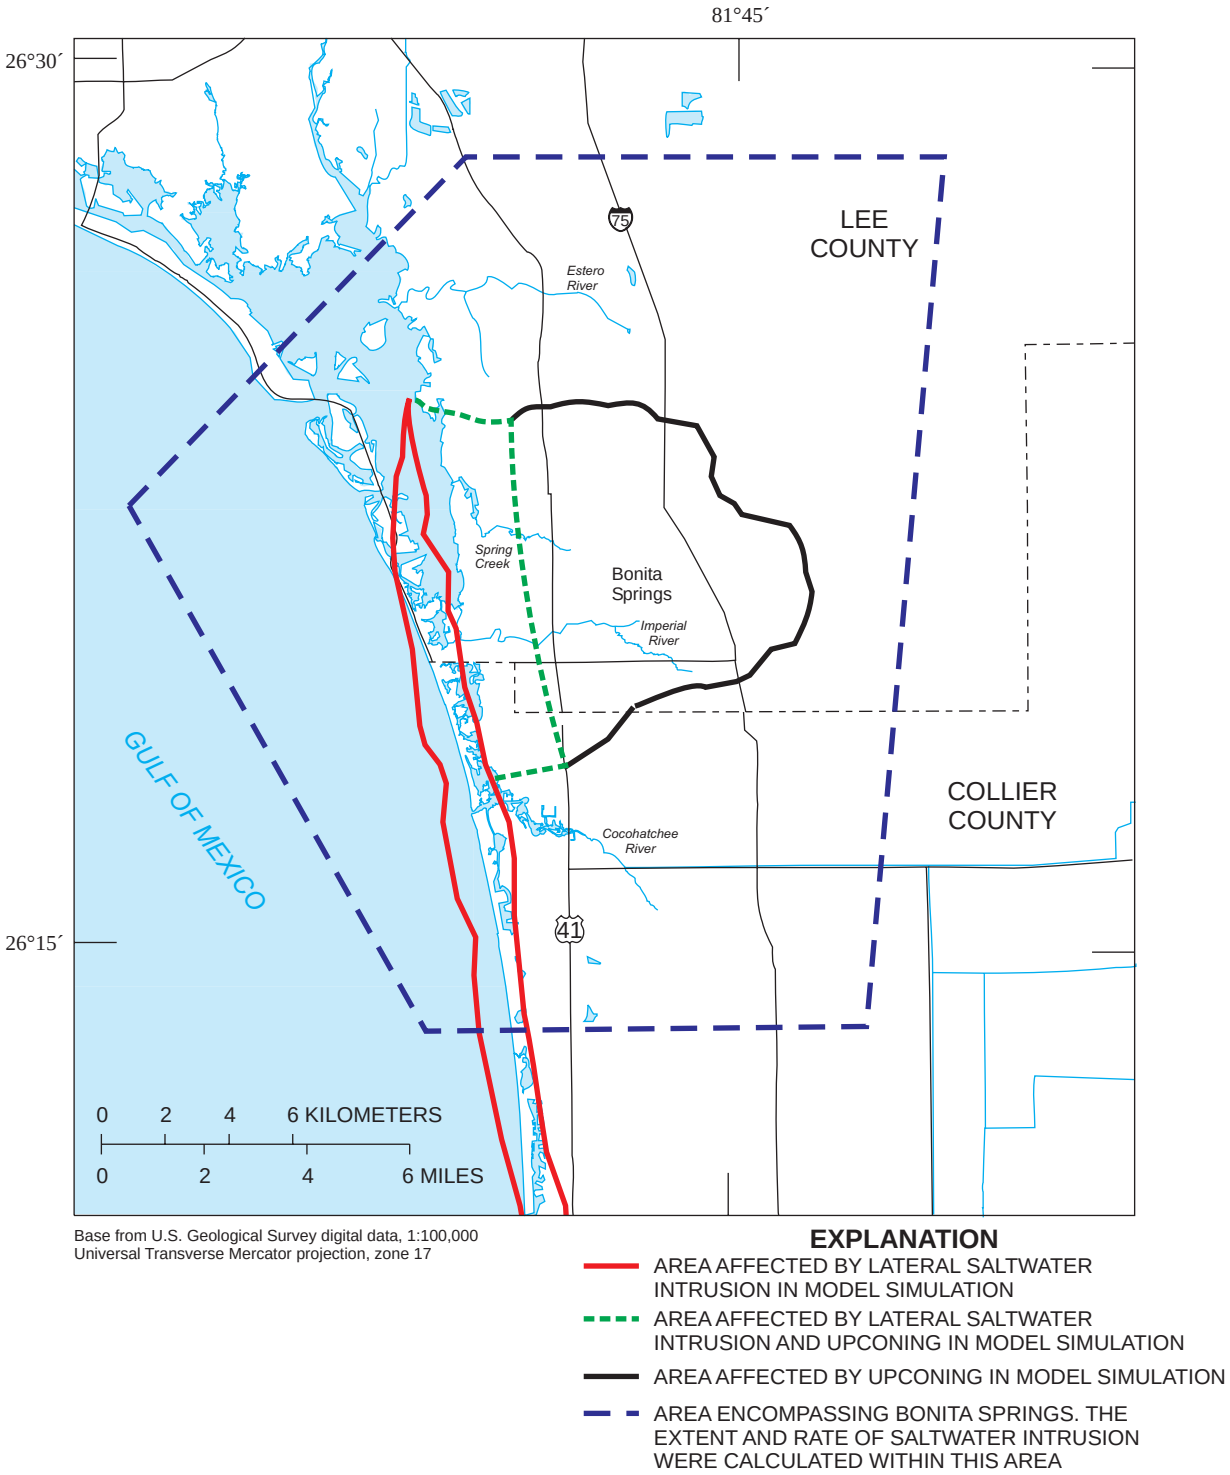

Figure 33. Simulated potential extent of saltwater intrusion in the lower Tamiami aquifer from the baseline scenario near Bonita Springs.

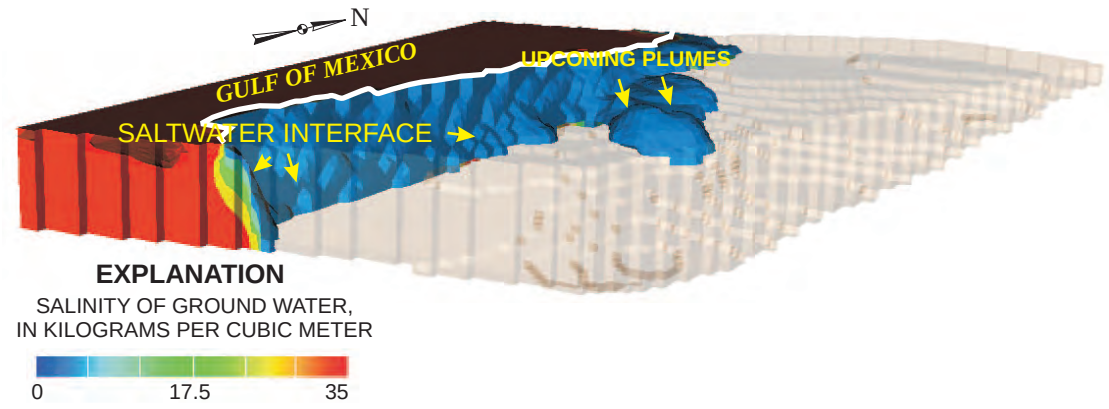

Figure 34. The saltwater interface and upconing plumes near equilibrium with calibrated March and September 1996 conditions in the water-table and lower Tamiami aquifers near Bonita Springs. The upconing plumes are directly beneath Bonita Springs. All shaded areas represent active model cells. Blue and tan cells are equivalent in salinity; the tan shading is used to highlight the topography of the base of the lower Tamiami aquifer.

established by identifying the saltwater intrusion mechanism that affected the largest inland area. A plume of higher salinity ground water (encompassing about 100 km^2 in area) developed in the lower Tamiami aquifer near Bonita Springs after 600 years of transport with calibrated March and September 1996 conditions. By animating model results, it was determined that this plume of higher salinity ground water developed from upconing of ground water in the underlying sandstone aquifer.

The baseline scenario suggests that lateral encroachment is the second most predominant mechanism of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs (figs. 33 and 34). The saltwater interface in the lower Tamiami aquifer near Bonita Springs moved about 1.5 km inland from its predevelopment position after 600 years of transport with calibrated March and September 1996 conditions. As a result, the rate of lateral encroachment averaged about 2.5 m/yr, which is the total distance that the saltwater interface moved (1.5 km) divided by the time length of the baseline scenario (600 years). Additionally, the baseline scenario suggests that lateral encroachment into the potentiometric depression (fig. 22) of the lower Tamiami aquifer was hindered by the presence of a ground-water mound located between the saltwater interface and the potentiometric depression (fig. 35). This simulated ground-water mound seems to force freshwater toward the coast and prevents further lateral encroachment. No field data are available, however, to verify the presence of the simulated mound. If it were shown through the collection of additional field data that the mound does not exist, then the effects of lateral encroachment may be much more severe.

Extent of Saltwater Intrusion

The extent of saltwater intrusion is defined herein as the areal or volumetric movement of saltwater from the predevelopment distribution to equilibrium with calibrated March and September 1996 conditions. Because Bonita Springs was the main area of concern, the extent of saltwater intrusion was computed for a subarea centered on Bonita Springs (fig. 33). The baseline scenario suggests that the areal extent of saltwater intrusion at the base of the lower Tamiami aquifer is about 100 km^2, and the volumetric extent of saltwater intrusion is about 70,000 hectare-meters (fig. 34). The volumetric extent of saltwater intrusion was computed using the same subarea, vertically extended only through the active cells representing the lower Tamiami aquifer. Within this volume, the extent of saltwater intrusion was computed by: (1) summing the volume of cells in the lower Tamiami

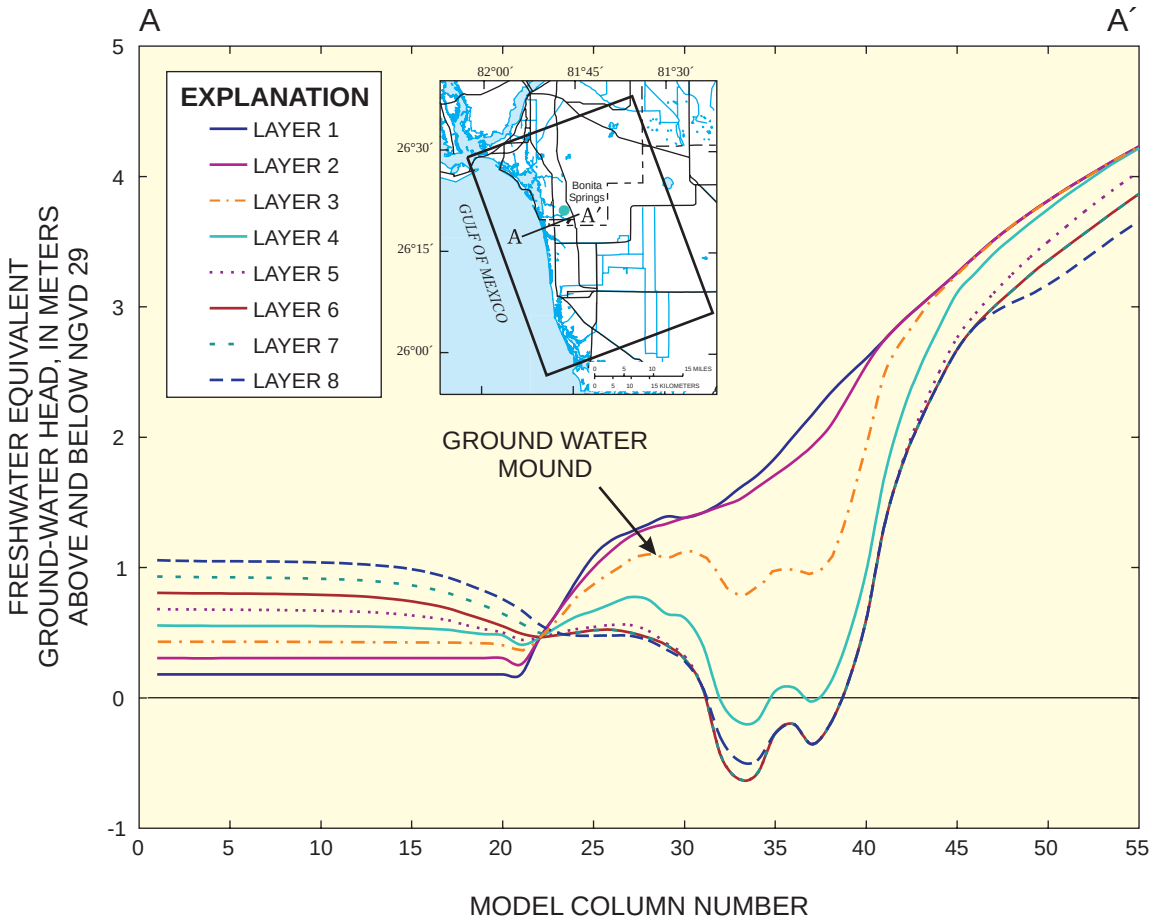

Figure 35. Cross section A-A' along row 40 of the model grid showing a mound of ground water between the cones of depression in the lower Tamiami aquifer and the saltwater interface.

aquifer with a salinity value less than the potable limit (a chloride concentration of about 250 mg/L) in the predevelopment distribution of saltwater, (2) summing the volume of cells in the lower Tamiami aquifer with salinity values less than the potable limit in the baseline scenario, and (3) subtracting the two volumes to isolate a volumetric extent of saltwater intrusion.

Areas affected by saltwater intrusion in the baseline scenario (fig. 33) coincide with areas that seem to be affected by saltwater intrusion as indicated in isochlor maps created by Schmerge (2001) and Knapp and others (1986) (fig. 16). There are discrepancies, however, between simulated salinities and salinities measured at the same location in the field. Possible causes of these discrepancies include that: (1) dispersive solute transport was not performed in the baseline scenario, and (2) the model was run for 600 years with 1996 conditions, so the results cannot be directly compared.

Sensitivity Analyses

The two goals of sensitivity analysis were to: (1) determine how uncertainty in the baseline scenario parameters and boundary conditions may affect solution results, and (2) determine which parameters and boundary conditions in the baseline scenario are most important to solution results. The phrase "important to solution results" is used rather than "influential on solution results" because *influence* has a specific statistical meaning related more to the occurrence and leverage characteristics of the observations used

during calibration. Solution results of primary interest for this study include mechanisms of saltwater intrusion and the potential extent of saltwater intrusion. Thus, sensitivity analyses were performed for both of these primary objectives. If the primary objective could be easily quantified, the two goals of sensitivity analyses (as stated above) were more completely accomplished. For example, the extent of saltwater intrusion was relatively easy to quantify in three dimensions; therefore, parameter values and parameter uncertainties most important to this primary objective were more easily determined.

Mechanisms of Saltwater Intrusion

The sensitivity analyses, described in this section, were used to help identify mechanisms of saltwater intrusion into the lower Tamiami aquifer near Bonita Springs. Identifying predominant mechanisms of saltwater intrusion was a difficult objective to quantify; therefore, sensitivity analysis scenarios were designed instead of using quantitative prediction-scaled sensitivities (PSS) as done by Poeter and Hill (1998). Two sensitivity analysis scenarios were designed to evaluate potential mechanisms of saltwater intrusion without changing simulated heads and flows from their calibrated values. It is important to maintain simulated heads and flows near observed values during sensitivity analyses so the model still resembles the system being studied (Poeter, 2001).

Sensitivity scenario 1 was designed to test the potential for downward leakage of saltwater from a tidal canal or river. This scenario was conducted by modifying the river boundary conditions in the baseline scenario. Unlike the baseline scenario, river cells (pl. 2) in sensitivity scenario 1 were assigned a salinity value of 35 kg/m^3 in an area about 8 to 16 km inland from the Gulf of Mexico along Spring Creek and the Estero, Imperial, and Cocohatchee Rivers (fig. 1). The MAE of water-level observations was 0.73 m using this modification to river-cell boundary conditions, which is the same as the MAE of water-level observations without this modification to river-cell boundary conditions. This suggests the modification did not substantially change heads from their calibrated values. Additionally, simulated baseflow was not substantially different from its calibrated value.

After 600 years of advective solute transport with the river modification noted above, the distribution of saltwater in the lower Tamiami aquifer is identical to the distribution of saltwater in the lower Tamiami aquifer in the baseline scenario (fig. 36). Ground-water flow vectors in sensitivity scenario 1 suggest baseflow from the aquifer to the river prevents salt in the river cells from leaking downward into the water-table aquifer and, subsequently, into the lower Tamiami aquifer. Field reconnaissance along the headwaters of the Imperial River during July 2000 confirmed the presence of baseflow from the aquifer to the Imperial River. Gaging stations on the northern and southern branches of the Estero River, Spring Creek, and Imperial River record flow during the dry season, suggesting ground water flows from the water-table aquifer to these rivers or creeks even in times of drought.

Sensitivity scenario 2 was designed to test a leaky artesian well as a mechanism of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs. This scenario was conducted by modifying a general-head boundary condition at the base of the lower Tamiami aquifer in one model cell (layer 7, row 38, column 28). This single general-head boundary cell was modified to represent a hypothetical leaky artesian ground-water well with connection to the lower Hawthorn producing zone (fig. 3). The external head for the general-head boundary was set to the average of water levels measured in well L-2310 (fig. 36) (Prinos and others, 1996). This well has casing that is open to the lower Hawthorn producing zone. During March and September 1996, average water levels in well L-2310 were adjusted for freshwater equivalence using a salinity value of 1.3 kg/m^3, which is similar to salinity values measured in the lower Hawthorn producing zone by Reese (2000). The conductance term for the general-head boundary was computed using the area of a 0.1-m diameter well and a hydraulic conductivity of 1 x 10^6 m/d. The high value of hydraulic conductivity is considered large enough to transmit water (like a leaky well would transmit) from the lower Hawthorn producing zone to the base of the lower Tamiami aquifer. The salinity of the general-head boundary, representing the lower Hawthorn producing zone locally, was set to the salinity value used to adjust average measured water levels for freshwater equivalence (1.3 kg/m^3). The MAE of water-level observations was 0.71 m using this modification to represent a leaky well, which was slightly less than the MAE to water-level observations without this modification.

The distribution of saltwater at the base of the lower Tamiami aquifer, after 600 years of advective solute transport using the general-head boundary mod-

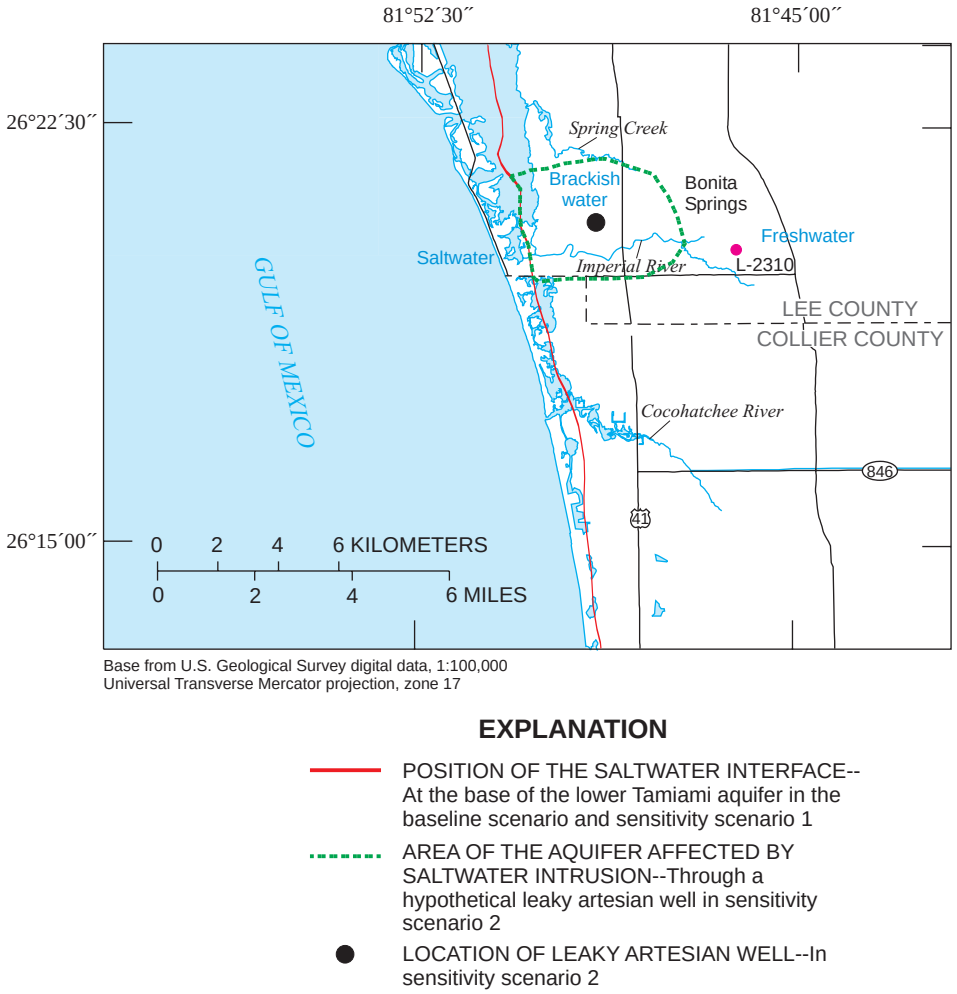

Figure 36. Distribution of saltwater at the base of the lower Tamiami aquifer at the end of the baseline scenario, and two sensitivity analysis scenarios.

ification noted above, is quite different than the distribution of saltwater at the base of the lower Tamiami producing zone in the baseline scenario (fig. 36). The different distribution of salinity suggests leaky wells with connection to the lower Hawthorn producing zone could transport large amounts of saltwater into areas of the lower Tamiami aquifer previously occupied by fresher ground water. These results probably have a physical basis because leaky artesian wells have often been identified as sources of saltwater intrusion in shallow aquifers in southwestern Florida (Burns, 1983; Schmerge, 2001).

Extent of Saltwater Intrusion

The sensitivity analyses, described in this section, were used to help identify the parameters and parameter uncertainties most important to estimating the extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs (table 7). Estimating the extent of saltwater intrusion was an objective relatively easy to quantify; therefore, quantitative PSS (Hill, 1998) were computed instead of using sensitivity analysis scenarios. PSS allow parameters to be ranked by relative importance. Furthermore, the contribution of uncertainty in a given input parameter to the overall uncertainty in a model increases as sensitivity coefficients increase (Zheng and Bennett, 2002). As discussed, these sensitivity coefficients are analogous to the PSS that are computed and described herein. Thus, the main contributors of uncertainty to estimating the extent of saltwater intrusion in the lower Tamiami aquifer may be identified by the PSS presented herein.

Table 7. Changes made to baseline scenario parameters for a sensitivity analysis of the extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs

Parameter	Change from baseline scenario
Sea level	Increased by 5 percent
Elevation of general-head boundary	Increased by 5 percent
River bottoms	Increased by 5 percent
Runoff for March 1996	Increased by 2.54 centimeters
Potentiometric surface of the sandstone aquifer	Increased by 0.5 meters
Ground-water pumpage	Increased by 10 percent
Horizontal hydraulic conductivity of water-table aquifer	Increased by 700 meters per day
Vertical hydraulic conductivity of Tamiami confining beds	Increased by 0.005 meter per day
Runoff September 1996	Increased by 2.54 centimeters
Horizontal hydraulic conductivity, zone 1, lower Tamiami aquifer	Increased by 130 meters per day
Salinity in sandstone aquifer	Increased by 0.3 kilogram per cubic meter
Horizontal hydraulic conductivity, zone 2, lower Tamiami aquifer (coral reef facies)	Increased by 170 meters per day
Vertical hydraulic conductivity of upper Hawthorn confining unit	Increased by 0.006 meter per day
Horizontal hydraulic conductivity of sandstone aquifer	Increased by 80 meters per day
River and canal stages	Increased both by 0.05 meter per day
River salinity	Increased by 0.3 kilogram per cubic meter
Pan evaporation multiplier for March 1996	Increased by 5 percent
Pan evaporation multiplier for September 1996	Increased by 5 percent
General-head boundary conductance	Increased by 100 percent
River conductance	Increased by 100 percent
Effective porosity	Decreased by 20 percent

The PSS were calculated using the volumetric estimate rather than the areal estimate of the extent of saltwater intrusion in the baseline scenario. The volumetric estimate is more representative of the extent of saltwater intrusion that would be observed in the real ground-water flow system near Bonita Springs (saltwater moves in three dimensions). The PSS were computed as:

$$PSS = (\Delta PD/\Delta B)(B/100)(100/PD), \qquad (16)$$

where ΔPD is the change in the volumetric extent of saltwater intrusion from the baseline scenario, ΔB is the perturbation of the parameter; B is the parameter value in the baseline scenario; and PD is the volumetric extent of saltwater intrusion in the baseline scenario. The resulting statistic is the ratio of the fractional change in the volumetric extent of saltwater intrusion after 600 years of transport to the fractional change in the parameter value.

Preliminary attempts to save time by shortening the time length of the baseline scenario (600 years) and, thus, the time length of PSS runs, resulted in zero sensitivity for many parameters because the change in the volumetric extent of saltwater intrusion (ΔPD) remained the same as the volumetric extent of saltwater intrusion in the baseline scenario (PD). Additionally, zero sensitivity was computed when parameter perturbations (ΔB) were too small. In theory, PSS should approach an exact value as the size of parameter perturbations (ΔB) decrease. However, Poeter and Hill (1998) explain that small parameter perturbations (ΔB) could result in zero sensitivity because, for instance, the volumetric extent of saltwater intrusion under small parameter perturbations (ΔB) could remain the same as the volumetric extent of saltwater

intrusion in the baseline scenario (*PD*) within the accuracy of the model output. Under this circumstance, ΔPD in equation 16 would be equal to zero, resulting in zero sensitivity. Conversely, parameter perturbations (ΔB) that are too large can result in inaccurate PSS because simulated heads and flows may no longer be near observed values, resulting in a model that no longer resembles the system being studied. Parameter perturbations listed in table 7 were determined based on this information.

Because the equations used to compute the extent of saltwater intrusion may be nonlinear with respect to some parameter values, the PSS can change with different perturbations in the parameter value (ΔB) (table 7). This change is described in more general terms by Zheng and Bennett (2002). Based on this description, it is also expected that if the equations used to estimate the extent of saltwater intrusion are linear with respect to a parameter value (B), then the different perturbations in the parameter value (ΔB) will result in the same PSS.

Apparently, runoff, pan evaporation multipliers, ground-water pumpage, sea level and salinity of the Gulf of Mexico, and the potentiometric surface of the sandstone aquifer (when ranked by PSS) are most important for estimating the extent of saltwater intrusion near Bonita Springs (fig. 37). Future efforts at estimating the extent of saltwater intrusion in this location would likely benefit from improved representation of these stresses and boundary conditions. For simplicity of reporting and communicating results, the sensitivity of evapotranspiration parameters and runoff can be grouped into net recharge, although it is notable that dry-season sensitivities for these two processes are higher than wet-season sensitivities (fig. 37). When trying to estimate the extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs, determination of net recharge during the dry season apparently is more important than during the wet season. This may be because the dry season generally comprises more days of a total year than the wet season.

The CSS that were computed during calibration (fig. 27) were compared with the PSS that were computed during sensitivity analysis of the extent of saltwater intrusion at equilibrium in the lower Tamiami aquifer near Bonita Springs (fig. 37). The CSS of evapotranspiration parameters and runoff can be grouped together to emphasize that observed conditions near Bonita Springs provided the most information for estimating net recharge. Additionally,

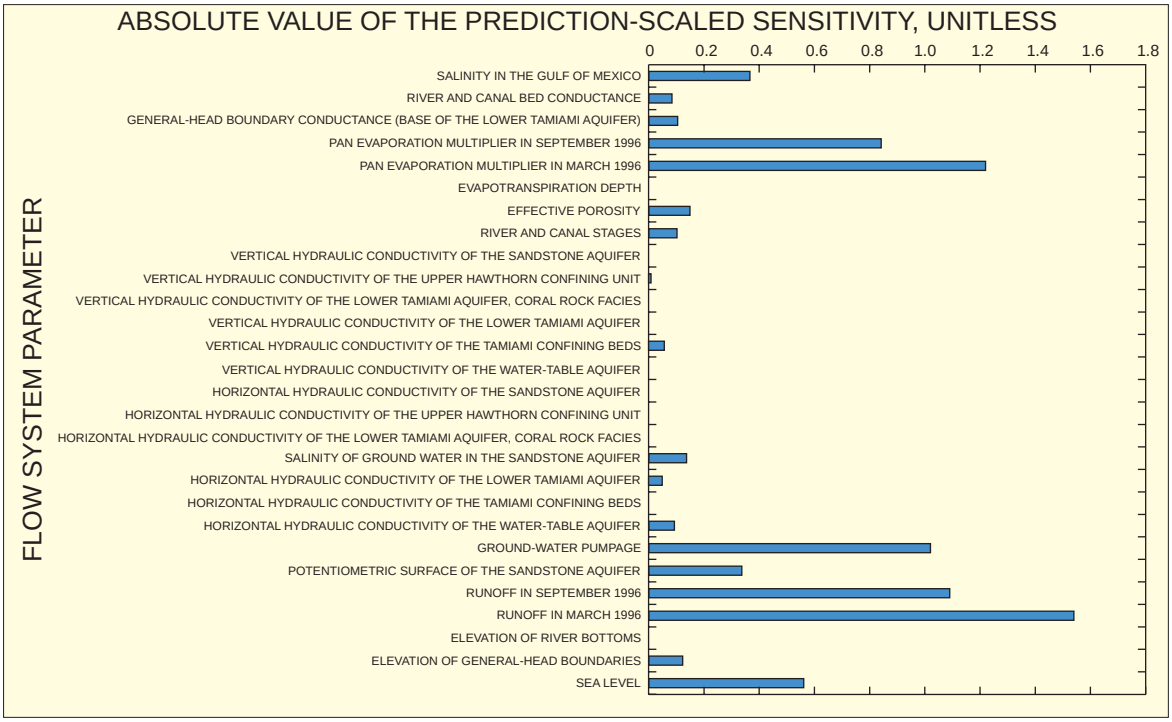

Figure 37. Sensitivity analysis of the extent of saltwater intrusion. Parameters with no visible bar have very small or zero sensitivity.

the PSS of evapotranspiration parameters and runoff (fig. 37) can be grouped together to emphasize net recharge as the most important parameter for estimating the extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs. The fact that observed conditions provided the most information for estimating net recharge (the parameter most important for estimating the extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs) is encouraging and supports the idea that calibrated ground-water flow models can adequately simulate saltwater movement.

The next most important parameter for estimating the extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs is ground-water pumpage, as evidenced by the PSS (fig. 37). Water level and flow observations used while calibrating the model provided relatively little information for estimating unmonitored ground-water pumpage rates as evidenced by the CSS (fig. 27), and the width of the 95-percent confidence intervals on estimates of unmonitored ground-water pumpage rates (table 5). Future efforts to simulate saltwater movement would benefit by improving the representation and estimates of ground-water pumpage, because this parameter was second in relative importance to estimating the extent of saltwater intrusion, but was not precisely estimated with UCODE.

Model Limitations

The model results and interpretations described in this report are limited by: (1) assumptions inherent to MODFLOW-88 and SEAWAT that may or may not be satisfied; (2) difficulty in characterizing small-scale heterogeneity that may greatly influence regional ground-water flow and saltwater movement; (3) the modeling approach; and (4) the inability to quantitatively assess uncertainty in a rigorous fashion for the modeling objectives. The primary objectives were to identify the predominant mechanisms of saltwater intrusion and to estimate the extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs.

The partial differential equations approximated by MODFLOW-88 and SEAWAT are based on many assumptions. Those assumptions relevant to simulating saltwater intrusion in the lower Tamiami aquifer near Bonita Springs are that: (1) ground water fully saturates the porous media in areas of ground-water flow, (2) ground-water flow is described by Darcy's law or a variable-density form of Darcy's law, (3) the fluid is incompressible, (4) the standard expression for specific storage in a confined aquifer is applicable, (5) isothermal conditions prevail, (7) fluid density is a linear function of ground-water salinity, and (8) the coordinate system is aligned with the principal axis of the permeability tensor so that this tensor is diagonal for anisotropic media. The natural system probably violates some of these assumptions, thus the relevance of model results and interpretations to the natural system are limited by the degree to which individual assumptions are violated.

The difficulty in characterizing small-scale heterogeneity limits model results, because this heterogeneity may greatly influence regional ground-water flow and saltwater movement in the study area. Complete and accurate characterization of heterogeneity in the lower Tamiami aquifer, including subsurface structural complexity, variations in hydraulic properties, and variations in stresses at multiple scales, was not attainable even with the numerous studies documented over the years. Thus, heterogeneity at multiple scales was averaged, interpolated, or zoned into finite-difference approximations that neglect small-scale particularities, which may be important in the true ground-water flow system in the lower Tamiami aquifer near Bonita Springs.

Clearly, the influence of heterogeneity in porosity at any one particular scale on movement of saltwater is not understood. Effective porosity was assigned a uniform value of 30 percent (Reese and Cunningham, 2000) in the baseline scenario. However, ground-water tracer tests suggest fractures and/or high permeability zones can give effective porosities of 2 to 4 percent (Langevin and others, 1998). Furthermore, some researchers have suggested decimeter-scale heterogeneities and preferential flow paths have the dominant effect on solute transport at the plume scale, with 15 percent of the aquifer involved in advective transport while 85 percent of the aquifer serves as a reservoir for essentially immobile solute (Zheng and Gorelick, 2001). Collectively, these investigations highlight the difficulty in characterizing small-scale heterogeneity and suggest the likelihood of a "dual porosity" system. Further research into this limitation would be useful.

Several assumptions and estimations were employed in the modeling approach that could limit the reliability of results. These include, but are not limited to: (1) the steady-state assumption, (2) estimating

stresses rather than hydraulic conductivities during model calibration, (3) the 7 to 5 ratio of dry- to wet-season months in a typical southwestern Florida water year, (4) neglecting the effects of dispersion on simulations of saltwater movement, and (5) initial conditions for simulating the movement of saltwater at equilibrium.

Steady-state flow occurs when at any point in the flow field, the magnitude and direction of the flow velocity are constant with time (Freeze and Cherry, 1979). Because longer term average values are being computed, a steady-state assumption was employed while computing the predevelopment distribution of saltwater, calibrating to March and September 1996 conditions, and moving saltwater at equilibrium. The steady-state assumption is limiting because transient particularities that could be important to saltwater movement in the lower Tamiami aquifer near Bonita Springs may not be considered. Additionally, using the steady-state assumption to calibrate to March and September 1996 conditions is limiting because it is possible the regional ground-water flow system is never at true steady state as defined by Freeze and Cherry (1979).

Most ground-water models are calibrated by adjusting hydraulic conductivity parameters until simulated results match observed field conditions. The model documented here was calibrated by estimating unmonitored ground-water pumpage and pan evaporation multipliers with UCODE. Unmonitored ground-water pumpage was estimated because accurately simulated water levels in the lower Tamiami aquifer beneath Bonita Springs was most important for accurately simulating saltwater movement—a primary objective of this study. Hydraulic conductivity was correlated with unmonitored ground-water pumpage and, therefore, could not be uniquely estimated together with UCODE. This was unfortunate because the model was more sensitive to hydraulic conductivity parameters, such as canal conductances and the vertical hydraulic conductivity of the Tamiami confining beds, than to pan evaporation multipliers. A better model fit may have resulted by estimating hydraulic conductivity parameters. Additional observations, particularly flow observations, could help obliterate the correlation between unknown pumpage and hydraulic conductivity parameters. Future modeling efforts would likely benefit from using additional flow observations while calibrating.

Previous studies have used a 7 to 5 ratio to represent the number of dry-season months to the number of wet-season months during a typical water year in southwestern Florida. The 7 to 5 ratio is potentially limiting because a plot of average monthly rainfall from 69 rainfall stations in southwestern Florida suggests the possibility that an 8 to 4 ratio may be more appropriate (fig. 38). The 7 to 5 ratio was used in this study to estimate annual average unmonitored ground-water pumpage rates, and also was used in the baseline scenario and during sensitivity of the baseline

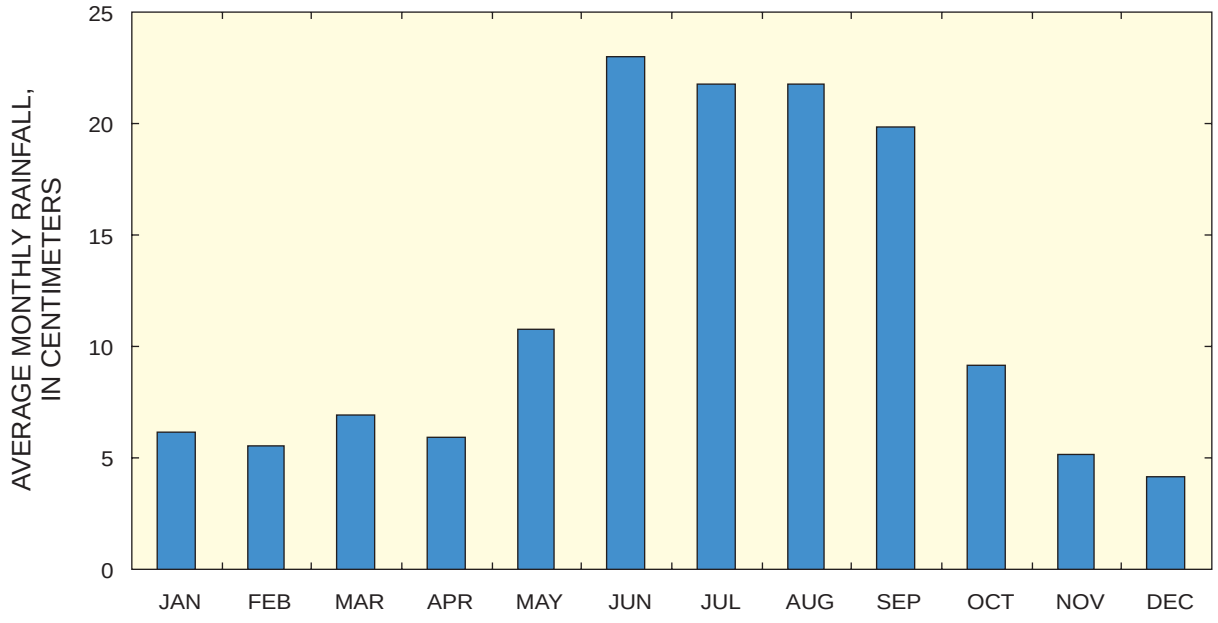

Figure 38. Average monthly rainfall from selected rainfall stations in southwestern Florida, 1909-99.

scenario. Using an 8 to 4 ratio would likely have little effect on identifying predominant mechanisms of saltwater intrusion and have little effect on sensitivity analysis of the baseline scenario. It is probable, however, that using an 8 to 4 ratio would increase estimates of unmonitored ground-water pumpage and increase estimates of the extent of saltwater intrusion.

Neglecting the effects of dispersion on simulations of saltwater movement limits the relevance of model results to the real nature of ground-water flow and saltwater movement in the study area. This is a limitation because: (1) the real nature of saltwater movement involves mixing, and (2) a dispersive solute-transport simulation suggests dispersion will reduce the extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs.

In a hypothetical dispersive solute-transport simulation, dispersivity in three dimensions was estimated using the relation defined in Gelhar and others (1992) and Zheng and Bennett (1995). Longitudinal dispersivity was set to 60 m, or one-tenth the horizontal model cell dimension (Gelhar and others, 1992). Transverse and vertical dispersivities were set to 6 m, or one-tenth the longitudinal dispersivity (Zheng and Bennett, 1995). Six hundred years of dispersive and advective solute transport was simulated using the same modeling approach employed in the baseline scenario. In general, dispersion reduced the extent of saltwater intrusion. These results are consistent with historical studies (Cooper, 1964; Glover, 1964; Henry, 1964; Kohout, 1964) of the effects of dispersion on the saltwater interface, which suggest that including the effects of dispersion moves the interface seaward.

Dispersion was not simulated while solving for the predevelopment distribution of saltwater, during the baseline scenario, and during sensitivity analysis of the baseline scenario due to the length of computer run times and uncertainty in estimates of dispersivity. Field estimates of dispersivity in the lower Tamiami aquifer near Bonita Springs could be useful to constrain the potential effects of dispersion on saltwater movement. If computer run times are substantially diminished, and if field data can be obtained to set reasonable values of dispersivity at the scale of the model grid, then detailed three-dimensional studies of the position and behavior of the “toe” of the saltwater interface in the lower Tamiami aquifer could be more conclusively accomplished.

The lack of initial conditions is a well documented limitation for studies of solute transport in ground water. Although maps of salinity distribution are available (Knapp and others, 1986; Schmerge, 2001), these maps are based on field data collected over time. Only sparse amounts of salinity data are available to instantaneously capture the distribution of saltwater at any given time. If salinity is known only at a few points within the region to be modeled, and assumed initial values are assigned in between, the unrealistic flows probably will be calculated by the variable-density ground-water flow simulator (Voss, 1999). A practical solution to this problem was found by attempting to solve for initial conditions using predevelopment stresses and boundary conditions assumed or extrapolated from contemporary data. This approach has several advantages, as outlined in the modeling approach section of the report, but still is limiting because more accurate solutions to the primary objectives of this study could be obtained if the true distribution of freshwater equivalent head and ground-water salinity were known. Airborne electromagnetic survey techniques (Fitterman and Deszcz-Pan, 1998), if successfully applied to the water-table and lower Tamiami aquifers in southwestern Florida, could represent another useful solution to the lack of data on initial conditions for saltwater intrusion simulations near Bonita Springs.

Parameter and conceptual uncertainty limit the applicability of the modeling results presented here. When parameters are changed within reasonable ranges, or combinations of parameters are changed within reasonable ranges, mechanisms of saltwater intrusion become more or less predominant, saltwater moves to different extents, and saltwater moves at different rates. This problem is exacerbated by conceptual uncertainty because the ground-water flow system could be represented equally well by many different boundary conditions, regional distributions of aquifer properties, and initial conditions. The effects of this uncertainty on the primary study objectives were indirectly addressed through sensitivity analyses. Linear 95-percent confidence intervals, computed for each primary modeling objective, would probably be a practical and useful type of analysis to directly address parameter uncertainty. The effects of parameter and conceptual uncertainty could be directly addressed using a composite range of confidence intervals for a reasonable set of conceptual models (Poeter, 2001). However, these analyses were considered beyond the scope of this investigation.

SUMMARY

Saltwater intrusion is a concern near Bonita Springs in southwestern Florida where the average annual potentiometric surface in some areas of the lower Tamiami aquifer is below sea level. Field data were analyzed, and model simulations were performed to: (1) spatially quantify modern and seasonal stresses, (2) help identify potential mechanisms of saltwater intrusion, (3) and estimate the potential extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs.

MODFLOW and the inverse modeling routine UCODE were used to spatially quantify modern and seasonal stresses in 1996 by calibrating a constant-density ground-water flow model. The model was calibrated by assuming hydraulic conductivity parameters were accurate and by estimating unmonitored ground-water pumpage and pan-evaporation multipliers with UCODE. Additionally, uncertainty in estimates of these parameters was quantified through 95-percent confidence intervals. These confidence intervals indicate more uncertainty or less reliability in the estimates of unmonitored ground-water pumpage than estimates of pan-evaporation multipliers due to the nature and distribution of observations used during calibration. Comparison of simulated water levels, streamflows, and net recharge with field data demonstrate the adequacy of the simulated water budget.

Net recharge and unmonitored ground-water pumpage are two components of the water budget of interest to water managers. Using modeling results for 1996, average net recharge to the water-table aquifer was estimated to range between 0 and 38 cm/yr, and unmonitored ground-water pumpage from the lower Tamiami aquifer was estimated to be 52,000 m^3/d. Net recharge less than zero occurred over less than 5 percent of the active model domain due to the close proximity of the water table to land surface. The average estimated rate of unmonitored ground-water pumpage in 1996 from the lower Tamiami aquifer (52,000 m^3/d) was almost as much as the monitored ground-water pumpage in 1996 from the water-table and lower Tamiami aquifers (59,000 m^3/d) in the active model domain.

Potential mechanisms of saltwater intrusion into the lower Tamiami aquifer near Bonita Springs include: (1) lateral inland movement of the freshwater-saltwater interface from the southwestern coast of Florida; (2) upward leakage from deeper, saline water-bearing zones through natural upwelling and upconing, both of which could occur as diffuse upward flow through semiconfining layers, conduit flow through karst features, or pipe flow through leaky artesian wells; (3) downward leakage of saltwater from surface-water channels; and (4) movement of unflushed pockets of relict seawater. Of the many potential mechanisms, field data and variable-density ground-water flow simulations suggest upconing is probably of utmost concern, and lateral encroachment is probably of second most concern in the lower Tamiami aquifer beneath Bonita Springs. This interpretation is uncertain, however, because the predominance of leaky wells with connection to deeper, more saline, and more pressurized aquifers was difficult to establish.

The potential extent of saltwater intrusion was estimated using a variable-density ground-water flow simulator and 1996 seasonal stresses. The potential extent of saltwater intrusion in the lower Tamiami aquifer beneath Bonita Springs is about 100 km^2 and 70,000 hectare-meters. The volumetric extent of saltwater intrusion was most sensitive to changes in recharge, ground-water pumpage, sea level, salinity of the Gulf of Mexico, and the potentiometric surface of the sandstone aquifer, respectively, as indicated by prediction-scaled sensitivities. Future efforts at estimating the extent of saltwater intrusion in this area would likely benefit from improved representation of these hydrologic stresses and boundary conditions.

Composite-scaled sensitivities that were computed while calibrating the model were compared with prediction-scaled sensitivities computed for the potential extent of saltwater intrusion predicted by the model. Composite-scaled sensitivities suggested observed conditions provided the most information for estimating net recharge. Prediction-scaled sensitivities suggested net recharge is the most important parameter for estimating the extent of saltwater intrusion in the lower Tamiami aquifer beneath Bonita Springs. This consistency was encouraging and supports the idea that calibrated ground-water flow models can be used to adequately simulate saltwater movement.

Predictive Modeling Results for the City of St. Petersburg's Deep Injection Well Systems

PREPARED FOR:	City of St. Petersburg
PREPARED BY:	CH2M HILL
DATE:	November 13, 1996
CITY TASK ORDER:	03-CH
CITY PROJECT:	94420-147
CH2M HILL PROJECT NUMBER:	103855.C0.06

Introduction

The City of St. Petersburg is pursuing injection well operating permits for 10 deep injection wells at its four Water Reclamation Facilities (WRFs). Solute transport modeling is being used as a tool to develop a better understanding of historical and projected water quality changes at the City's four injection sites. The City has negotiated consent orders with the Florida Department of Environmental Protection (FDEP) to continue operation of the deep injection wells while outstanding permitting issues are addressed. As part of the consent order process, the City is developing technical data in support of the injection well operating permits. Technical Memorandum No. STM-3 is the third in a series of technical memoranda related to solute transport modeling conducted in support of the re-permitting process. Technical Memorandum No. STM-1, *Development of the Solute Transport Conceptual Model*, was submitted to the FDEP Technical Advisory Committee (TAC) in February 1995. Background information and the conceptual approach to the modeling was described in STM-1. Technical Memorandum No. STM-2, *Solute Transport Model Calibration for the City of St. Petersburg's Deep Injection Well Systems*, was presented to the FDEP TAC in October 1995. In STM-2, the numerical representation of the conceptual model was presented, and simulated and observed water quality and water level trends were compared at each of the four WRFs.

In this Technical Memorandum (STM-3), *Predictive Modeling Results for the City of St. Petersburg's Deep Injection Well Systems*, the calibrated model simulations presented in STM-2 are extended into the future to evaluate possible changes in water quality in selected hydrogeologic zones. The results of this effort are intended to provide insight to the City and the FDEP TAC to aid in development of an appropriate permitting strategy for each WRF.

Predictive Modeling Approach

Predictive models for each WRF use the same properties and setup developed during model calibration. The purpose of the calibration was to establish the degree to which the

idealized flow system of the conceptual model approached the observed overlying aquifer response to reclaimed water injection. The calibration process involved comparing model-derived water quality and water level distributions with the observed historical data. Based on the relative comparison, selected model input was systematically revised to improve correlation between the simulated and observed aquifer response. The conceptual model layout and the model input properties of the final calibrated model for each WRF are provided in Appendix A. STM-1 and STM-2 document the development of the conceptual model and the calibration process in great detail.

Each calibrated model has been modified to simulate injection of reclaimed water through the year 2005. This 10-year period represents two FDEP permitting cycles, which provides FDEP an opportunity to re-visit the modeling twice during this time period. With the exception of the Albert Whitted WRF model, the 10-year period extrapolates out less than the historical period of record, increasing confidence in the model simulation results. The calibrated models, completed in October 1995, were updated to reflect the actual annual average daily injection rates for 1994 and 1995, and continued injection at an assumed annual average daily injection rate through the year 2005. Forecasts of future reclaimed water injection are not available; Demand for reuse water, however, is expected to rise at a rate greater than the rate of expansion of wastewater service, further reducing the volume injected at the City's facilities.

The City is studying reclaimed water Aquifer Storage Recovery (ASR) as a mechanism to provide seasonal storage of reclaimed water, resulting in the ability to add new reuse customers to the reuse system. The City has been somewhat limited to date in its ability to add new customers because of the need to maintain a reliable dry season supply of reclaimed water to its existing customers. Additional conservation efforts under way by the City are also expected to result in less excess reclaimed water disposal via deep well injection. Finally, inflow and infiltration improvements are underway which should further reduce future wet weather disposal by deep well injection. It is reasonable, therefore, to assume that the average annual daily injection rate for the next 10 years will be less than or equal to the lowest observed annual average daily injection rate for each WRF. In fact, the City's long-term goal is to be able to maximize the use of its valuable freshwater resources, further minimizing flows to the injection wells. For each simulation, the assumed future injection rate was specified as the minimum average annual daily injection rate on record. Table 1 lists the average annual daily injection rate and associated operational period.

Using the calibrated models, simulated TDS concentration output data were compiled for locations in the model grid corresponding to actual observation wells. This provides a comparison with the actual observed values at each observation well. For the predictive models, TDS concentration data were compiled for locations in the model chosen to provide the greatest insight for evaluating various re-permitting options. These locations were chosen to make predictions of the TDS concentration in the zones corresponding to permitting considerations. The average across Zone A of each model was selected because this was the only zone yielding significant quantities and qualities of water to be potentially economically viable for future development in southern Pinellas County (through membrane processes, for example). The base of the Underground Source of Drinking Water (USDW [i.e., the depth at which the pre-injection TDS concentration equaled 10,000 ppm]) was also selected because many permitting options available to the City involve regulations restricting fluid movement and water quality degradation above this point.

Table 1
Injection Rates Used For Solute Transport Model Predictions

Southwest WRF Model:

Injection Period			Time (Days)	Time since 9/10/79 (days)	Average Injection Rate Over Period (MGD)	Q (million gallons)
9/10/79	to	5/10/82	973	973	4.4	4301
5/11/82	to	7/1/83	417	1390	15.0	6255
7/2/83	to	12/31/83	183	1573	14.9	2727
1/1/84	to	12/31/84	366	1939	13.3	4868
1/1/85	to	12/31/85	365	2304	10.0	3650
1/1/86	to	12/31/86	365	2669	6.5	2373
1/1/87	to	12/31/87	365	3034	11.5	4198
1/1/88	to	12/31/88	366	3400	12.8	4685
1/1/89	to	12/31/89	365	3765	6.9	2519
1/1/90	to	12/31/90	365	4130	6.7	2446
1/1/91	to	12/31/91	365	4495	3.9	1424
1/1/92	to	12/31/92	366	4861	3.0	1098
1/1/93	to	12/31/93	365	5226	4.8	1752
1/1/94	to	12/31/94	365	5591	3.8	1376
1/1/95	to	12/31/95	365	5956	5.2	1913
1/1/96	to	12/31/05	3653	9609	3.0	10959

Total Volume Injected = 56,540 million gallons

Average Overall Inj. Rate = 5.88 MGD

Northeast WRF Model:

Injection Period			Time (Days)	Time since 6/9/80 (days)	Average Injection Rate Over Period (MGD)	Q (million gallons)
6/9/80	to	12/31/85	2031	2031	6.1	12389
1/1/86	to	12/31/86	365	2396	3.8	1387
1/1/87	to	12/31/87	365	2761	6.7	2446
1/1/88	to	12/31/88	366	3127	7.5	2745
1/1/89	to	12/31/89	365	3492	6.6	2409
1/1/90	to	12/31/90	365	3857	5.9	2154
1/1/91	to	12/31/91	365	4222	5.5	2008
1/1/92	to	12/31/92	366	4588	3.8	1391
1/1/93	to	12/31/93	365	4953	4.1	1497
1/1/94	to	12/31/94	365	5318	3.9	1420
1/1/95	to	12/31/95	365	5683	3.4	1226
1/1/96	to	12/31/05	3653	9336	3.4	12274

Total Volume Injected = 43,344 million gallons

Average Overall Inj. Rate = 4.64 MGD

Table1 (continued)
Injection Rates Used For Solute Transport Model Calibration

Northwest WRF Model:

Injection Period			Time (Days)	Time since 1/1/85 (days)	Average Injection Rate Over Period (MGD)	Q (million gallons)
1/1/85	to	12/31/85	364	364	4.7	1711

Total Volume Injected = 19,898 million gallons

Average Overall Inj. Rate = 3.21 MGD

Distances of 0.25, 0.5, 1, 2, and 3 miles from each WRF were selected to evaluate potential water quality changes at various distances under the injection scenarios modeled. The simulated TDS concentrations were plotted with respect to time, and are discussed in the following section.

Results of Predictive Modeling

Results from each of the four predictive models are presented graphically. The first figure for each model shows a radial cross-section with injection at the site represented as a single injection well on the left side of the model. The simulated TDS distribution from the last time step of each model (December 31, 2005) is contoured using the TDS values from each model node. To gauge the extent of water quality changes, the pre-injection TDS distribution is also shown (shaded) on the figure. Because multiple injection wells are simulated as a single well, these cross-sections are more representative of the TDS distribution in the aquifer system at distance (i.e., greater than approximately 2,000 feet from the injection wells). Closer in, water quality may respond more closely to individual injection well operations. It should be noted that the models simulate changes in the TDS concentration, and not the extent of reclaimed water migration. Justification for modeling TDS changes in lieu of the reclaimed water fraction was discussed in STM-1 (CH2M HILL, February 1995).

Two data plots are presented for each predictive model. The "Predicted Average TDS in Zone A" represents hypothetical observation wells at 0.25, 0.5, 1, 2, and 3 miles from each WRF. The hypothetical observation wells are assumed to be completed through the entire thickness of Zone A of the upper Floridan aquifer. The average TDS value is computed as the mean of the TDS concentration from model nodes in Zone A at the appropriate radial distance from the injection well.

In contrast with the simple averaging of node values of TDS discussed previously, the TDS at the base of the USDW is taken as a weighted average of the two nodes whose initial pre-injection TDS values straddle the 10,000 ppm concentration. The TDS value reported in the plots is weighted such that the initial TDS equals 10,000 ppm.

Southwest WRF

Figure 1 shows the cross-section of the model at the Southwest WRF with the TDS distribution at the end of year 2005 contoured. The model indicates increases in TDS in Zone A, but the increases are slight and limited to approximately a 1-mile radius from the site. Decreases in TDS concentration in the zones underlying Zone A indicate the presence of reclaimed water.

Figure 2 illustrates the simulated TDS concentration in Zone A from hypothetical wells located 0.25, 0.5, 1, 2, and 3 miles from the center of injection at the Southwest WRF. Model results indicate that at a distance of 0.25 miles from the site, the TDS concentration is predicted to increase from approximately 5,600 ppm to 6,700 ppm. At 1 mile from the site, the model predicts only a slight increase, from approximately 5,600 ppm to 6,100 ppm. This is considered to be within the range of discernible water quality changes, and the slight

increase would not likely change the usability of this groundwater resource from previously available applications.

Figure 3 illustrates the simulated TDS concentration at the base of the USDW from hypothetical wells located 0.25, 0.5, 1, 2, and 3 miles from the center of injection. For the Southwest model, the bottom of the USDW occurs in the semi-confining unit below Zone A (semi-confining unit A/B) at an approximate depth of 420 feet below land surface. At a distance of 0.25 miles from the site, the simulated TDS concentration is predicted to increase from 10,000 ppm to a maximum value of approximately 13,000 ppm before dropping slightly after the year 2001. At a 1-mile distance from the center of injection, TDS concentrations at the base of the USDW are predicted to increase to approximately 11,700 ppm. At distances of 2 and 3 miles from the site, the model predicts a negligible TDS change at the base of the USDW.

Northwest WRF

Figure 4 shows the cross-section of the model at the Northwest WRF with the TDS distribution at the end of year 2005 contoured. Simulated water quality changes in Zone A are indicated within approximately 4000 feet of the injection well. Some freshening has occurred in Zone A, although at distances between 1,000 and 4,000 feet of the well, TDS concentrations increased only modestly. Freshening in the zones underlying Zone A in the vicinity of the injection well indicates the presence of reclaimed water.

Figure 5 illustrates the simulated TDS concentration in Zone A from hypothetical wells located 0.25, 0.5, 1, 2, and 3 miles from the site. The model predicts that at a distance of 0.25 miles from the site, the TDS concentration will increase from approximately 5,100 ppm to a maximum of 7,500 ppm in the year 2002, before freshening slightly following the arrival of reclaimed water. Beyond 1 mile, little discernible change in TDS is predicted in Zone A.

Figure 6 illustrates the simulated TDS concentration at the base of the USDW from hypothetical wells located 0.25, 0.5, 1, 2, and 3 miles from the site. For the Northwest model, the bottom of the USDW occurs in the semi-confining unit below zone A (semi-confining unit A/B) at an approximate depth of 360 feet below land surface. At a distance of 0.25 miles from the site, the simulated TDS concentration increased from 10,000 ppm to a maximum value of approximately 13,000 ppm in late 1994. By the end of the simulation, the TDS concentration 0.25 miles from the site is predicted to decrease to approximately 9,200 ppm. Beyond 1 mile from the site, the model predicts a slight increase in TDS at the base of the USDW. This increase would most likely be indiscernible beyond 2 miles from the injection well.

Albert Whitted WRF

Figure 7 shows the cross-section of the model for the Albert Whitted WRF with the TDS distribution at the end of the year 2005 contoured. Within 500 feet of the injection well, some freshening is predicted to occur in Zone A. Conversely, between 500 and 5,000 feet of the well, TDS concentrations are predicted to increase modestly. Model results indicate that freshening in zones above the injection zone will be restricted to an area within 1,000 feet of each injection well.

CH2MHILL

Figure 8 illustrates the simulated TDS concentration in Zone A from hypothetical wells located 0.25, 0.5, 1, 2, and 3 miles from the site. As with the other models, the most significant changes in water quality are predicted to occur within 0.25 miles of the injection well. The model predicts that at a distance of 0.25 miles from the site, the TDS concentration will increase from approximately 3,000 ppm to approximately 6,000 ppm over the simulation period. At a distance of 0.5 miles from the site, however, only a modest increase in TDS concentration (to approximately 3,500 ppm) is predicted. At distances greater than 1 mile, no change is discernible at the end of year 2005.

Figure 9 illustrates the simulated TDS concentration at the base of the USDW from hypothetical wells located 0.25, 0.5, 1, 2, and 3 miles from the site. For the Albert Whitted model, the bottom of the USDW occurs in the permeable unit A/BB at an approximate depth of 400 feet below land surface. Significant increases in TDS concentration occur out to about 2 miles from the site. At a distance of 3 miles from the modeled injection well, a relatively modest increase in TDS concentration is predicted, from 10,000 ppm to approximately 11,200 ppm.

Northeast WRF

Figure 10 shows the cross-section of the model at the Northeast WRF with the TDS distribution at the end of year 2005 contoured. Water quality changes are primarily limited to zones below the USDW, as relatively low permeability semi-confining units at the site restrict vertical migration of injected fluids.

Competent confinement at the Northeast WRF is further demonstrated in Figure 11, which illustrates the simulated TDS concentration in Zone A from hypothetical wells located 0.25, 0.5, 1, 2, and 3 miles from the site. The model predicts only insignificant increases in TDS concentration, even at a distance of 0.25 miles from the site.

Figure 12 illustrates the simulated TDS concentration at the base of the USDW from hypothetical wells located 0.25, 0.5, 1, 2, and 3 miles from the site. For the Northeast WRF model, the bottom of the USDW is located in the middle of Zone A at a depth of approximately 200 feet below land surface. Because the base of the USDW occurs in Zone A, Figure 12 resembles Figure 11 very closely, showing only relatively insignificant increases in TDS concentrations even at a distance of 0.25 miles from the site.

Summary

Solute transport modeling is being used to evaluate historical and potential future water quality changes that may occur in the vicinity of each of the City of St. Petersburg's WRFs as a result of operation of the City's deep injection well systems. This modeling is being used as technical support for the City's pending Class V injection well operating permits, to provide the City and the regulatory agencies responsible for permitting the deep injection system with an understanding of the estimated water quality changes that may occur. Model conceptualization and calibration have been presented in previous technical memoranda submitted to the FDEP (STM-1 and STM-2). This technical memorandum presents the results of the initial predictive modeling conducted at each of the four injection sites.

Northeast Chart 1 11/13/96

Figure 12

The predictive modeling used historical flow data through December 1995. An additional 10 years of projected flow data were used to estimate and evaluate the possibility of future water quality changes within the USDW at each site. The 10-year period represents two FDEP permitting cycles. Projected injection rates were estimated as minimum historical flows in response to conditions presented in this technical memorandum.

Discernible water quality changes at the base of the USDW can be expected to occur within the following approximate radial distances from each injection site:

- Albert Whitted WRF -- Up to 3 miles
- Northeast WRF -- 0.25 miles or less
- Northwest WRF -- 2 miles or less
- Southwest WRF -- 1 mile or less

In addition, discernible water quality changes in Zone A can be expected to occur within the following approximate radial distances from each injection facility:

- Albert Whitted WRF -- 0.5 miles or less
- Northeast WRF -- 0.25 miles or less
- Northwest WRF -- 0.5 miles or less
- Southwest WRF -- 0.25 miles or less

The predictive models suggest that outside of these radial distances, water quality changes—although they may occur—are expected to be indiscernible and insignificant, and should not restrict the potential to develop future groundwater resources relative to previously available uses.

The extent of predicted water quality changes at the base of the USDW at the Albert Whitted WRF is most likely an over-statement of what is actually occurring in the area. The model was calibrated to best-fit onsite monitoring data and assumes homogeneous conditions exist for approximately 7 miles surrounding this injection site. Conditions encountered at the other three injection sites, however, suggest that the Albert Whitted WRF hydrogeologic conditions are anomalous and indicate that a localized fracture most likely exists in the area. To assume that this degree of leakance exists beyond a very short distance from the wells is to be overly conservative in estimating water quality changes that may be occurring at distance.

The results of the predictive modeling are reasonable and largely consistent with historical observed data, except for the monitoring data available from the Northeast WRF injection system. Reasons for the difference between observed and modeled water quality changes at the Northeast WRF are primarily a result of integrity problems associated with the cluster well, as discussed in detail in STM-2, which have been repaired. The modeled results are supported by the minimal amount of reclaimed water which has arrived at the lowermost monitoring interval (M-2) at the Northeast WRF.

Recommendations

Based on the results of the initial predictive modeling, CH2M HILL offers the following recommendations:

1. Continue to operate the injection wells on an as-needed basis as a backup to the reclaimed water reuse program. The solute transport modeling conducted to date suggests that water quality changes observed with the deep injection well program are localized and will not adversely impact future water resource availability in southern Pinellas County.

2. Continue pursuing the reclassification of the existing Class I deep injection wells to Class V. Solute transport modeling suggests that salinity increases are predicted to continue at the base of the USDW and in Zone A within a short distance of each WRF. Class V injection system regulations are not as stringent in restricting fluid movement across the base of the USDW. The deep injection system currently functions more as a Class V injection system than as a typical Florida Class I domestic injection well.

3. Continue to develop additional reuse customers, as available, to further decrease the amount of future injection to the deep injection wells. Investigate reclaimed water ASR as a method to seasonally store and re-use excess available reclaimed water during the wet periods.

4. Meet with FDEP to discuss the results of the solute transport modeling used to support issuance of Class V operating permits for the City's deep injection well program.

Sea level: In this report, “sea level” refers to the National Geodetic Vertical Datum of 1929 (NGVD of 1929)—a geodetic datum derived from a general adjustment of the first-order level nets of both the United States and Canada, formerly called Sea Level Datum of 1929.

The standard unit for transmissivity (T) is cubic meter per day per square meter times meter of aquifer thickness. This mathematical expression reduces to meter squared per day.

Temperature in degrees Celsius (°C) can be converted to degrees Fahrenheit (°F) as follows:
°F = 1.8(°C) + 32

Preliminary Assessment of Injection, Storage, and Recovery of Freshwater in the Lower Hawthorn Aquifer, Cape Coral, Florida

By Vicente Quiñones-Aponte *and* Eliezer J. Wexler

Abstract

A preliminary assessment of subsurface injection, storage and recovery of fresh canal water was made in the naturally brackish lower Hawthorn aquifer in Cape Coral, southwestern Florida. A digital modeling approach was used for this preliminary assessment, incorporating available data on hydrologic conditions, aquifer properties, and water quality to simulate density-dependent ground-water flow and advective-dispersive transport of a conservative ground-water solute (chloride ion).

A baseline simulation was used as reference to compare the effects of changing various operational factors on the recovery efficiency. A recovery efficiency of 64 percent was estimated for the baseline simulation. Based on the model, the recovery efficiency increases if the injection rate and recovery rates are increased and if the ratio of recovery rate to injection rate is increased. Recovery efficiency decreases if the amount of water injected is increased; slightly decreases if the storage time is increased; is not changed significantly if the water is injected to a specific flow zone; increases with successive cycles of injection, storage, and recovery; and decreases if the chloride concentrations in either the injection water or native aquifer water are increased. In everal hypothetical tests, the recovery efficiency fluctuated between 22 and about 100 percent.

Two successive cycles could bring the recovery efficiency from 60 to about 80 percent. Interlayer solute mass movement across the upper and lower boundaries seems to be the most important factor affecting the recovery efficiency. A sensitivity analysis was performed applying a technique in which the change in the various factors and the corresponding model responses are normalized so that meaningful comparisons among the responses could be made. The general results from the sensitivity analysis indicated that the permeabilities of the upper and lower flow zones were the most important factors that produced the greatest changes in the relative sensitivity of the recovery efficiency. Almost equally significant changes occurred in the relative sensitivity of the recovery efficiency when all porosity values of the upper and lower flow zones and the leaky confining units and the vertical anisotropy ratio were changed.

The advective factors are the most important in the Cape Coral area according to the sensitivity analysis. However, the dispersivity values used in the model were extrapolated from studies conducted at the nearby Lee County Water Treatment Plant, and these values might not be representative of the actual dispersive characteristics of the lower Hawthorn aquifer in the Cape Coral area.

INTRODUCTION

Cape Coral, a coastal suburban community in western Lee County (fig. 1), is a fast growing city in southwestern Florida, with the population increasing at a rate of 8.5 percent during the year ending in April 1989 (City of Cape Coral, Planning Division, written commun., 1989). The city had less than 500 residents in 1960, but became the largest city in Lee County by 1983. The number of permanent residents in 1990 was estimated at more than 73,600. Temporary residents from the northern United States and Canada typically increase the population by about 20 percent during the winter months (City of Cape Coral, Planning Division, 1988).

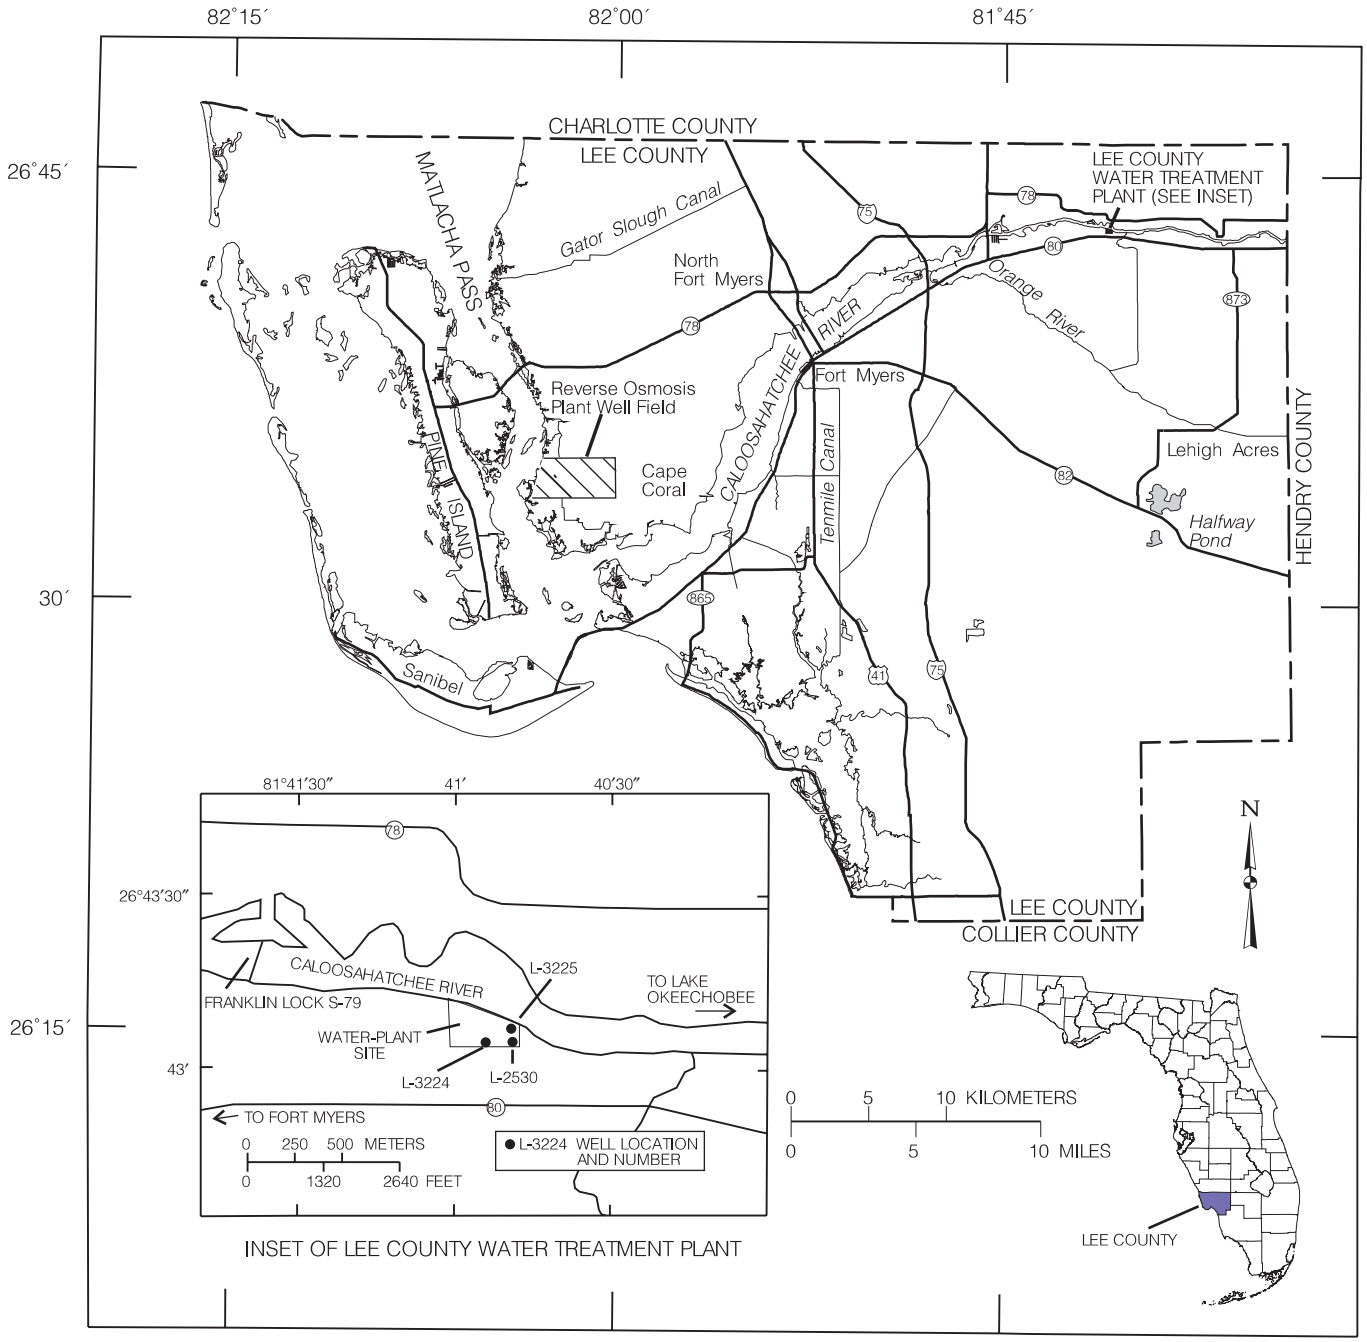

Figure 1. Location of the Cape Coral study area, wells, and the Lee County Water Treatment Plant site.

The rapidly increasing population has placed a stress on the potable water supply for Lee County. The upper Hawthorn aquifer (also referred to as the mid-Hawthorn aquifer) is the principal source of fresh ground water in Cape Coral. This aquifer is moderately permeable and has been subjected to severe drawdowns, particularly during a recent 3-year drought period (1989-91). At present (1994), the most reliable municipal water supply to Cape Coral (and nearby Pine Island) is brackish water from the lower Hawthorn aquifer that is treated at a 52,990 m^3/d reverse-osmosis (RO) plant. Drawdowns in this moderately permeable aquifer have also been substantial. Increased population and water demands in Charlotte County to the north and upgradient of Cape Coral could have an effect on the amount of water available in the two aquifers.

Demand for water is seasonal with peak use occurring during the dry season (November-April) when monthly precipitation averages less than 51 mm (National Oceanic and Atmospheric Administration,

1944-88). Lawn, golf course, agricultural irrigation, and public-supply demands are highest during this period. Temporary water-use restrictions have been implemented occasionally during recent years because of drought conditions and could become permanent as the demand for water becomes more acute.

Alternative water supplies or a means of augmenting existing supplies is a major concern to water-management officials. For this reason, the U.S. Geological Survey, in cooperation with the City of Cape Coral and the South Florida Water Management District, began a study in October 1986 to assess the feasibility of subsurface injection, storage, and recovery of freshwater (SISRF) in Cape Coral. The objectives of the study were to: (1) define the runoff pattern of the freshwater canal system, (2) assess quantities of excess runoff occurring during the wet season, and (3) assess the feasibility of conserving the excess runoff through subsurface storage. This report involves the development and testing of a digital model for assessing hypothetical SISRF tests in Cape Coral.

Although a site seems favorable for SISRF, the recovery efficiency at a particular site can only be determined by establishing a full-scale test facility and conducting full cycle testing under various conditions. Pilot tests are generally too expensive for preliminary assessments, such as this study. However, recent SISRF tests conducted by the U.S. Geological Survey at the Lee County Water Treatment Plant (Fitzpatrick, 1986a) can provide information, which when supplemented with less expensive computer-modeling techniques, yield usable preliminary information on recovery efficiency for an SISRF operation in Cape Coral.

Purpose and Scope

This report presents the results of a preliminary assessment of the subsurface injection, storage, and recovery operation in the lower Hawthorn aquifer in Cape Coral, Fla., using a digital modeling technique. Model simulations were made to assess: (1) recovery efficiencies for injected water; (2) the effect of repeated cycles, length of storage period, injection rates, and volumes of injected water on recovery efficiency; and (3) the relation between recovery efficiencies and the uncertainty in values for hydrogeologic properties. Hydrogeologic data from boreholes in Cape Coral and at the Lee County Water Treatment Plant were used to estimate hydraulic characteristics of the lower Hawthorn aquifer.

A modified SUTRA (**S**aturated-**U**nsaturated **TRA**nsport) ground-water flow and solute-transport digital model was used for the simulations. Data from an earlier study at the Lee County Water Treatment Plant were used to calibrate and test the model, and the model was then applied to simulate a hypothetical injection and recovery operation in Cape Coral. Nearly 30 simulations calculated recovery efficiencies for various changes in injection and recovery rates, volumes of water injected, storage time, and solute concentrations.

Description of Study Area

The city of Cape Coral occupies an area of 259 km^2 in Lee County, southwestern Florida (fig. 1). The development of the area, originally a low-lying pineland subject to frequent flooding, began in 1958 and continued to the early 1960's with the construction of a 724-km drainage canal system that interlaces the entire area (Knapp and others, 1984).

The Cape Coral watershed is similar to most southern Florida watersheds in that it is characterized by sheetflow runoff conditions and swamp type vegetation. Surface-water runoff in these watersheds is exclusively derived from rainfall. Rainfall is subdivided into surface-water runoff, evapotranspiration, and natural recharge to the shallow surficial aquifer. Some of the recharge to shallow aquifers returns to the drainage canals in Cape Coral. Many of the canals (totaling about 193 km in length) convey saltwater because they are affected by tidal reaches of the Caloosahatchee River and bays in the Gulf of Mexico. The remaining canals on higher lands convey surface-water runoff collected from the watershed. Although canals that convey fresh surface-water runoff and those that contain saltwater are connected, the movement of saltwater into the freshwater canals is impeded by a series of weir structures with crests that are above sea level.

The freshwater canal system contains two different systems, the north Cape Coral canal system and the south Cape Coral canal system. The canal systems are separated by U.S. Highway 78 with the northern system bounded by Gator Slough. Dredge spoil obtained during canal construction was used to raise land surface as much as 0.62 m in some areas (Fitzpatrick, 1986b). H.R. La Rose indicates that flow through the canals responds to seasonal patterns (U.S. Geological Survey, written commun., 1994). Records for the north Cape Coral canal system indicate that canal flow (not including flood peaks) ranges from 0.85 to 2.83 m^3/s during wet seasons and can be as low as 0.003 m^3/s during dry seasons.

Cape Coral has a subtropical climate with temperatures that are moderated by the Gulf of Mexico. The average annual temperature is 23°C with monthly averages ranging between 28°C in August and 18°C in January. Annual precipitation averages 1,372 mm. Hurricanes have caused damage in the past with high-velocity winds, rainfall, and tidal surges in Lee County. Additional data on local climate are available in a summary report by the Lee County Planning Department (1977).

Subsurface Injection, Storage, and Recovery of Freshwater Concept

Subsurface injection, storage, and recovery of freshwater in saline aquifers underlying southern Florida is a method of water-supply augmentation that has received increased attention in recent years. The SISRF concept is particularly suited for southern Florida where there is: (1) a surplus of freshwater during the wet season; (2) lack of suitable surface storage reservoirs because of the high cost of land, low relief, and high rates of evapotranspiration; and (3) availability of moderately permeable aquifers near the surface which contain brackish water (defined in the table below).

The average monthly rainfall in Cape Coral is more than 178 mm during the wet season (May-October). Most of this water ultimately discharges to the tidal reach of the Caloosahatchee River or Matlacha Pass through an extensive network of drainage canals totaling about 483 km. In the SISRF concept, part of the surface freshwater discharge is intercepted, treated for removal of suspended solids, chlorinated, and then injected through wells into the lower Hawthorn aquifer or deeper aquifers. Water is stored in the aquifers for 3 to 6 months and recovered during the dry season (November-April) to augment supply or meet peak demand. This cyclic procedure of injection, storage, and recovery is repeated on an annual basis.

Success of an SISRF cycle is measured by the recovery efficiency—defined as the volume of mixed injected and native aquifer waters recovered that meets a prescribed chemical standard, expressed as a percentage of the volume of water initially injected (Meyer, 1989). Most recent studies of SISRF, including this study, have assumed the Florida Department of Environmental Protection (1993) recommended level of 250 mg/L (milligrams per liter) for chloride ion as the standard which is equivalent to about 500 to 600 mg/L total dissolved solids. Generally, the degree of water is expressed as a percent of seawater in terms of total dissolved solids. The U.S. Geological Survey has adopted the following classification:

Classification	Total dissolved solids concentration (milligrams per liter)	Percent seawater
Freshwater	<1,000	<2.9
Slightly saline (brackish water)	1,000 - 3,000	2.9 - 8.6
Moderately saline (brackish water)	3,000 - 10,000	8.6 - 29
Very saline (saltwater)	10,000 - 35,000	29 - 100
Brine	>35,000	>100

Factors Affecting Recovery Efficiency

Merritt (1985) and Merritt and others (1983) studied the potential for SISRF in southern Florida and described a number of physical mechanisms that control the recoverability of freshwater and determine the suitability of the receiving aquifer for SISRF. The three dominant processes are buoyancy stratification, mixing due to hydrodynamic dispersion, and downgradient displacement of the injected freshwater.

Buoyancy stratification describes the tendency for the lighter freshwater to rise through the aquifer as it moves outward from the injection well and overrides the denser, native saltwater. Native saltwater in the lower part of the injection zone is drawn into the well during recovery, whereas potable water remains in the upper part of the zone. Buoyancy stratification is controlled by several factors, including: (1) the density contrast between native and injected waters, (2) permeability of the injection zone, and (3) the thickness of the injection zone (Merritt, 1985). These studies indicate that the effect of buoyancy stratification is smaller in relatively thin aquifers of moderate permeability and containing native water of low total dissolved solids concentration. These type of aquifers, therefore, are suitable for SISRF. Confinement of the injection zone by low-permeability materials can also aid in limiting the upward movement of freshwater.

Hydrodynamic dispersion is the mixing of solutes between zones of high and low solute concentrations as a result of molecular diffusion and mechanical dispersion. Molecular diffusion is caused by the flux of solute particles from areas of high solute concentration to areas of low solute concentration. The effect of molecular diffusion is independent of the fluid velocity. Mechanical dispersion is caused by mixing of solutes due to variations in fluid velocities at the microscopic scale. Enhanced mechanical dispersion or macrodispersion is caused by fluid velocity variations resulting from local differences in hydraulic conductivity.

Mechanical dispersion is dependent on the fluid velocity. At the relatively large fluid velocities during injection and recovery cycles, the effects of mechanical dispersion are generally greater than those of molecular diffusion.

Dispersive mixing causes the formation of a transition zone between the native and injected waters. The size of this zone depends on the rate of injection, length of injection period, and the solute-concentration difference between native and injected waters. Because fluid velocities are highest near the well, most of the mixing occurs at the beginning of the injection process. As injection continues, the transition zone moves outward at continually decreasing fluid velocities, leading to decreasing dispersive mixing. Merritt (1985) reported that the growth of the transition zone did not keep pace with the growth of the freshwater zone for long injection periods, thus providing for enhancement of the recovery by injecting larger volumes of water.

The effect of downgradient movement of the freshwater zone on recovery efficiency depends on the length of the cycle and the regional ground-water flow velocities. It is possible to design multiple-well injection systems in situations where flow velocities are high and storage periods are long, similar to those described by Merritt (1985) or Kimbler and others (1975). These multiple well systems can be used to offset the effects of downgradient movement.

The lower Hawthorn aquifer beneath Cape Coral seems to meet most of the criteria for consideration in an SISRF scheme. The aquifer has moderate permeability with mean values representing the vertical distribution of hydraulic conductivity that ranges from 21.3 to 41.4 m/d (estimated using data from Missimer and Associates, Inc., 1985). The aquifer, confined by low-permeability leaky units on the top and bottom, has a thickness of about 60 m. The native water is brackish with chloride concentrations (500-600 mg/L), total dissolved solids concentrations (greater than 1,000 mg/L), and densities (1,001 kg/m^3) not much different from the treated surface water that is proposed to be injected. Rates of regional movement of ground water are generally lower in the northern part of Cape Coral and are higher in the vicinity of the RO wells to the south (fig. 1). Other factors in favor of SISRF are: (1) the artesian heads to be overcome by forced pumping are relatively low; (2) the aquifer is moderately permeable, allowing reasonable rates of pumping be maintained; and (3) well-construction costs would probably not be much higher than for typical water-supply wells in the area.

Another factor that can affect SISRF efficiency is clogging of the aquifer around the injection wellbore. This clogging can be caused by bacterial growth, suspended sediments in the injected water, and chemical precipitation of solutes caused by chemical reactions between the injected fluid and the aquifer material or native water. Removal of sediments and disinfection of the water would likely be required before injecting surface waters. Geochemical models can be used to predict the reactions likely to occur during rock-water interaction and mixing of injected and native waters; additional treatment requirements for the injected water could then be determined. However, the analysis of the well-clogging potential was beyond the scope of this study.

GENERAL HYDROGEOLOGIC SETTING

The geology of Lee County and the Cape Coral area has been described by previous investigators, including Wedderburn and others (1982), Knapp and others (1984), and Missimer and Associates, Inc. (1984). The upper 228 m of sediments in the Cape Coral area are composed of the upper part of the Suwannee Limestone of Oligocene age, the Tampa Limestone and the Hawthorn Formation of Miocene age, the Tamiami Formation of Pliocene age, and undifferentiated deposits chiefly of Pleistocene and Holocene age (fig. 2).

The Suwannee Limestone underlying Cape Coral is predominantly a very pale orange to tan medium-grained limestone, but tends to be sandy and slightly phosphatic (Knapp and others, 1984). The top of the unit generally dips to the south-southeast and ranges from 183 m below sea level at the northern border of Cape Coral to about 229 m below sea level at the southeastern end (Missimer and Associates, Inc., 1984). The base of the unit lies between 274 and 366 m below sea level although few wells in the area penetrate beyond the upper part of the Suwannee Limestone.

Earlier reports by the U.S. Geological Survey divide the Miocene age sediments into two units, the Tampa Limestone and Hawthorn Formation. Recent studies (Wedderburn and others, 1982; Missimer and Associates, Inc., 1984) refer to the Tampa Limestone as the Tampa Formation and, although lithologically distinctive, include these sediments within the Hawthorn Formation.

The Tampa Limestone is present from about 150 to 200 m below land surface and is described by Wedderburn and others (1982) as a very light orange to white,

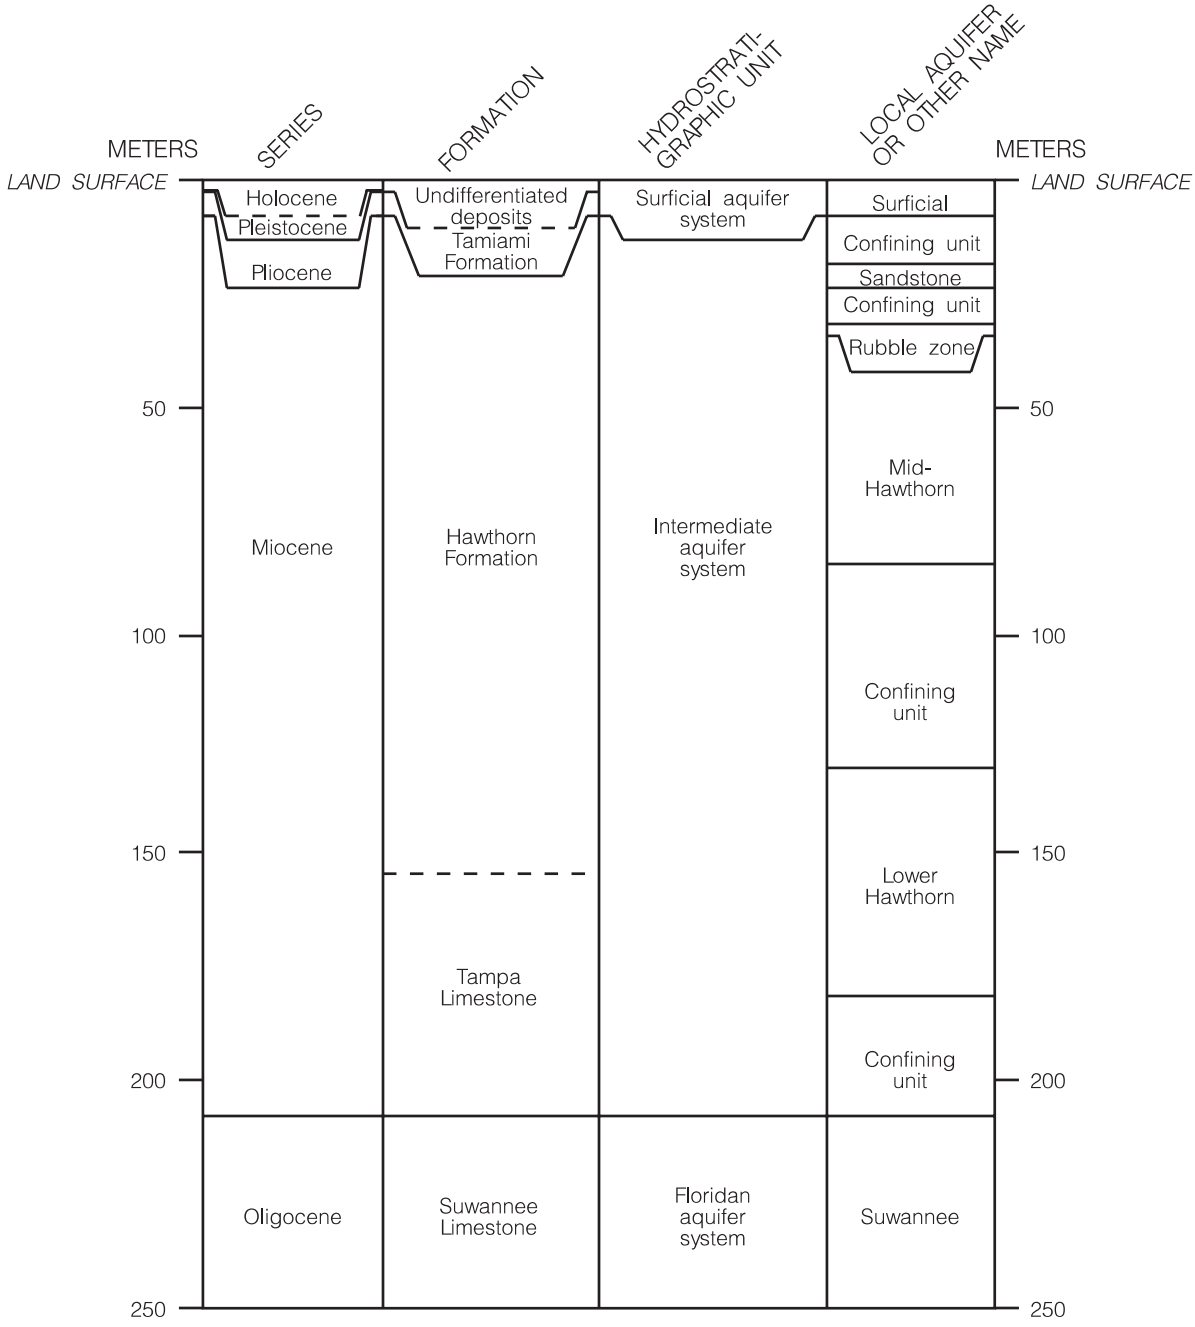

Figure 2. Profile showing geologic formations, hydrostratigraphic units, and local aquifers underlying Cape Coral (modified from La Rose, 1990).

biogenic, micritic, very fine grained limestone with up to 10 percent quartz sand. The Hawthorn Formation is a predominantly clastic unit. The thickness of the formation is about 150 m (Wedderburn and others, 1982). The Hawthorn Formation consists of a series of highly heterogeneous, interbedded clayey phosphatic dolosilts and phosphatic sandy dolomites and limestones (Wedderburn and others, 1982). The upper part of the Hawthorn Formation is a slightly sandy, dolomitic, phosphatic limestone with a maximum thickness of 46 m (Wedderburn and others, 1982). The top of this bed is about 30 m below sea level beneath Cape Coral and dips primarily to the southeast reaching 53 m below sea level in the southeastern corner of Cape Coral. Local names for zones within the upper part of the Hawthorn Formation have been listed by Missimer and Associates, Inc. (1984) and include the Cape Coral clay, Lehigh Acres sandstone, and Fort Myers clay.

Pliocene and Pleistocene age sediments range from 6.1 to 12.2 m thick in the study area (Missimer and Associates, Inc., 1984). Locally, four geologic formations occur within these undifferentiated sediments: (1) the Pamlico sand, (2) the Fort Thompson formation, (3) the Caloosahatchee formation, and (4) the Pinecrest member of the Tamiami Formation. Detailed stratigraphic descriptions are given by Missimer and Associates, Inc. (1984).

Hydrogeology of the Lower Hawthorn Aquifer

The lower Hawthorn aquifer occurs in the lower part of the Hawthorn Formation and the upper part of the Tampa Limestone (fig. 2). The lower Hawthorn aquifer in Cape Coral occurs from about 128 to 188 m below land surface, having an average thickness of 60 m. However, the thickness of its water-yielding zone is less than 30 m (La Rose, 1990). The lower Hawthorn aquifer is confined by thick, leaky clay sequences above and below. Because of this confinement and the higher heads in the upgradient recharge area, this aquifer is considered to be an artesian system with a producing capacity ranging from 0.019 to 0.032 m^3/s in large-diameter wells under natural flow conditions.

Although abundant water is available from the lower Hawthorn aquifer, high chloride concentrations (greater than 500 mg/L) preclude its direct use for public-water supply. Water from the lower Hawthorn aquifer is used to feed RO desalination plants in Cape Coral. According to an interpretation of the hydrogeologic system by La Rose (1990), recharge to the lower Hawthorn aquifer comes from the mid-Hawthorn aquifer north of the study area where the upper confining unit pinches out in Hillsborough, Polk, Manatee, and Hardee Counties.

Hydraulic Characteristics of the Lower Hawthorn Aquifer

Three individual flow zones in the lower Hawthorn aquifer at the Lee County Water Treatment Plant are identified by Fitzpatrick (1986a) using data from geophysical logs (caliper, flow velocity, fluid resistivity, and fluid temperature) during pumping and injection conditions (table 1).

The percentages of flow from the individual zones at the Lee County Water Treatment Plant (table 1) are estimated from caliper/velocity borehole studies conducted by Fitzpatrick (1986a). The aquifer is characteristic of a leaky confined aquifer with hydraulic characteristics as follows (Fitzpatrick, 1986a):

$$T = 7.526 \times 10^{-4}\ m^2/s \text{ to } 8.601 \times 10^{-4}\ m^2/s,$$

$$S = 1 \times 10^{-4}, \text{ and}$$

$$K_v'/b' = 0.01 \text{ per day} = 864 \text{ per second}$$

where,

T is transmissivity;
S is storage coefficient;
K_v' is vertical hydraulic conductivity of the confining beds; and
b' is thickness of the confining beds.

The hydraulic characteristics of the individual flow zones at the Lee County Water Treatment Plant are estimated using the following procedure:

$$Q_T = Q_1 + Q_2 + Q_3 \quad (1)$$

where,

Q_T is the total flow rate through the well; and
Q_i (i = 1,2,3) represents the flow components from the different flow zones.

Table 1. General hydrogeologic characteristics of flow zones and confining units in the lower Hawthorn aquifer at the Lee County Water Treatment Plant and Cape Coral

Location	Flow zones and leaky confining units (meters below land surface)	Thickness (meters)	Percent of flow from this zone	Hydraulic conductivity (meters per second)	Intrinsic permeability (square meters)
Lee County Water Treatment Plant	153.9–160.0	6.1	30	3.775×10^{-5}	3.846×10^{-12}
	160.0–167.6	7.6	5	5.044×10^{-6}	5.140×10^{-13}
	167.6–176.8	9.2	65	5.468×10^{-5}	5.572×10^{-12}
Cape Coral	198.0–213.3	15.3	34	1.065×10^{-4}	1.085×10^{-11}
	213.3–222.5	9.2	2	1.041×10^{-5}	1.061×10^{-12}
	222.5–231.6	9.1	64	3.370×10^{-4}	3.435×10^{-11}

For each flow zone:

$$Q_i = 2\pi r T_i \frac{dh_i}{dr} \quad (2)$$

where,

r is radial distance from pumping well;
dh_i is the head change in the different flow zones; and
dr is the change in distance from the pumping well.

Assuming no head gradient among the flow zones, $dh_i/dr = dh/dr$, and uniform head in the wellbore:

$$Q_T = 2\pi r(T_1 + T_2 + T_3)\frac{dh}{dr} = 2\pi r T \frac{dh}{dr} \quad (3)$$

and

$$T = T_1 + T_2 + T_3 = K_1 b_1 + K_2 b_2 + K_3 b_3 . \quad (4)$$

For example, if T is the composite transmissivity estimated from an aquifer test, assuming that equation 4 can be applied, $Q_i/Q_T = T_i/T$ and $T_i = K_i b_i$ gives the hydraulic conductivity of each zone. If $T = 7.68 \times 10^{-4}$ m^2/s (aquifer test), 30 percent of the total flow (Q_T) comes from zone 1 (flowmeter survey), and this zone has a thickness of 6.1 m:

$$T_1 = \frac{Q_i}{Q_T} T = 0.30 \times 7.68 \times 10^{-4} (m^2/s) = 2.30 \times 10^{-4} (m^2/s),$$

and

$$K_1 = \frac{T_1}{b_1} = \frac{2.30 \times 10^{-4} (m^2/s)}{6.1 \text{ m}} = 3.775 \times 10^{-5} \text{ (m/s)},$$

The hydraulic conductivity (K_i) values for the different flow zones are given in table 1. Aquifer matrix permeability (k_i, intrinsic permeability) values from table 1 are then computed using:

$$k_i = \frac{\mu}{\rho} \frac{K_i}{g} \quad (5)$$

where,

μ is dynamic viscosity of the fluid [M/LT];
ρ is fluid density [M/L^3]; and
g is gravitational acceleration [L/T^2].

Although the general hydrogeologic framework of the lower Hawthorn aquifer at the two sites (Cape Coral and the Lee County Water Treatment Plant) is similar, the magnitude of the hydraulic characteristics is somewhat different. Analysis of flow velocity and caliper borehole logs (fig. 3) in Cape Coral indicated a similar flow zoning, occurring at different depths below land surface and with different thicknesses and hydraulic coefficients (table 1). The upper flow zone and the low permeability unit seem to be thicker in Cape Coral, but the distribution of flow across these hydrogeologic units is almost the same (table 1).

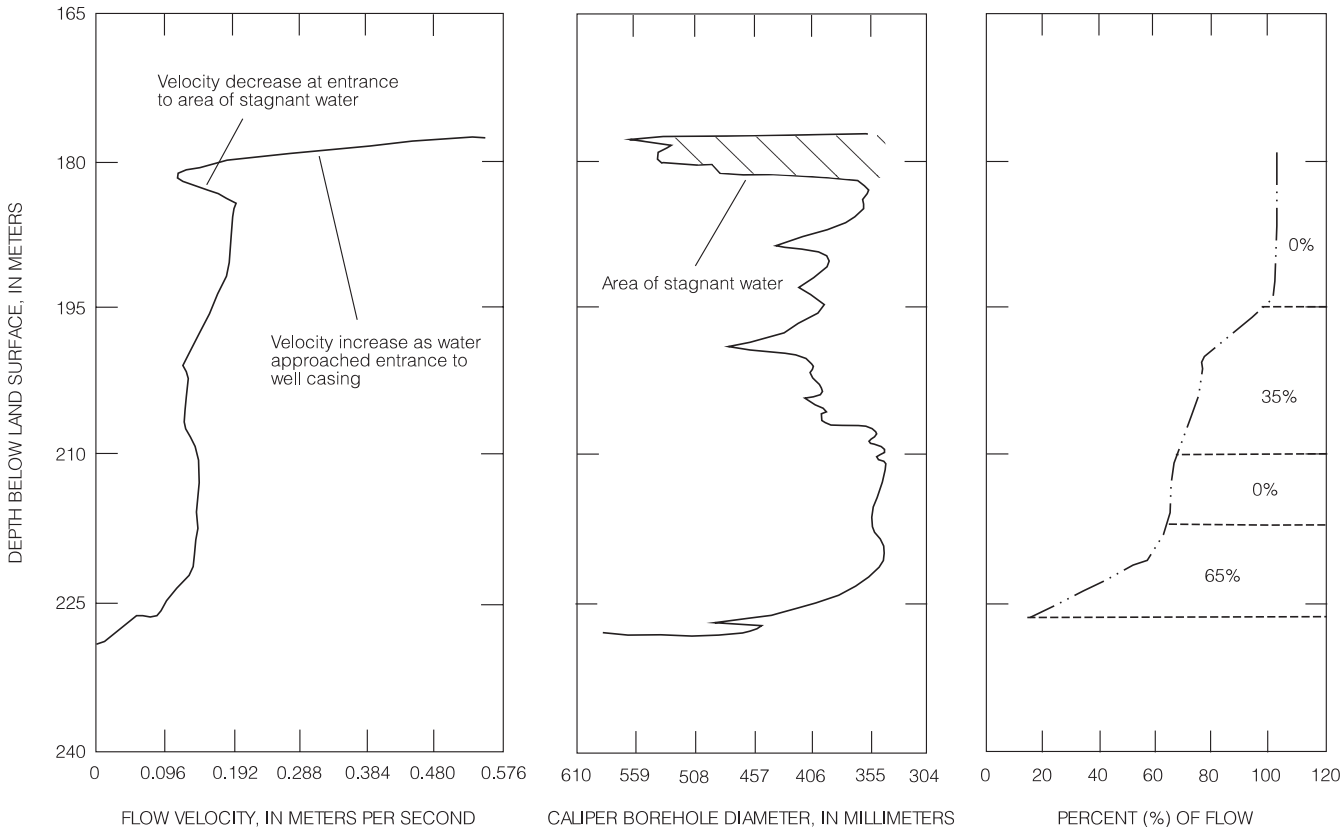

Figure 3. Percent of total flow estimated using velocity and caliper borehole logs for well L-M-2426 at Cape Coral.

Apparent transmissivity values are estimated for several wells in Cape Coral (table 2), using specific capacity values from step-drawdown tests conducted by Missimer and Associates, Inc. (1985), and the empirical equation by Brown (1963). Estimated transmissivity values range from 149 to about 807 m^2/d (fig. 4 and table 2) with a geometric mean value of about 414 m^2/d. Values of hydraulic conductivity and intrinsic permeability are estimated for the lower Hawthorn aquifer in Cape Coral (table 1), using the geometric mean of the transmissivity values and equations 1 to 5.

Table 2. Specific capacity and apparent transmissivity values for wells completed in the lower Hawthorn aquifer at Cape Coral

[Specific capacity values from Missimer and Associates, Inc. (1985); apparent transmissivity values estimated using the empirical equation by Brown (1963)]

Well identification number	Specific capacity (liters per second per meter)	Apparent transmissivity (meters squared per day)
L-M-2417	4.74	496.7
L-M-2418	5.20	546.4
L-M-2419	3.97	409.8
L-M-2420	5.55	583.6
L-M-2421	3.35	347.7
L-M-2422	4.57	496.7

L-M-2428	4.14	397.4
Geometric mean		414.3
Standard deviation		203.7

THEORETICAL BACKGROUND

The ability to assess whether SISRF could be an economical water-supply alternative is enhanced by the capability to predict the movement of water and solutes under the conditions of injection, storage, and recovery. Digital models have been developed by the U.S. Geological Survey and others to simulate the density-dependent flow of ground water and the transport of solutes in ground-water systems. These models can utilize data on fluid and aquifer properties to estimate recovery efficiencies under conditions expected at a particular study area.

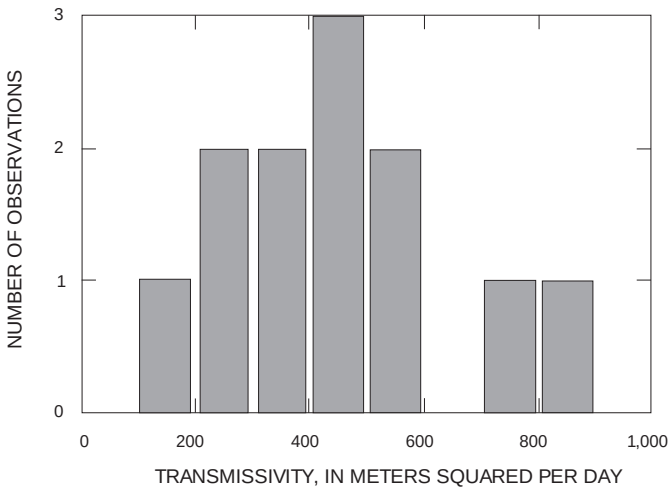

Figure 4. Histogram of apparent transmissivity values estimated from wells tapping the lower Hawthorn aquifer at Cape Coral.

Simulation of density-dependent ground-water flow and solute transport requires the solution of two governing partial differential equations subject to appropriate boundary and initial conditions. The first equation describes transient ground-water flow under conditions where density differences due to solute concentrations can affect flow. The second equation describes the movement and spread of solutes within the flowing ground water using data on the distribution of ground-water velocities obtained by solving the first equation. The two equations are solved iteratively, as the distribution of solute concentrations needed to solve the first equation is initially estimated and updated after solving the second equation. The theoretical background of the governing equations is discussed in the next section.

Density-Dependent Ground-Water Flow Equation

The rate of ground-water flow is assumed to be governed by Darcy's law, which when written in terms of fluid pressure (rather than piezometric head), is:

$$q = -k(\nabla\rho - \rho g z)/\mu \qquad (6)$$

where,

q is specific discharge (flow rate per unit cross-sectional area) [L/T];
k is the intrinsic permeability of the aquifer materials [L^2];
∇ is the gradient operator [1/L];
p is the fluid pressure [M/LT^2];
ρ is the fluid density [M/L^3];
g is the gravitational acceleration vector [L/T^2];
z is the elevation above a reference datum [L]; and
μ is the dynamic viscosity of the fluid [M/LT].

Using Darcy's law and the principle of conservation of fluid mass, a mass-balance equation can be written as:

$$\frac{\partial(n\rho)}{\partial t} = -\nabla \bullet (\rho q) \pm Q_p \qquad (7)$$

where,

n is aquifer porosity [dimensionless], and

Q_p is mass of fluid injected (+) or withdrawn (-) per unit time per unit volume of aquifer [M/L^3T].

The dependence of fluid density on solute concentration has an important effect on the mass-balance equation, which can be seen by expanding the first term in equation 7:

$$\frac{\partial(n\rho)}{\partial t} = \frac{\rho\partial n\partial p}{\partial p\partial t} + \frac{n\partial\rho\partial p}{\partial p\partial t} + \frac{n\partial\rho\partial c}{\partial c\partial t} \ , \qquad (8)$$

or

$$\frac{\partial(n\rho)}{\partial t} = \frac{S_s\partial p}{\partial t} + \frac{n\partial\rho\partial c}{\partial c\partial t} \qquad (9)$$

where,

c is solute concentration (mass of solute/mass of water) [dimensionless]; and

S_s is specific pressure storativity of the aquifer

given by $S_s = [(1\text{-}n)\,\alpha + n\,\beta]$ for an unconsolidating aquifer [LT^2/M] where,

α is compressibility of the aquifer solid matrix [LT^2/M], and

β is compressibility of water [LT^2/M].

The determination of fluid pressures at any given time, which affects the rates of fluid movement, requires the prior or simultaneous determination of the rate of change in fluid concentration over time. The specific discharge, as determined by Darcy's law, is also dependent on solute concentration through the density and viscosity terms (eq. 6), which is only slightly dependent on solute concentration.

A system of equations, such as equation 7, can be simultaneously solved for a given set of boundary conditions, aquifer properties, fluid densities, and rates of recharge or withdrawals from the aquifer. The solution will be in terms of the pressure at all points in the aquifer. The average pore velocity, v, can then be determined from the distribution of hydraulic head by Darcy's law:

$$v = -\frac{q}{n} \qquad (10)$$

where,

n is the effective porosity of the aquifer [dimensionless].

Advection and Hydrodynamic Dispersion

Movement of solutes through a porous medium is controlled by advection and hydrodynamic dispersion. Advective transport describes the movement of solute particles along the mean direction of fluid flow at a rate equal to the average pore-water velocity. Hydrodynamic dispersion describes the spread of solute particles along and transverse to the direction of average fluid flow in response to molecular diffusion and mechanical dispersion.

Molecular diffusion produces a flux of solute particles from areas of high to low solute concentrations; its effect is independent of the fluid velocity. Mechanical dispersion is the mixing of solutes caused by variations in fluid velocities at the microscopic scale. Velocity variations are caused by several factors, including: (1) velocity distributions within the pore space, (2) variations in pore size, (3) differences in path lengths for different solute particles, and (4) the effect of converging and diverging flow paths (Bear, 1979). Mechanical dispersion is dependent on fluid velocity, and at the relatively large pore-water velocities expected during injection and recovery phases, the effects are greater than those of molecular diffusion. Fluid movement during the storage phase is mainly from buoyancy forces, and at these low velocities, molecular diffusion can have a more significant role in solute movement.

Dispersive flux, J, can be described by Fick's first law as:

$$J = -D_m \nabla c \qquad (11)$$

where,

c is the volumetric concentration of solute [M/L^3]; and

D_m is the second rank tensor containing the coefficients of mechanical dispersion [L^2/T].

Mechanical dispersion coefficients are related to the average pore velocity by the dispersivity of the medium (Scheidegger, 1961). The coefficients of dispersivity are dependent on properties of the medium including permeability, length of a characteristic flow path, and tortuosity. In an isotropic medium (with respect to dispersion), the coefficients of mechanical dispersion can be expressed in terms of two components: (1) longitudinal dispersivity (α_L), which represents dispersion in the direction of the flow path; and (2) transverse dispersivity (α_T), which represents dispersion in the direction perpendicular to the flow path. Transverse dispersivities are usually smaller than longitudinal dispersivities by a factor of 5 to 20 (Freeze and Cherry, 1979).

The nine components of the symmetric mechanical dispersion tensor can be expressed in terms of v (the average pore-water velocity vector) and the velocity components v_x, v_y, and v_z (Bear, 1979). In a system where ground-water flow is horizontal (v_z=0), the components of the mechanical dispersion tensor are:

$$\begin{aligned} D_{xx} &= (\alpha_L v_x^2 + \alpha_T v_y^2) / |v| \\ D_{xy} &= D_{yx} = (\alpha_L - \alpha_T) v_x v_y / |v| \\ D_{yy} &= (\alpha_L v_y^2 + \alpha_T v_x^2) / |v| \\ D_{xz} &= D_{zx} = D_{yz} = D_{zy} = 0 \\ D_{zz} &= \alpha_T |v|. \end{aligned} \quad (12)$$

For radially symmetric irrational flow (v_Θ=0) systems, subscripts x and y are replaced by r and z, respectively.

The hydrodynamic dispersion tensor can be written as:

$$D_h = D_m + D_d \underline{I} \quad (13)$$

where,

D_h is the second order hydrodynamic dispersion tensor [L^2/T];
D_m is the mechanical dispersion tensor [L^2/T];
D_d is the coefficient of molecular diffusion [L^2/T]; and
$\underline{I}$ is the identity tensor.

Macrodispersion

Longitudinal dispersivities typically range from 0.100 to 10.00 mm in laboratory experiments with homogeneous materials and have been estimated as much as 90 m from field studies of contaminant plumes (Freeze and Cherry, 1979). The larger values in field studies are related to increased mixing (on a macroscopic scale) because of local variations in aquifer hydraulic and dispersive characteristics.

Most studies of radial injection have assumed that macrodispersive fluxes can be represented by Fick's law with a constant dispersion coefficient. However, recent studies of transport in porous media have indicated that dispersion can increase away from the source and reach an asymptotic value after travel distances of hundreds or thousands of feet (Gelhar and Axness, 1983). Dispersivities are scale dependent at short distances with values increasing away from the contaminant source as larger scale heterogeneities occur (Gelhar and others, 1979). Recent developments in the macrodispersion theory are discussed by Anderson (1984).

In this study, aquifer dispersivity values were estimated from the analysis of field test data from a previous study (Fitzpatrick, 1986a). Values of aquifer dispersivity used in the different simulations and sensitivity analyses are discussed in later sections. Limitations of the advective-dispersive model must be recognized along with the other limitations introduced because of uncertainties in aquifer properties.

Advective-Dispersive Solute-Transport Equation

A version of the variable-density advective-dispersive solute-transport equation modified for saturated flow and conservative solute species presented by Voss (1984) is:

$$\frac{\partial(n\rho c)}{\partial t} = -\nabla\cdot(n\rho v c) + \nabla\cdot[ns(Dd\,\underline{I} + Dm)\cdot\nabla C] + Q' c^* \quad (14)$$

where,

Q' is the volumetric injection rate per unit area of aquifer [L/T]; and

c^* is volumetric solute concentration in the injected fluid [M/L^3].

When applying equation 14 to freshwater injection in an aquifer, flow can be assumed to be either: (1) radially symmetric about the injection well (regional flow is negligible), or (2) horizontal and the solute concentration and fluid density are vertically uniform (regional flow is considered). In the latter case, the term c represents the vertically averaged concentration at a point in the aquifer. For this study, the first option was used.

The term $Q' c^*$ represents only sources of solute mass. Withdrawals of fluid from the aquifer do not need to be considered in the transport equation because the concentration of solute in the fluid withdrawn from the aquifer c^* is identical to the solute concentration c. The source term from equation 14 is incorporated as part of the boundary conditions.

PRELIMINARY ASSESSMENT OF INJECTION, STORAGE AND RECOVERY OF FRESHWATER

Solution of the two governing partial-differential equations generally requires sophisticated digital models. These models use numerical approximation techniques that determine aquifer pressure and solute concentrations at a finite number of points and at specified time intervals. SUTRA (**S**aturated-**U**nsaturated **TRA**nsport), a computer code based on the Galerkin finite element technique (Voss, 1984), was applied in this study. Modifications were made to the code to compute the solution in terms of a regular rectangular grid with the intention of minimizing computer storage and time (apps. 1 and 2). Appendix 1 contains the hierarchic levels of subprograms in the original SUTRA version and in the modified SUTRA version, hereafter referred to as QSUTRA.

Subprograms PLOT, CONNEC, BANWID, NCHECK, and PINCHB were not included. All of these subprograms, except for PLOT, were used in the original SUTRA version to process information related to the irregularity of element shapes forming the mesh or grid. A new subprogram (FOPEN) was added to open files and assign unit numbers (apps. 1 and 2) (C.I. Voss, U.S. Geological Survey, written commun., 1994). Subprogram SOLVEB, which includes the algorithms to solve the system of equations (eqs. 7 and 15), was substituted by subprograms SOLVEC and LSORA (apps. 1 and 3). SOLVEC uses the incomplete Cholesky-conjugate gradient method (Kuiper, 1987) to solve a system of ground-water flow equations (eq. 7). LSORA uses the line successive overrelaxation method (Young, 1954) to solve a system of solute-transport equations (eq. 15). Some other changes to the code are highlighted in the program listing (app. 2).

QSUTRA was tested by applying it to Henry's (1964) density-dependent flow problem described in Voss (1984, p. 196-203). This problem was selected because it provides a good opportunity to test the capabilities of QSUTRA in solving nonlinearities occurring in variable density flow problems. Comparison of results from QSUTRA and SUTRA for Henry's (1964) problem are presented in appendix 4. As shown in appendix 4, concentration profiles from QSUTRA and SUTRA are identical. Also, QSUTRA and SUTRA estimates of flux across one model boundary compare very well.

Simulations of freshwater injection, storage, and recovery in the lower Hawthorn aquifer were made using the QSUTRA code with a radial coordinates grid. The following assumptions are made: (1) the effect of the background hydraulic gradient is negligible, (2) the aquifer is divided into vertically adjacent layers characterized in the model as homogeneous with respect to the hydraulic and transport characteristics, (3) the hydraulic and transport characteristics are homogeneous along the radial direction of flow, and (4) the aquifer characteristics are isotropic along the horizontal (radial) direction. Assumptions 2 and 3 are made because of the lack of information on the spatial variability of the hydraulic and transport characteristics. Estimates of the transport characteristics of the lower Hawthorn aquifer were made using data from previous freshwater injection tests (Fitzpatrick, 1986a) conducted at the Lee County Water Treatment Plant (fig. 1).

Grid Design

Although the configuration of the lower Hawthorn aquifer at the Lee County Water Treatment Plant and Cape Coral are similar, differences on the thickness of the flow zones and on the magnitude of the hydraulic properties precluded the use of the same model grid for both sites. Two finite-element grids were required. The first grid was used for calibrating and testing the model with data from field tests conducted at the Lee County Water Treatment Plant and documented (Fitzpatrick, 1986a). The second grid was used to represent the hydrogeologic conditions at the Cape Coral site. Transport characteristics obtained from simulating Fitzpatrick's tests were extrapolated to the Cape Coral area.

The Lee County Water Treatment Plant site grid consists of 1,400 elements and 1,491 nodes (fig. 5A), and the Cape Coral grid consists of 2,100 elements and 2,201 nodes (fig. 6A). Both grids extend out radially to 10,384 m (figs. 5A and 6A). The Cape Coral grid was used to conduct hypothetical tests of freshwater injection, storage, and recovery in the lower Hawthorn aquifer in the study area (fig. 1). The grids are very fine (2 m) in the vicinity of the injection well so as to avoid errors associated with numerical dispersion (artificial dispersion introduced by inappropriate spatial discretization) and high aspect ratios (large difference between sides of an element). At a distance of 100 m, element lengths increased to 4 and 8 m at 120 m from the well. Beyond 160 m, element lengths were successively doubled until a maximum length of 4,096 m was reached. The thickness of elements remained constant (2 m). The part of the finite-element grids extending to a distance of 160 m from the injection well is shown in figures 5B and 6B, and the entire finite-element grids are shown in figures 5A and 6A.

Boundary and Initial Conditions

Boundary conditions were set at r=0, r=10,384 m, z=144.8 m below land surface, and z=184.8 m below land surface for the Lee County Water Treatment Plant model, and set at r=0, r=10,384 m, z=186 m below land surface, and z=246 m below land surface for the Cape Coral model—the limits of the finite-element grids (figs. 5 and 6). Boundaries at the top and bottom of the aquifer (upper and lower limits of the modeled zone) were set constant for pressure and concentration. The solute concentration was set equal to the solute concentration of the native water at these boundaries, and the pressures were set equal to the hydrostatic pressures at the specific depths where the boundaries were located.

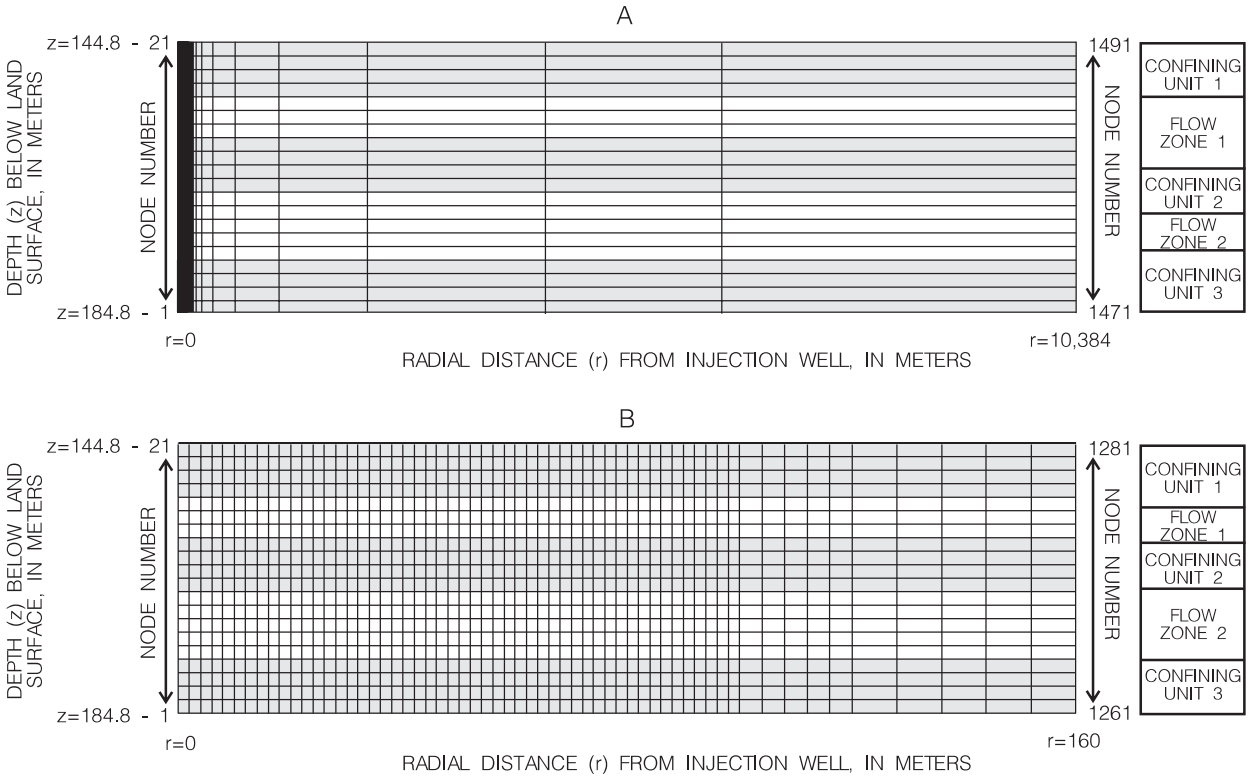

Figure 5. Sectional views of the cylindrical coordinate finite-element grid used to study previous subsurface injection, storage, and recovery of freshwater in the lower Hawthorn aquifer at the Lee County Water Treatment Plant.

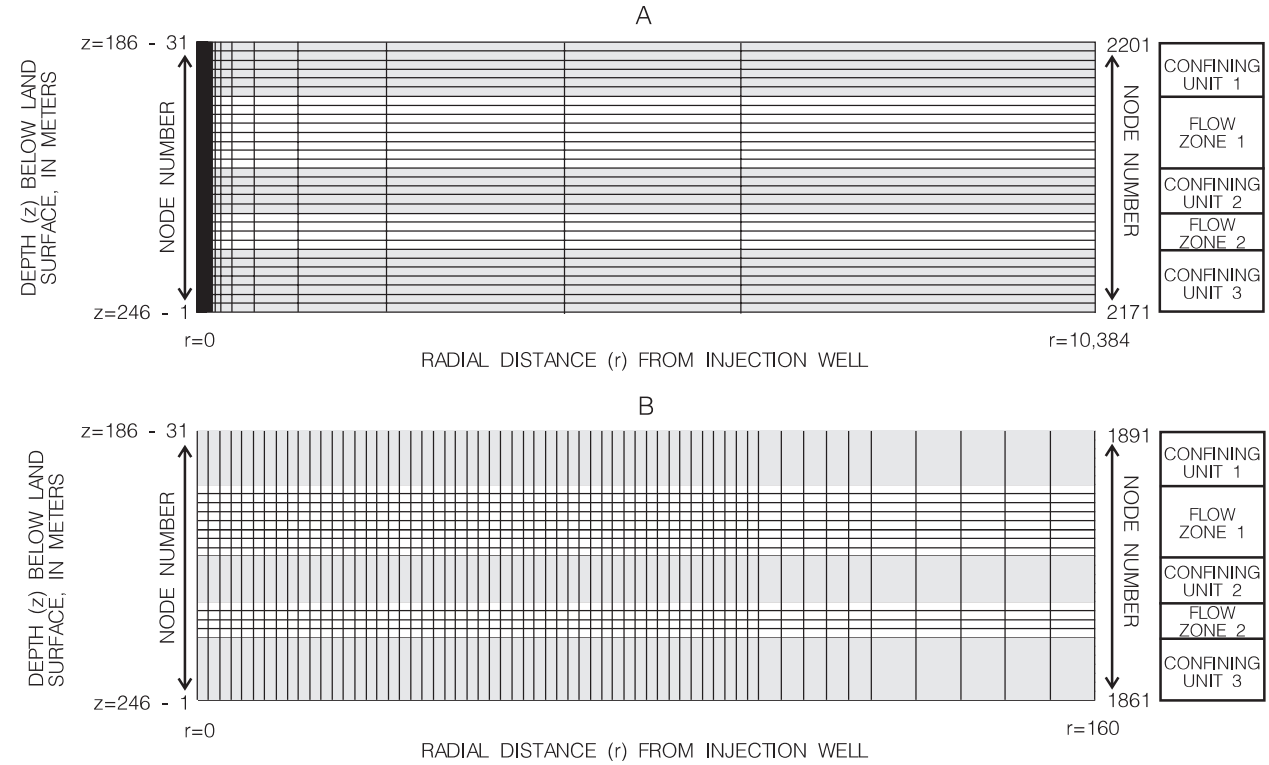

Figure 6. Sectional views of the cylindrical coordinate finite-element grid used to study hypothetical subsurface injection, storage, and recovery of freshwater in the lower Hawthorn aquifer at Cape Coral.

One limitation setting of these types of boundary conditions (constant pressure and concentration on top and bottom) is that if injected or mixed water passes across these boundaries, the model would be unable to consider it during the recovery pumping because the concentrations along these boundaries are assumed to represent a constant value. However, for the present study, these boundary conditions yielded the best representation of the actual aquifer in terms of approximating measured pressure and concentration changes in observation wells and in the injection well during recovery. Also, these boundary conditions would yield more conservative estimates of recovery efficiency. The lack of detailed hydrogeologic information beyond these boundaries precluded the location of the boundaries farther from flow zones receiving the injection water. An attempt was made to locate the boundaries farther from the injection source by extrapolating the hydrogeologic information, but the results were discouraging in terms of matching field measured pressure and concentration changes.

At r=10,384 m, no-flow/no-transport boundary conditions were specified. This boundary was intentionally located far from the injection source to prevent any effect that it might have on the determination of pressures and concentrations in the aquifer segment affected by the injection. Boundary conditions at the well (r=0) were set by specifying a mass flux equal to the injection rate. The flux was proportionally distributed among the boundary nodes along the length of the injection zone using the aquifer hydraulic characteristics (K) as a weighting factor. The solute concentration in the injected water during injection was specified at the well boundary (r=0). A flux average concentration for water withdrawn during recovery was calculated from concentration values at boundary nodes representing the well.

The hydraulic conductivity value of the upper and lower confining zones was modified using the model to replicate the effect of these leaky units on pressure and concentration changes in the main flow zones (discussed later). Although more sophisticated boundary types are currently available, they are not available in QSUTRA, and this study lacks the field data to justify their application. For large volumes of water injected (larger than those used in this study), the vertical and horizontal boundaries can become invalid yielding unrealistic model results.

Initial pressures were assumed to be hydrostatic and set equal to an equivalent freshwater head of 10.49 m above sea level for the Lee County Water Treatment Plant model and 7.62 m for the Cape Coral area model. Initial solute concentration was set equal to solute concentration in the native water. For this study, fluid density was assumed to depend only on solute concentration. Fluid density was calculated by the model based on initial solute concentrations and the following functional relation between density and solute concentration:

$$\rho = \rho_i + (\rho_n - \rho_i)\,[(C-C_i)/(C_n-C_i)] \qquad (15)$$

where,

ρ_i is density of injected water [M/L^3];

ρ_n is density of native water [M/L^3]l;

C is solute concentration in the mixed water [M/L^3];

C_i is solute concentration in the injected water [M/L^3]; and

C_n is solute concentration in the native water [M/L^3].

Solute Source

Chloride ion, the dominant conservative anion in the native aquifer water and the injected surface water, was selected as the solute to be modeled. Chloride concentrations in water samples from the lower Hawthorn aquifer ranged from 500 to 550 mg/L at the Lee County Water Treatment Plant and from 350 to 750 mg/L in Cape Coral (Missimer and Associates, Inc., 1985). The model computes relative or normalized concentrations that range from 0.1 to 1, where 0.1 represents concentration in the injected water and 1 represents concentration in the native water.

Time Steps

Initial time-step sizes were kept equal or smaller than 400 seconds to avoid numerical dispersion associated with a large time-step size. The time-step size was increased during the injection phase in such a way that the injected water front (neglecting dispersion) moved a constant distance during each successive time step. The final time-step size from the injection phase was used and kept constant for the entire simulation of the storage period. During the recovery phase, the time-step size was gradually reduced from its maximum value as the injected water front moved closer to the well. Generally, except for the first time step in each run, only two iterations per time step were needed to resolve the nonlinearities of the density-dependent flow equation (eq. 7).

Model Simulation Results for the Lee County Water Treatment Plant—Calibration and Testing

Data from a study by Fitzpatrick (1986a) were used in this study to define the hydrogeologic system and to provide a basis for estimating the hydraulic and transport characteristics for the lower Hawthorn aquifer in Cape Coral. The conceptual model for the Lee County Water Treatment Plant site was developed on the basis of interpretation of velocity, caliper, fluid resistivity, and fluid temperature borehole logs and interpretation of aquifer-test data (Fitzpatrick, 1986a). The conceptual model consists of two main flow zones and three leaky confining units (fig. 5). Aquifer hydraulic characteristics, boundary conditions, and nodes subject to them were previously described.

Two injection, storage, and recovery tests and results (table 3) from the study by Fitzpatrick (1986a) were useful in calibrating the model (tests 2 and 3). Test 3 was used for model calibration and test 2 for model testing. Data for test 3 were obtained for the injection well (L-3225) and two observation wells (L-2530 and L-3224), about 43 and 102 m, respectively, from the injection well. The calibration of the model was performed using the classical interactive process in which the model variables were changed within realistic limits, until a satisfactory match to the measured data was obtained. Initial model variables were set according to data presented in table 1 and information previously described in this report.

Increases in hydraulic head at observation wells L-2530 and L-3224 were used to calibrate the hydraulic variables. The permeability of the flow zones is assumed to be isotropic, and no attempt was made to change it. However, the permeability of the leaky confining units was decreased from an estimated value of 1.89×10^{-13} to 1.67×10^{-13} m^2 to obtain a satisfactory match between observed and modeled head change data (fig. 7A). The permeability is assumed to be isotropic in the vertical and horizontal directions. Following the hydraulic calibration, data on chloride concentration changes in the two observation wells (L-2530 and L-3224) were used to calibrate the transport model for effective porosity and longitudinal and transverse dispersivities. The model yielded better results when using an effective porosity of 0.12, a longitudinal dispersivity (α_L) of 3.0 m, and a transverse dispersivity (α_T) of 0.3 m for a ratio of $\alpha_T/\alpha_L = 0.1$ (fig. 7B). However, the model did not fit the field test data for the early arrival times of the injected water front at well L-2530 (fig. 7B). Several simulations were made varying the effective porosity, dispersivity values (α_L and α_T), and the aquifer permeability without obtaining a good match to the field data from well L-2530, while simultaneously matching the field data from well L-3224. This is probably because of the nature of flow in a part of the aquifer, which according to the borehole velocity logs (fig. 3), seems to have cavernous porosity, whereas the model is based on equations that are developed for a porous media system.

Table 3. Results of two injection, storage, and recovery of freshwater tests conducted from a previous study in the lower Hawthorn aquifer at the Lee County Water Treatment Plant

[Tests conducted by Fitzpatrick (1986a). Recovery time indicates time since the beginning of recovery when chloride concentration of recovered water approached background concentration of native aquifer water]

Test number	Average injection rate (cubic meters per day)	Average recovery rate (cubic meters per day)	Total volume injected (cubic meters)	Injection time (days)	Storage time (days)	Recovery time (days)	Average chloride concentration of injected water (milligrams per liter)
2	1,635	899	26,160	16	47	50	171
3	1,423	818	109,571	77	98	150	69

Model results for test 3 were compared with field data at the injection well (L-3225) for the recovery phase. Although a satisfactory match was obtained for breakthrough at observation wells L-2530 and L-3224, model predicted values for recovery chloride concentrations at the injection well (L-3225) were low compared to field measured values. Different porosity values were assigned to the main flow zones and the leaky confining units in an attempt to improve the model predictions at the injection well while keeping a good match at the two observation wells. A combination of porosity values of 0.15 for the main flow zones and 0.05 for the leaky confining units yielded satisfactory results (fig. 8). The characteristics used in the calibrated model and the fluid, solute, and rock matrix properties used in the simulations are listed in tables 4 and 5, respectively.

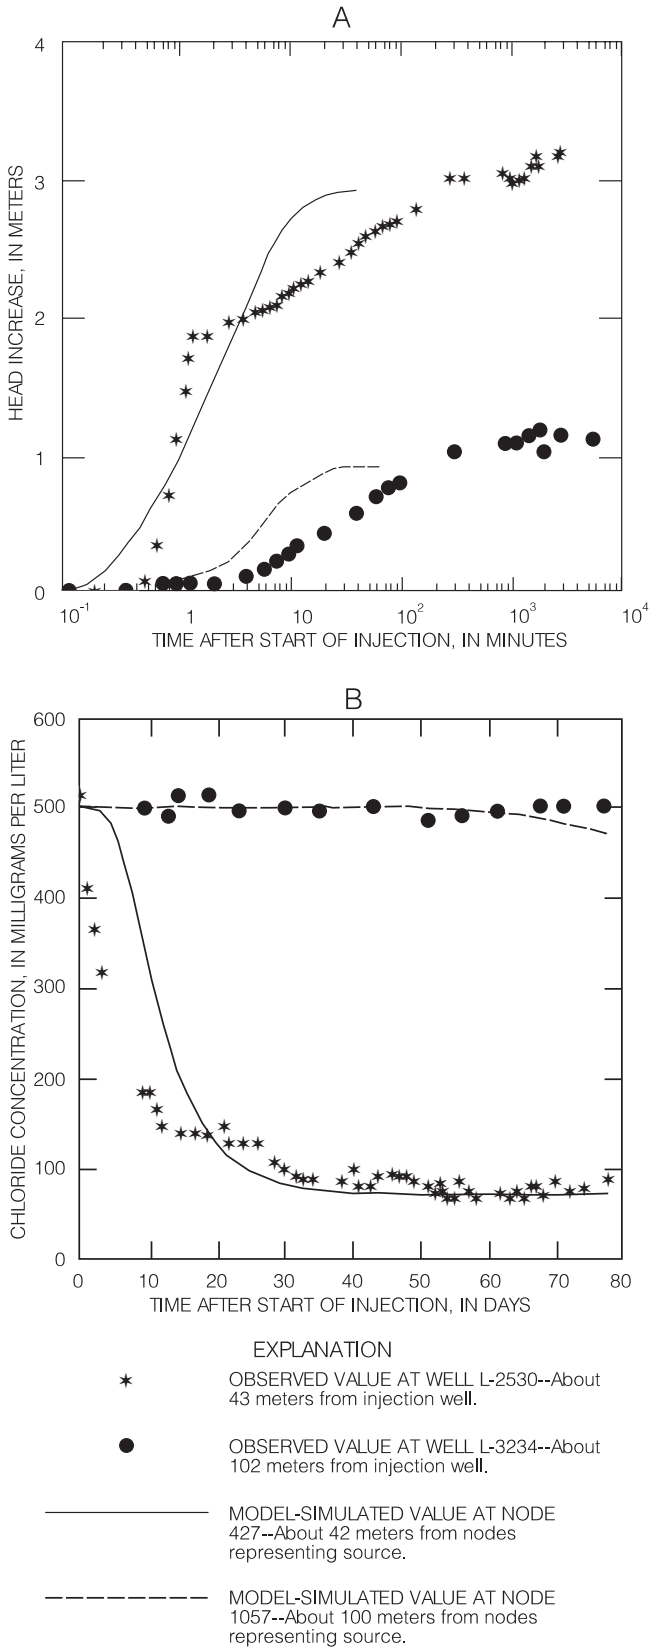

Figure 7. Observed and model simulated head increase during the first 7 days of injection and chloride concentration breakthrough curves at observation wells L-2530 and L-3224 during the injection phase of test 3 at the Lee County Water Treatment Plant.

The model was tested using chloride concentration data at the injection well (L-3225) during the recovery phase of test 2 (Fitzpatrick, 1986a). The test simulation was made using the same hydraulic and transport characteristics from the calibration run for test 3. The resulting chloride concentration breakthrough curve produced by the model was low compared to the field data (fig. 9). In an attempt to provide a closer match of the field data, the longitudinal and transverse dispersivity values were increased from 3.0 and 0.3 m to 5.0 and 0.5 m, respectively. This change resulted in a good match of the field measured data by the model-generated data (fig. 9). According to the present knowledge on the scale dependency of the dispersion coefficient (Gelhar and others, 1979; Gelhar and Axness, 1983; and Mercado, 1984), the value used to effectively simulate test 2 was expected to be smaller than its counterpart for test 3. However, the dispersivity value from test 2 was larger than that from test 3, but the difference between the values was small (α_L = 3.0 m and α_T = 0.3 m for test 3; α_L = 5.0 m and α_T = 0.5 m for test 2). No further attempt was made in this study to explain the differences in the dispersivity values between the two tests because detailed field information was unavailable.

Model Simulation Results for Cape Coral—Effects of Operational Factors on Recovery Efficiency

A series of hypothetical SISRF tests were made for the lower Hawthorn aquifer in Cape Coral using the digital modeling technique. Estimates of the hydrologic and transport characteristics from the analysis of previous test data (Fitzpatrick, 1986a) were used in a baseline simulation with other factors represented by values from studies in similar geologic units. The baseline simulation was used as a reference to study the effects of changing a series of SISRF operational factors on the recovery efficiency. The hydrologic and transport characteristics used in the baseline simulation were selected as the best possible representation of the actual field values in Cape Coral. These characteristic values might not necessarily represent the entire spatial spectrum of possible values in the lower Hawthorn aquifer. Therefore, the characteristic values used in the simulations are subject to some uncertainty. The effects on the recovery efficiency of the rates of injection and recovery; volume of water injected; storage time; injection into selected flow zones; successive cycles of injection, storage, and recovery; and chloride concentrations of injected and native waters were also studied using the digital model.

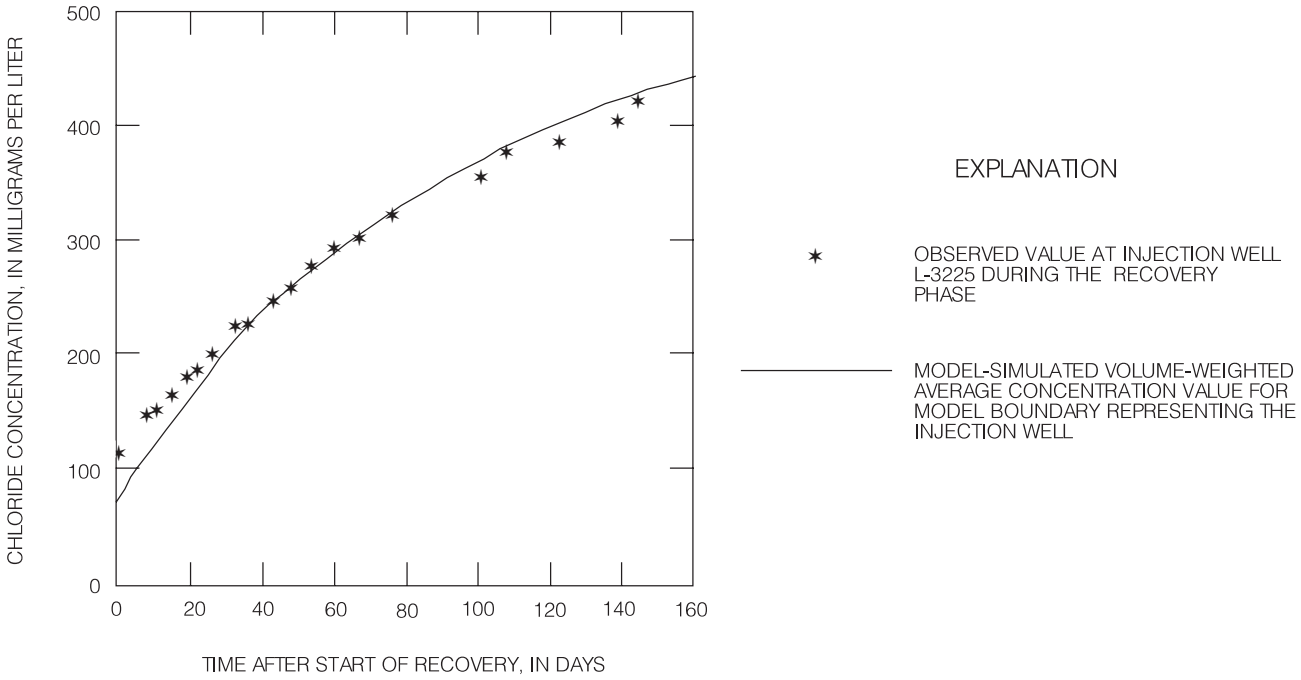

Figure 8. Observed and model-simulated chloride concentration in water recovered from injection well L-3225 during the recovery phase of test 3 at the Lee County Water Treatment Plant (data from Fitzpatrick, 1986a).

Table 4. Characteristics of flow zones and confining units used to model the lower Hawthorn aquifer at the Lee County Water Treatment Plant

Flow zones and leaky confining units (meters below land surface)	Permeability (square meters)	Effective porosity (percent)	Specific pressure storativity (kilograms per meter per second squared)$^{-1}$	Longitudinal dispersivity (meters)	Transverse dispersivity (meters)
144.8–152.8	1.670×10^{-13}	5	1.36×10^{-10}	3.0	0.3
152.8–158.8	3.846×10^{-12}	15	1.68×10^{-10}	3.0	.3
158.8–166.8	5.140×10^{-13}	5	1.36×10^{-10}	3.0	.3
166.8–176.8	5.572×10^{-12}	15	1.68×10^{-10}	3.0	.3
176.8–184.8	1.670×10^{-13}	5	1.36×10^{-10}	3.0	.3

Table 5. Fluid, solute, and rock matrix properties used in the simulations

Property	Value
Dynamic viscosity of native water, in kilograms per meter per second	0.001
Dynamic viscosity of injected water, in kilograms per meter per second	0.001
Density of native water, in kilograms per cubic meter	1,001.0
Density of injected water, in kilograms per cubic meter	1,000.1
Coefficient of molecular diffusion, in meters squared per second	5.0×10^{-10}
Fluid compressibility, in (kilograms per meter per second squared)$^{-1}$	4.4×10^{-10}
Rock matrix compressibility, in (kilograms per meter per second squared)$^{-1}$	1.2×10^{-10}

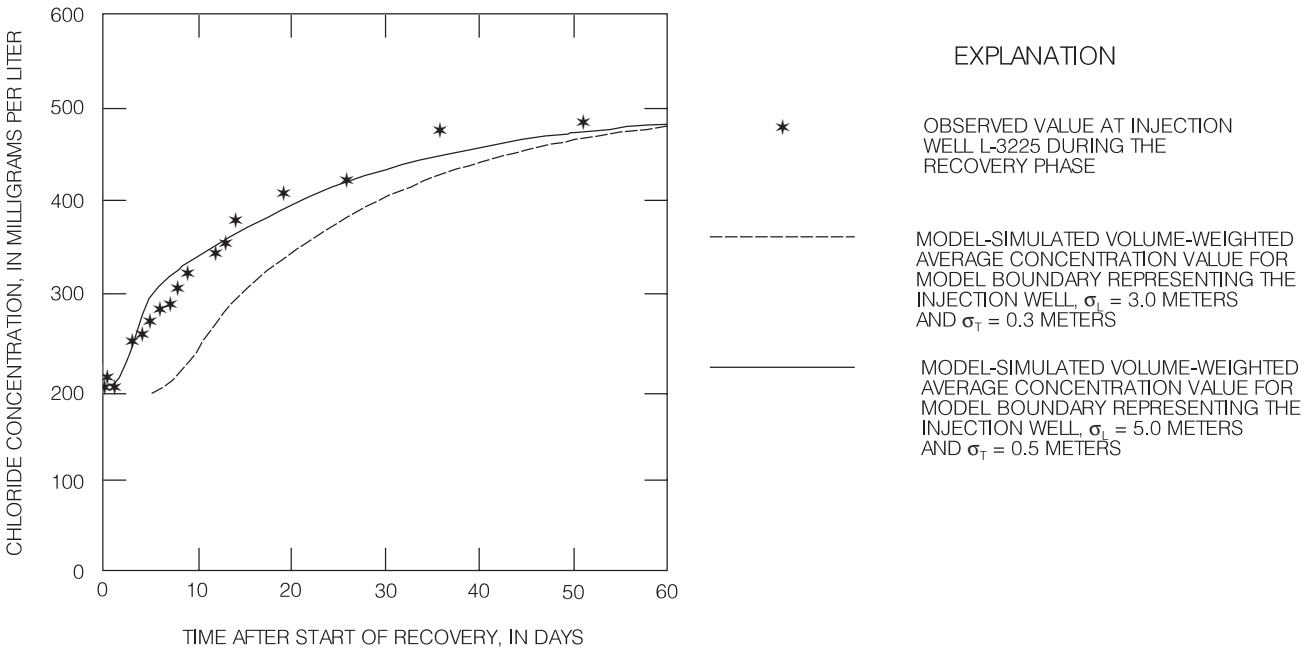

Figure 9. Observed and model-simulated chloride concentration in water recovered from injection well L-3225 during the recovery phase of test 2 at the Lee County Water Treatment Plant (observed data from Fitzpatrick, 1986a).

Baseline Simulation

A baseline simulation was made using the previously described model grid (fig. 6), estimated hydraulic and transport characteristics (tables 1, 5, and 6), and the conditions presented in table 7. The growth of the injected water body and the chloride distribution profiles (mixing zone) during the injection phase of the baseline simulation are depicted in figure 10. Although the injected water body in the lower main flow zone has twice the radial extent of its counterpart in the upper main flow zone, the difference between the chloride distribution profiles of the two flow zones was not significant (fig. 10). The injected water front was about 50 m from the injection well in the lower main flow zone and 25 m from the injection well in the upper main flow zone at the end of the injection phase (fig. 10D). A vector representation of the pore-water velocity field was generated by the model (fig. 11). This velocity vector shows that the injected water, in general, is moving: (1) horizontally outward along the two main flow zones, (2) vertically upward from the upper main flow zone into the upper confining zone, (3) vertically downward from the lower main flow zone into the lower confining zone, and (4) vertically upward from the lower main flow zone through the middle confining zone into the upper main flow zone (fig. 11). A similar vector representation was generated by the model during the recovery phase, but the vectors point in the opposite direction (fig. 12).

Table 6. Characteristics of flow zones and confining units used to model the lower Hawthorn aquifer at Cape Coral

Flow zones and leaky confining units (meters below land surface)	Permeability (square meters)	Effective porosity (percent)	Specific pressure storativity (kilograms per meter per second squared)$^{-1}$	Longitudinal dispersivity (meters)	Transverse dispersivity (meters)
186.0–198.0	1.061×10^{-12}	5	1.36×10^{-10}	3.0	0.3
198.0–214.0	1.085×10^{-11}	15	1.68×10^{-10}	3.0	.3
214.0–224.0	1.061×10^{-12}	5	1.36×10^{-10}	3.0	.3
224.0–232.0	3.435×10^{-11}	15	1.68×10^{-10}	3.0	.3
232.0–246.0	1.061×10^{-12}	5	1.36×10^{-10}	3.0	.3

Table 7. Conditions and results for recovery times and efficiencies for the baseline simulation and other simulations of subsurface freshwater injection, storage, and recovery for the lower Hawthorn aquifer at Cape Coral

[Recovery time is when the preestablished chloride concentration limit of 250 milligrams per liter is reached]

Simulation number	Injection rate (cubic meters per day)	Recovery rate (cubic meters per day)	Recovery rate/ injection rate (dimension-less)	Volume of injected water (cubic meters)	Injection time (days)	Storage time (days)	Chloride concentrations, milligrams per liter		Recovery time (days)	Recovery efficiency (percent)

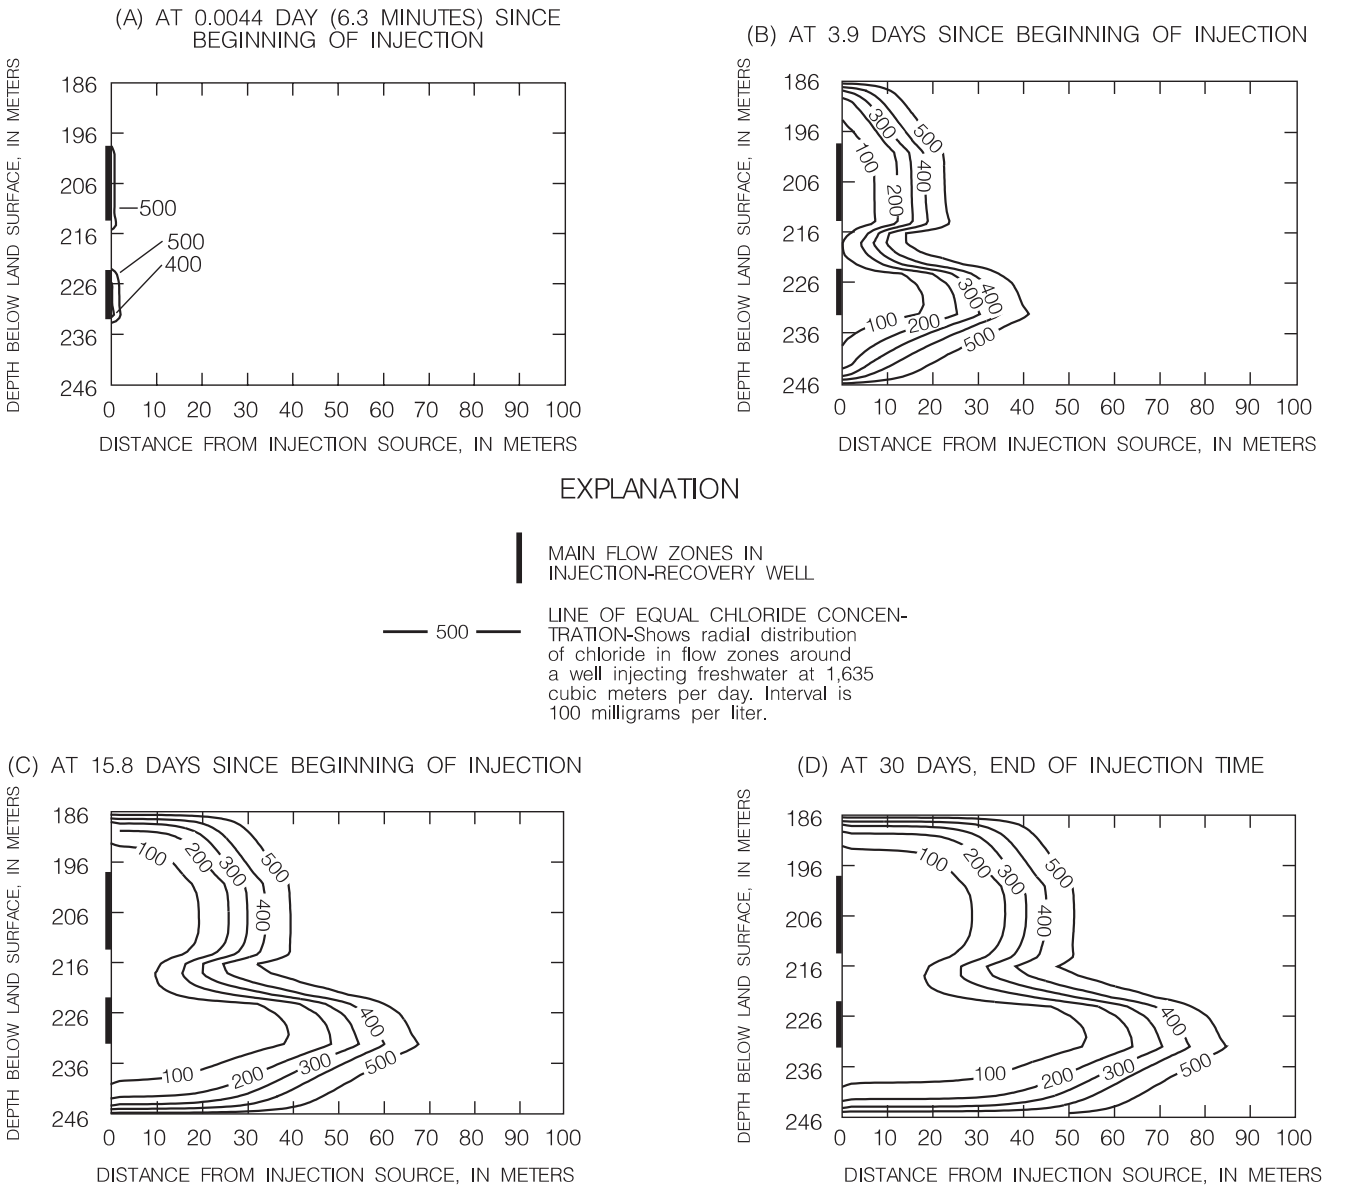

Figure 10. Chloride distribution profiles at different times during the injection phase of the baseline simulation.

A 64 percent recovery efficiency value was obtained for the baseline simulation for the preselected 250-mg/L chloride concentration limit. The thickness of the mixing zone at the end of the recovery phase grew from 1.5 to 2 times compared to its thickness at the end of the injection phase (figs. 13 and 10D). Some residual injected water was still inside the injection zones at the end of recovery (fig. 13). A subsequent injection phase would result in a wider mixing zone and a higher recovery efficiency.

A simulation was made with the same parameters that were used in the baseline simulation but using no-flow/no-transport boundaries at the top and bottom limits of the model. This simulation was conducted to test the effect on the recovery efficiency of using a constant pressure/constant concentration boundary condition to represent interlayer solute mass movement across these boundaries. The simulation yielded a recovery efficiency of 83 percentage points, which is 19 percentage points higher than the value estimated from the baseline simulation (64 percentage points). This indicates that the constant pressure/constant concentration boundaries are important in the determination of the recovery efficiency and that this type of boundary would yield more conservative estimates of the recovery efficiency.

Rates of Injection and Recovery

The effect of the rates of injection and recovery on the recovery efficiency was studied with eight simulations using different injection and recovery rates and injection rate/recovery rate ratios (simulations 2-9 in table 7). In simulations 2 to 5, the injection rate (Q_I) and the recovery rate (Q_R) were each changed by 25, 50, 200, and 400 percent from the value used in the baseline simulation. In simulations 6 to 9, the ratio of Q_R/Q_I was changed by 25, 50, 200, and 400 percent from the baseline simulation ratio ($Q_R/Q_I = 1$).

The results of the simulations indicated that when the injection rate was decreased by 25 and 50 percent while keeping Q_R/Q_I equal to 1, an insignificant decrease in the recovery efficiency occurred (fig. 14 and table 7). However, when the injection and recovery rates were increased by 200 and 400 percent, the recovery efficiency increased from 64 percent (for the baseline simulation) to 68 and 92 percent, respectively (fig. 14 and table 7). Although in a previous hypothetical study (Merritt, 1985) no relation was reported between the rates of injection and recovery and the

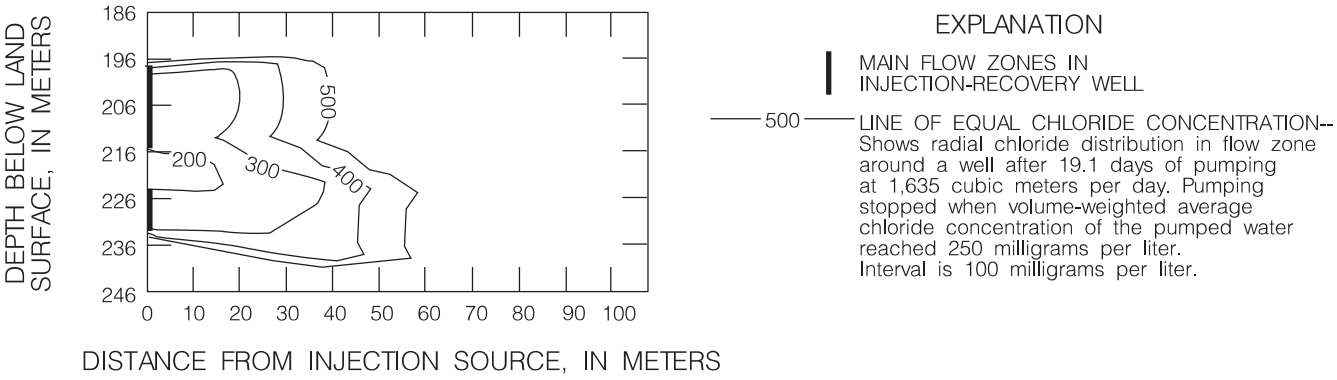

Figure 13. Chloride distribution profile at the end of the recovery phase of the baseline simulation.

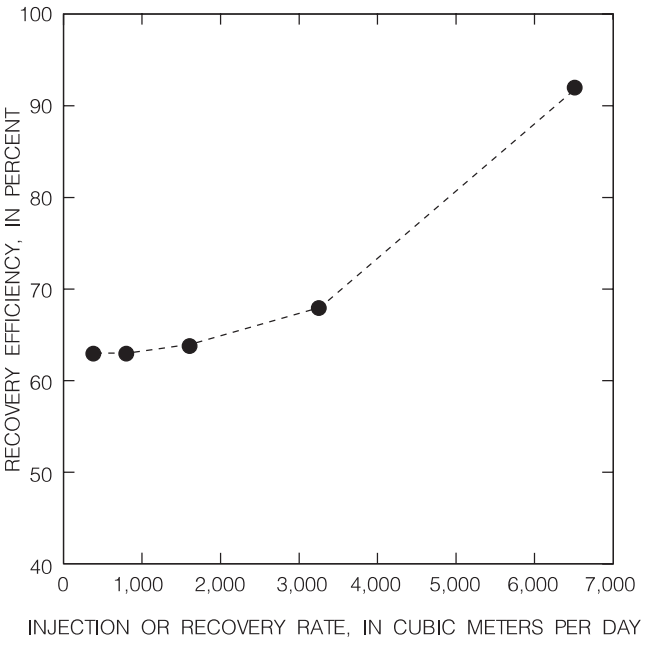

Figure 14. Relation between recovery efficiency and injection or recovery rate in the lower Hawthorn aquifer for $Q_R/Q_I = 1$.

recovery efficiency, the injected solute mass was confined by the upper and lower boundaries, keeping the injected mass near the well region and precluding mass migration across the upper and lower model boundaries. Because the mass of injected water was confined, no vertical movement occurred, and therefore, the duration and rate of injection and recovery were not important. Leakance occurs in most confined aquifers, and interlayer solute mass movement provides mechanics for mass migration, thereby affecting the recovery efficiency.

For the recovery rate/injection rate (Q_R/Q_I) ratios of 25 and 50 percent, the recovery efficiency decreased slightly (fig. 15 and table 7). For Q_R/Q_I ratios of 200 and 400 percent, the recovery efficiency increased from 64 percent (for the baseline simulation value) to 68 and 93 percent, respectively (fig. 15 and table 7). This relation can be explained by the fact that vertical mass transfer in leaky aquifers can be significant. For fast recovery rates, the vertical migration of mass would be smaller, providing for higher recoverability.

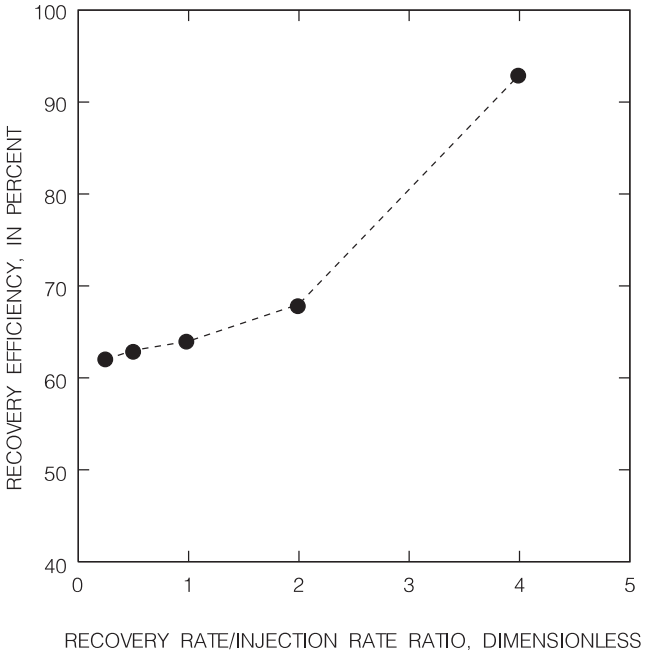

Figure 15. Relation between recovery efficiency and recovery rate/injection rate ratio in the lower Hawthorn aquifer.

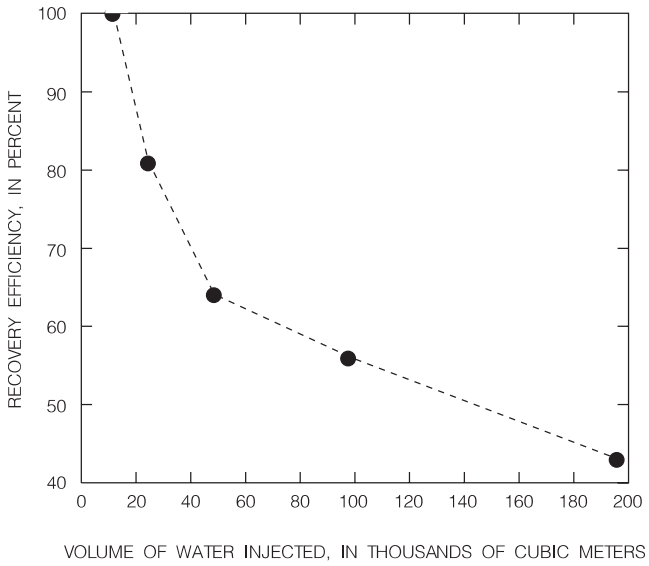

Figure 16. Relation between recovery efficiency and volume of water injected in the lower Hawthorn aquifer.

Volume of Water Injected

The effect of injecting different size volumes was studied using four simulations in which the injected volume was changed by 25, 50, 200, and 400 percent from the baseline simulation value (simulations 10-13 in table 7). This was accomplished by decreasing or increasing the injection time, while keeping the same injection rate used in the baseline simulation. Results from these simulations show that for the range of injected volumes tested in this study the recovery efficiency decreases as the volume of water injected increases (fig. 16 and table 7). Initially, the recovery efficiency decreases at a great rate as the volume of water injected is increased, but an asymptote is approached at a recovery efficiency value of about 40 percent (fig. 16); however, this result cannot be generalized. Some investigators (Merritt, 1985; Quiñones-Aponte and others, 1989) reported that the relation between the volume of water injected and the recovery efficiency can change direction for different ranges of volumes of water injected. For instance, the recovery efficiency for a range of small volumes of water injected can increase as the volume of water injected increases, and the recovery efficiency for a range of large volumes of water injected can decrease as the volume of injected water increases. The type of aquifer (confined or leaky) and boundary conditions can also affect the relation between volume of water injected and recovery efficiency. The leaky nature of the aquifer represented in this study model provides for transfer of injected water into low-permeability units. For longer injection times, larger volumes of water would migrate into and across the low-permeability units, thus reducing the potential for freshwater recovery.

Storage Time

The effect of storage time duration was assessed by increasing the duration of the storage time from the baseline simulation value of 0 days. Four simulations were made using storage times of 5, 30, 90, and 180 days (simulations 14-17 in table 7). Results from the simulations indicated that the storage time did not greatly affect the recovery efficiency, showing only a 4 percentage point decrease in recovery efficiency when the storage time was increased from 0 to 180 days (fig. 17 and table 7). However, the present model does not consider the regional background flow, which, combined with the storage time, could significantly reduce the recovery efficiency. Quiñones-Aponte and others (1989) interpreted actual SISRF tests and suggested that the recovery efficiency generally decreases as the storage time increases, but the rate of decrease in recovery efficiency would also depend on the volume of water injected. When small volumes of water are injected, the storage time has a stronger effect on reducing the recovery efficiency than when large volumes are injected (Quiñones-Aponte and others, 1989). The effect of storage time on the recovery efficiency would become overshadowed by the effect of the volume of water injected when the volume injected is large.

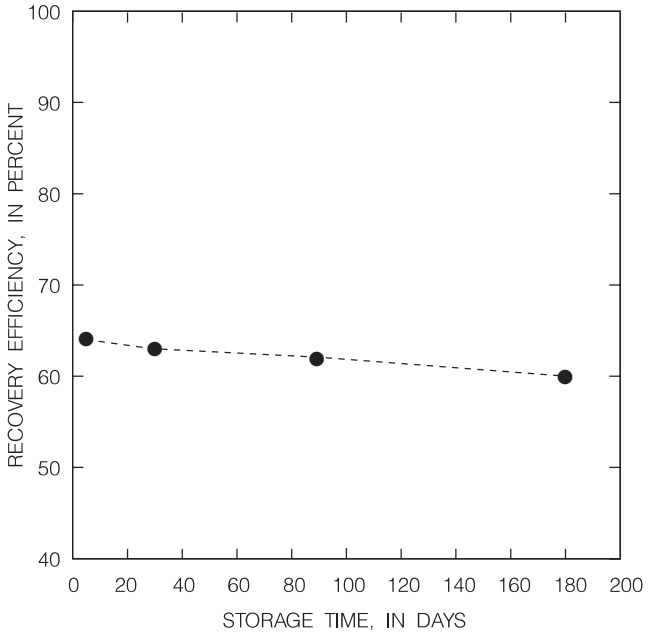

Figure 17. Relation between recovery efficiency and storage time in the lower Hawthorn aquifer.

Water Injected into Selected Flow Zones

The effect of injection into selected flow zones on recovery efficiency was studied by individually injecting the same volume of water at the same rate (volume and rate used for the baseline simulation) to each of the two more permeable flow zones. Two simulations were made—injection into the upper flow zone (198-213.3 m) and injection into the lower flow zone (222.5-231.6 m). The recovery efficiency did not change significantly; however, the configuration of the lines of equal chloride concentration at the end of the injection phase for both simulation cases revealed a sharp contrast between cases (fig. 18) and compared to their counterpart for the baseline simulation (figs. 18 and 10D). Model results indicated that the recovery efficiency in both cases decreased by a very small amount (simulations 18 and 19 in table 7) compared with the baseline simulation, which is not significant if the errors associated with the numerical method are taken into consideration. Merritt (1985) reported similar results; however, to generalize these results, a more-detailed study focusing on this aspect (injection into different flow zones) is needed.

When the injection well is open to all of the flow zones, a potential problem is the occurrence of interflow from higher to lower permeability zones through the wellbore during storage time. Water from flow zones under higher hydraulic pressure flows through the wellbore into flow zones under lower hydraulic pressure. This potential problem was not assessed by the model presented in this report; however, it should be considered for the design of actual injection wells.

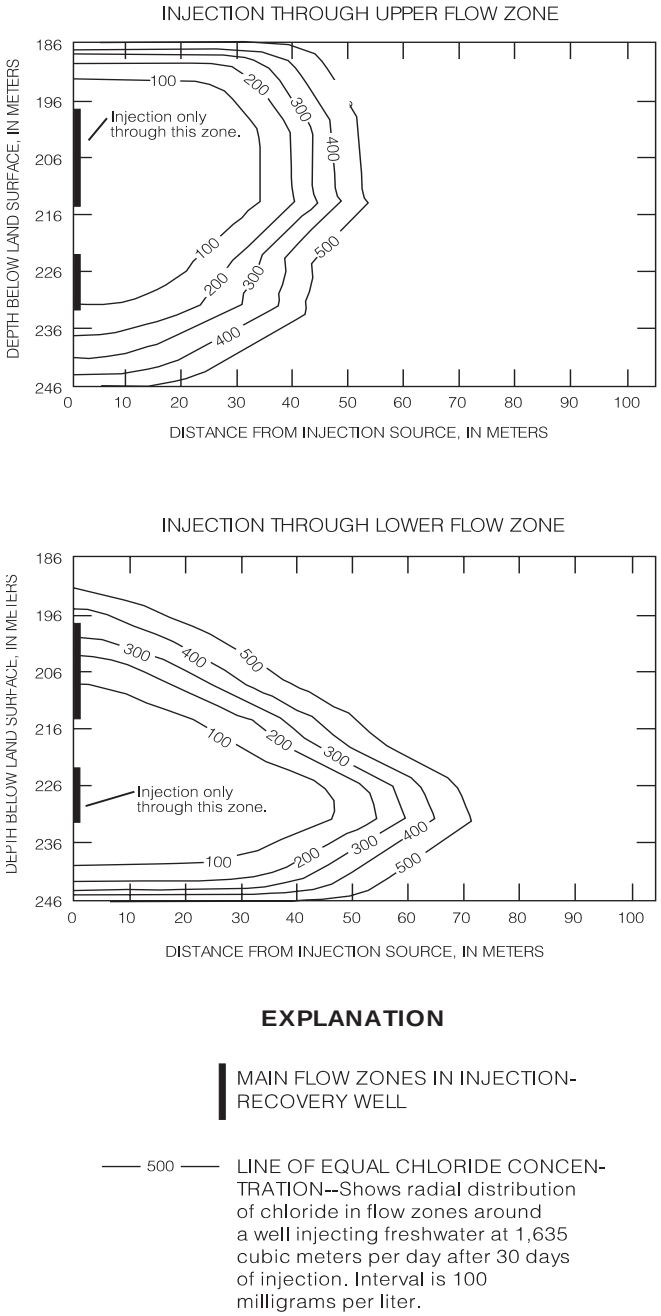

Figure 18. Chloride distribution profiles at the end of a 30-day injection period for the cases of injection into the upper and lower flow zones.

Successive Cycles of Injection, Storage, and Recovery

Five consecutive simulations were made to study the effect of successive cycles of injection, storage, and recovery on the recovery efficiency. The different factors were not changed from the baseline simulation values; however, a storage time of 180 days was used for each cycle (simulations 20-24 in table 7). Results from the preceding cycle were used as initial values for simulating the following cycle. Model results were similar to those reported by Merritt (1985). The rate of improvement on recovery efficiency with successive SISRF cycles was higher during the early cycles, increasing from about 60 to 84 percent during the first three cycles (fig. 19). Recovery efficiency increased from about 84 to 88 percent for cycles 3, 4, and 5 (fig. 19). It can be inferred from Merritt (1985, fig. 12) that the relation between recovery efficiency and the number of SISRF cycles approaches an asymptote after a certain number of cycles, where for practical purposes, no improvement of recovery efficiency occurs. The asymptote is reached at earlier cycle numbers for aquifers having small longitudinal dispersivity values (Merritt, 1985).

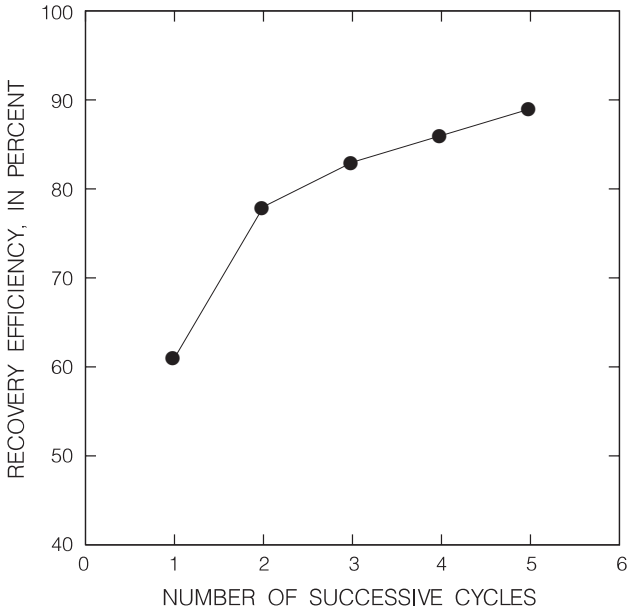

Figure 19. Relation between recovery efficiency and successive subsurface injection, storage, and recovery of freshwater cycles in the lower Hawthorn aquifer.

Chloride Concentrations in Injected and Native Waters

Four simulations were made to study the effects of different chloride concentrations in the injected and native waters. The chloride concentration in the injected water was changed in two simulations by increasing the value used in the baseline simulation by 200 and 400 percent. The chloride concentration in the native water in the remaining two simulations was changed in the same manner. The recovery efficiency in all of the simulations indicated reductions ranging from 9 percentage points (from the baseline simulation value) for 100 mg/L of chloride concentration in injected water to 42 percentage points (from the baseline simulation value) for 2,000 mg/L of chloride concentration in native water (simulations 25-28 in table 7). The analysis indicates: (1) the changes in the quality of injected water could result in reduction of the recovery efficiency; and (2) increases in the chloride concentration in native water because of saltwater intrusion, upconing, or other factors can decrease the recovery efficiency (table 7).

Sensitivity Analysis

Simulations were made to determine the sensitivity of the model-predicted recovery efficiency to variation in modeled aquifer characteristics, including permeability, ratios of anisotropy, longitudinal and transverse dispersivities, molecular diffusion, and effective porosity. The sensitivity analysis was conducted to assess the uncertainty of estimating the aquifer hydraulic and transport properties. A sensitivity analysis provides the means to identify the most important aquifer characteristics.

The relative sensitivity approach developed by Simon (1988) was applied in this sensitivity study. In the relative sensitivity approach, modeled aquifer characteristics are varied from an optimum or calibrated value by different arbitrarily selected percentages. An objective function is used to represent the overall changes in model results because of a change in the optimum aquifer characteristic value.

For this sensitivity analysis, the recovery efficiency was used as an objective function. Relative changes in the objective function values (recovery efficiency values) were related to relative changes in the different aquifer characteristics. Each of the selected aquifer characteristic values was changed individually while keeping the other values unchanged. According to Simon (1988), the first relative change in the recovery efficiency value from the baseline simulation value can be defined by:

$$REFFREL_i = \frac{ACV_b(REFF_i - REFF_b)}{REFF_b(ACV_i - ACV_b)} \qquad (16)$$

where,

$REFFREL_i$ is the relative change in the recovery efficiency;
$REFF_i$ is the recovery efficiency for a given change in an aquifer characteristic value;
$REFF_b$ is the recovery efficiency for the baseline simulation;
ACV_i is the changed or modified aquifer characteristic value; and
ACV_b is the aquifer characteristic value used in the baseline simulation.

Subsequent relative changes can be defined by:

$$REFFREL_i = \frac{ACV_b(REFF_i - REFF_{i-1})}{REFF_b(ACV_i - ACV_{i-1})} . \qquad (17)$$

For this sensitivity analysis, the parameters were divided into two categories—hydraulic and transport. The general results from the two categories, which are described in the following sections, indicated that the permeability values of the upper and lower flow zones were the most important factors and produced the greatest changes in the relative sensitivity of the recovery efficiency (fig. 20A-C). In second place of importance,

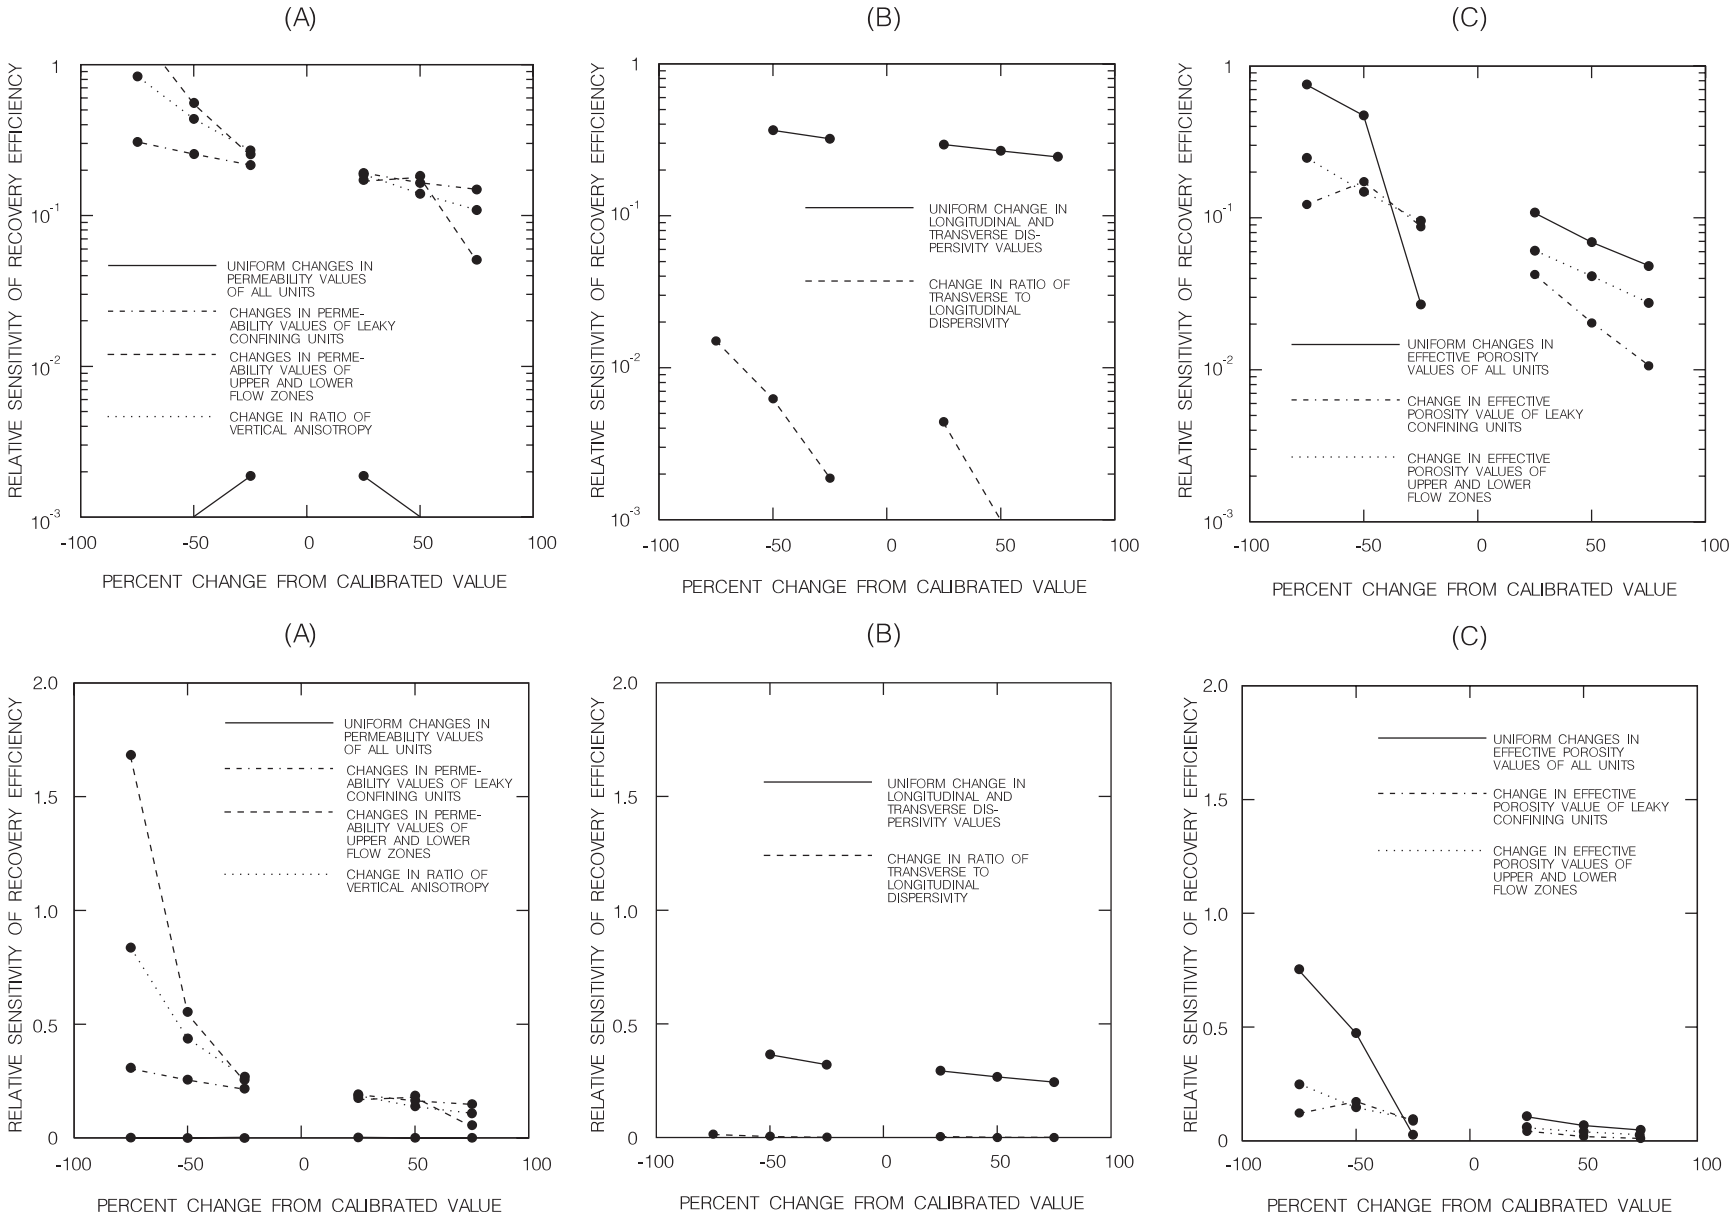

Figure 20. Relative sensitivity of recovery efficiency to variations in (A) permeability values and vertical anisotropy ratio, (B) longitudinal and transverse dispersivities and the ratio of transverse to longitudinal dispersivities, and (C) effective porosity.

but of about equal significance between them, are changes in the relative sensitivity of the recovery efficiency, produced by changing all the porosity values (porosity values of the upper and lower flow zones and the leaky confining units) and those produced by changing the vertical anisotropy ratio (fig. 20C). The fact that permeability, vertical anisotropy, and porosity are the most important factors indicates that the advection process is the most important transport process for this study. Another general observation is that the effect of changing the characteristic values on the relative sensitivity of the recovery efficiency increases when the values are decreased and decreases when the values are increased for all cases (figs. 20A-C).

Permeability and Vertical Anisotropy

The aquifer permeability determines the specific discharge or Darcy's velocity (eq. 6), which in turn, is combined with the effective aquifer porosity to determine the average pore-water velocity (eq. 10). The average pore-water velocity is directly used in the advective term of the transport equation (eq. 14) and indirectly used through the hydrodynamic dispersion tensor (eq. 12) in the dispersive term of the transport equation (eq. 14). Uncertainty in the permeability value would, therefore, affect the advective and dispersive components of the transport computations. The sensitivity of the model to the permeability value was limited to changing the magnitude of the permeability tensor and the vertical anisotropy. Other factors having potential effects on the permeability, such as horizontal anisotropy and heterogeneity, were not considered in this analysis because of the lack of available information.

The magnitude of the permeability was changed in three different ways: (1) uniform changes in all permeability values, (2) changes in permeability values of the leaky confining units, and (3) changes in permeability values of the upper and lower flow zones. The permeability values of the upper and lower flow zones (seemingly the most important in the permeability category) produced the greater changes in the relative sensitivity of the recovery efficiency when the calibrated value was decreased or increased, but showed greater effects when the permeability values were decreased (fig. 20A). Changes in the permeability value of the leaky confining units indicated some sensitivity when the value was increased or decreased by 25 percent, but for greater changes the relative sensitivity was not significantly affected (fig. 20A). It can be inferred from figure 20A that a uniform change in the permeabilities of model layers representing all flow zones and leaky confining units produced an insignificant effect on the recovery efficiency.

Vertical anisotropy, the ratio of vertical to horizontal permeability, was also studied. Changes in the ratio of horizontal to vertical permeability produced the second greatest changes in the relative sensitivity of the recovery efficiency in the permeability category (fig. 20A).

Hydrodynamic Dispersion and Effective Porosity

The hydrodynamic dispersion tensor describes the combined effects of the flow field, aquifer matrix, and molecular diffusion on the transport of solute particles (eq. 13). Flow field and aquifer matrix effects are represented by mechanical dispersion (eq. 12), whereas molecular diffusion is described by Fick's law. The effect of hydrodynamic dispersion on the relative sensitivity of recovery efficiency was studied through the different components of the hydrodynamic dispersion coefficient. The longitudinal and transverse dispersivities represent the dispersive mechanisms of the process. Although molecular diffusion is also a component of the hydrodynamic dispersion coefficient, it is widely recognized among scientists that the effect of molecular diffusion is negligible when compared to longitudinal and transverse dispersivities. Therefore, no attempt was made to study the effects of changing the coefficient of molecular diffusion in this study.

Two different tests were made for the longitudinal and transverse dispersivity values. Both dispersivity values were simultaneously changed by the same percentage in the first test, keeping the ratio of transverse to longitudinal dispersivity equal to 1/10. The ratio of transverse to longitudinal dispersivity was changed in the second test, keeping the longitudinal dispersivity value constant while changing the transverse dispersivity value. The results from the analysis indicated that the uniform change in both transverse and longitudinal dispersivity values produced more significant changes in the relative sensitivity of the recovery efficiency than when the ratio of transverse to longitudinal dispersivities was changed (fig. 20B). In both cases, the relative sensitivity of the recovery efficiency decreased as the dispersivity values or ratio of transverse to longitudinal dispersivity were increased (fig. 20B).

Effective porosity is a factor in the ground-water hydraulic equation (eq. 7) and the advective-dispersive solute-transport equation (eq. 14) in the storage term. However, this porosity has a double effect on the

advective dispersive solute-transport equation (eq. 14). In addition to the effect on the storage term for the transport equation, the effective porosity value is combined with the specific discharge (obtained from the ground-water flow equation) to determine the average pore-water velocities, which are used to represent the advection term in the transport equation (eq. 14).

The effective porosity values were changed in three different ways: (1) the porosity values of all the different layers representing the hydrogeologic units were changed by the same percentage from their calibrated values, (2) changes were made to porosity values of the upper and lower flow zones, and (3) changes were made to porosity values of the leaky confining units. Results from the analysis indicated that the most significant changes in the relative sensitivity of the recovery efficiency (and seemingly the most important in the hydrodynamic dispersion category) were produced by changing the porosity values of all layers using the same percentage (figs. 20B and 20C). The second most significant changes to the relative sensitivity of the recovery efficiency were produced by changing the porosity of the upper and lower flow zones (fig. 20C). Smaller changes in the relative sensitivity of the recovery efficiency were produced when porosity values of the leaky confining units were changed (fig. 20C). These results suggest that a specific combination of porosity values of the flow zones and the leaky confining units is needed to provide an adequate representation of the transport system.

LIMITATIONS

Confidence in the model and in the resulting simulations is limited by a number of factors. These factors can be segregated into two categories—the hydrogeologic information and the aspects of the model code. Among the hydrogeologic information, the most important limiting factors in this study were lack of:

- Complete understanding about the spatial variability of the hydraulic conductivity or permeability values (heterogeneity),
- Field information on changes in the magnitude of the hydraulic conductivity or permeability in the horizontal and vertical directions (horizontal and vertical anisotropies),
- Field information on the porosity values,
- Knowledge about the potential effect of fractures or solution cavities on the flow and transport processes (result of effective secondary porosity),
- Real SISRF tests in the Cape Coral area, and
- Assumptions made to represent the top and bottom boundary conditions as having constant solute concentration and pressure.

The computer code (QSUTRA) used in this study has some intrinsic limitations:

- The fact that the code provides only for two-dimensional simulations precluded the study of the effect of background regional flow on the displacement of the injected water when the cylindrical (radial) coordinate option was used;
- When the Cartesian coordinate option is used, the assumption of vertical homogeneity and isotropy must be made, and such an assumption would be unrealistic for the Cape Coral site; and
- In QSUTRA, the solute-transport equation for transient compressible fluid flow is represented by an analogous numerical expression where porosity, thickness, and fluid density are kept constant by producing a mass-balance error. This affects the determination of velocities and dispersion coefficients (Goode, 1990; 1992). However, this intrinsic error is not expected to greatly affect the simulation of field-scale problems in which the uncertainty and variability of the modeled aquifer characteristics overshadow the potential effects from the intrinsic mass-balance error.

SUMMARY AND CONCLUSIONS

A preliminary assessment of subsurface injection, storage, and recovery of freshwater (SISRF) was made as a potential alternative to the growing water-supply problems of Cape Coral in Lee County, southwestern Florida. A digital modeling approach was used for this preliminary assessment to research the actual potential of SISRF without having to spend the large amounts of money required for real field testing of this technique.

The hydrogeologic framework used for this study was modified or developed from the interpretation of data from previous studies. Aquifer characteristics were estimated from interpretation of data from previous studies. A combination of caliper and flow-velocity borehole geophysical logs was used to estimate the percentages of flow entering different flow zones. These percentages of flow and information on the aquifer transmissivity were used to estimate permeability values for the different flow zones.

A general presentation was made of the density-dependent ground-water flow and advective dispersive solute-transport equations. A modified version of the computer code SUTRA (QSUTRA) and a cylindrical coordinates grid were used for this preliminary assessment because of the lack of information required to represent the real three-dimensional ground-water flow and transport system.

Dispersive characteristics were estimated on the basis of data from a previous study at the Lee County Water Treatment Plant. This was accomplished by calibrating a model for the Lee County Water Treatment Plant site and testing this model using field data from a previous study. A second model was made for the Cape Coral area using local hydraulic characteristics and adopting the dispersive characteristics estimated for the Lee County Water Treatment Plant site model.

A series of 28 hypothetical tests of subsurface injection, storage, and recovery of freshwater were made for the lower Hawthorn aquifer in Cape Coral using the digital modeling technique to assess the efficiency of this operation in the subject aquifer. A baseline simulation was used as reference to compare the effects of changing some operational factors on the recovery efficiency. A recovery efficiency of 64 percent was estimated for the baseline simulation. This recovery efficiency represents the total amount of water pumped during the recovery phase before the 250-milligrams per liter chloride limit is reached divided by the total amount of injected water. The effects of the following operational factors were assessed using the model: rates of injection and recovery; volume of water injected; storage time; injection into selected flow zones; successive cycles of injection, storage, and recovery; and chloride concentrations in injected and native aquifer waters.

A summary of the simulation results from the model, which is based on the limited knowledge of the aquifer, indicates that the recovery efficiency increased when the injection rate and recovery rates were increased, and when the ratio of recovery rate to injection rate was increased. Recovery efficiency decreased when the amount of water injected was increased; decreased slightly when the storage time was increased; was not changed significantly when the water was injected to a specific flow zone; increased with successive cycles of injection, storage, and recovery; and decreased when the chloride concentrations in either the injected water or native aquifer water were increased. The different simulation results for storage time might be unrealistic because the cylindrical coordinates used in the model did not consider the regional background flow, which was an important factor in previous studies.

The higher recovery efficiencies were obtained for three simulation tests for which the duration of injection and recovery phases was shorter. This is expected because of the nature of the conceptual system in which migration of the solute particles to areas beyond the vertical boundaries will reduce the recoverability for tests of longer duration. The recovery efficiency fluctuated from its baseline value of 64 percent to an upper value of about 100 percent and to a lower value of 22 percent in all of the simulations.

Interlayer solute mass movement across the upper and lower boundaries seems to be the most important factor affecting the recovery efficiency. A simulation that was conducted with the same parameters used for the baseline simulation, but representing the top and bottom boundaries as impermeable (no flow and no solute transport), yielded a recovery efficiency value of 83 percentage points. This value is 19 percentage points higher than the estimated value from the baseline simulation showing that this boundary is important in determining the recovery efficiency, and that using constant pressure and constant solute concentration, boundaries will yield more conservative estimates of the recovery efficiency.

The sensitivity analysis was performed applying the relative sensitivity technique in which changes in the different factors and model responses are normalized to make a meaningful comparison of the model responses due to changes in the different factors. Two categories of factors were recognized for the sensitivity analysis—aquifer permeability and hydrodynamic dispersion. Several combinations of changes were made for factors of the two categories. For instance, a factor was changed only for a specific flow zone. The general results from the sensitivity analysis indicated that the permeability values of the upper and lower flow zones are the most important factors, producing the overall greater changes in the relative sensitivity of the recovery efficiency. In second place of importance, but of about equal significance between them, are changes in the relative sensitivity of the recovery efficiency, produced by changing all the porosity values (porosity values of the upper and lower flow zones and the confining beds) and those produced by changing the vertical anisotropy ratio.

Model results indicate that high recovery efficiencies (from 64 to about 100 percent) can be achieved for different SISRF operational schemes. Two successive injection, storage, and recovery cycles can increase the recovery efficiency from 60 to about 80 percent. Combinations of different operational factors also can be used to maintain high recovery efficiencies. The advective factors (pore-water velocities derived from permeability and porosity values) were apparently the most

important to the model sensitivity in the Cape Coral area. However, the dispersivity values used for the lower Hawthorn aquifer in the Cape Coral area model were not field values, but values that were extrapolated from the model of the lower Hawthorn aquifer at the Lee County Water Treatment Plant site. These dispersivity values might not be representative of the actual dispersive characteristics of the lower Hawthorn aquifer in the Cape Coral area. The model presented in this report is a generalized version of the actual hydrogeologic system and could be refined if additional information on the advective and dispersive characteristics of the aquifer is made available.

Process-Based Interpretation of Tracer Tests in Carbonate Aquifers

by Steffen Birk[1,3], Tobias Geyer[2], Rudolf Liedl[1], and Martin Sauter[2]

Abstract

A tracer test in a carbonate aquifer is analyzed using the method of moments and two analytical advection-dispersion models (ADMs) as well as a numerical model. The numerical model is a coupled continuum-pipe flow and transport model that accounts for two different flow components in karstified carbonate aquifers, i.e., rapid and often turbulent conduit flow and Darcian flow in the fissured porous rock. All techniques employed provide reasonable fits to the tracer breakthrough curve (TBC) measured at a spring. The resulting parameter estimates are compared to investigate how each conceptual model of flow and transport processes that forms the basis of the analyses affects the interpretation of the tracer test. Numerical modeling results suggest that the method of moments and the analytical ADMs tend to overestimate the conduit volume because part of the water discharged at the spring is wrongly attributed to the conduit system if flow in the fissured porous rock is ignored. In addition, numerical modeling suggests that mixing of the two flow components accounts for part of the dispersion apparent in the measured TBC, while the remaining part can be attributed to Taylor dispersion. These processes, however, cannot reasonably explain the tail of the TBC. Instead, retention in immobile-fluid regions as included in a nonequilibrium ADM provides a possible explanation.

Introduction

Ground water flow in carbonate aquifers is often focused in solution conduits that comprise only a small percentage of total aquifer porosity. The majority of aquifer storage, however, is generally provided by the fissured porous rock. The permeability contrast between the highly conductive conduit system and the much less conductive fissured porous rock poses a great challenge to the hydrogeological characterization of carbonate aquifers, mainly because location and geometry of the conduit system are generally known inadequately. In particular, some standard investigation techniques, such as pumping tests, are often of limited value for aquifer characterization. Ground water tracing, which is the subject of this paper, appears to be a more promising method for the characterization of conduit-dominated carbonate aquifers.

A qualitative tracer detection can be sufficient in investigations that aim at identifying point-to-point connections, e.g., for the delineation of spring catchments. However, the information provided by such qualitative tracer tests is insufficient for making quantitative transport prediction in these aquifers. More detailed information can be obtained from quantitative ground water tracing. Brown et al. (1969), Brown and Ford (1971), and Atkinson et al. (1973) demonstrated that the type of conduit network can be inferred from ground water tracing if both tracer concentration and discharge are measured in a sinking stream (i.e., one that disappears underground) and at the resurgence. Smart (1988) inferred a more detailed structural model of a karst aquifer from a series of tracer tests. More recently, a method has been suggested that provides estimates for flow and transport parameters, such as mean flow velocity and longitudinal dispersion, as well as for geometric conduit parameters, such as conduit volume and diameter, from an evaluation of the tracer breakthrough curve (TBC) and the spring discharge (Field and Nash 1997; Field 1999). Any such quantitative interpretation, however, is likely to depend on the conceptual model of flow and transport processes that form the basis of the analysis. The purpose of this paper is to examine the role of model selection in the

interpretation of tracer tests in carbonate aquifers. To this end, a tracer test conducted at a field site in southwest Germany is analyzed using several standard techniques, namely the method of moments and two types of one-dimensional advection-dispersion models (ADMs). In addition, a numerical flow and transport model is introduced and applied to the data. This numerical model accounts for both conduit flow and Darcian flow within the fissured porous rock and does not require the specification of dispersion coefficients, as these are directly determined from the conduit properties based on an approach introduced by Taylor (1954). Results from all of these analyses are compared to investigate how the different underlying conceptual models affect the interpretation of tracer-test results.

Modeling Techniques

ADMs are based on the transport equation

$$\frac{\partial c}{\partial t} = -v\frac{\partial c}{\partial x} + D\frac{\partial^2 c}{\partial x^2} \tag{1}$$

where c = concentration, t = time, v = velocity, x = distance along the direction of flow, and D = dispersion coefficient. The dispersion coefficient is commonly assumed to be proportional to the flow velocity, i.e., $D = \alpha v$, where the proportionality constant α is termed dispersivity. In this work, the program CXTFIT version 2.1 (Toride et al. 1999) is employed to calibrate an analytical solution of the ADM to a measured TBC.

In addition to the ADM given by Equation 1, CXTFIT provides analytical solutions to an ADM that is extended by a first-order mass transfer term and a supplementing equation accounting for retention in immobile-fluid regions. The parameters that must be adjusted in this nonequilibrium ADM include not only flow velocity and dispersion coefficient but also the mobile fraction of water as well as a mass transfer coefficient determining the rate of mass transfer between mobile and immobile water. Field and Pinsky (2000) provide a detailed description of both versions of the ADM and their application to tracer tests in carbonate aquifers.

The method of moments evaluates the first and second statistical moments of the TBC in order to obtain estimates for the flow velocity and the dispersivity, respectively. Field and Nash (1997) describe fundamentals of this method and its application for tracer-test analysis in carbonate aquifers. QTRACER software (Field 1999) was used to conduct the analysis.

Using the flow velocity v resulting from the ADM or the method of moments, an estimate for the phreatic conduit volume V can be obtained if the mean discharge $\bar{Q}$ is known:

$$V = \bar{Q}\frac{L}{v} \tag{2}$$

where L = flow distance. The conduit volume can easily be transformed into the corresponding diameter of a circular conduit (e.g., Field and Nash 1997).

The aforementioned standard techniques can be criticized from a process-based viewpoint for at least two reasons. First, the method of moments and the ADMs yield estimates for the dispersion coefficient by evaluating statistical moments or by model calibration, respectively, but the nature of the process creating such dispersion is undefined in either case. Second, one-dimensional transport between injection site and karst spring is assumed. This approach may be appropriate to describe tracer transport between a stream sink and its resurgence if tributaries and losses between sink and resurgence are negligible. In many karst catchments, however, drainage occurs mainly via the subsurface, and surface water is rare. Consequently, the tracer is injected, e.g., into a sinkhole and flushed with an amount of water that is very small compared to the water volume discharged at the spring. Thus, the injected tracer solution is diluted along the flowpath due to mixing with the regional flow component that feeds the spring. The method of moments and the one-dimensional ADMs do not explicitly account for this mixing process. A numerical modeling approach that includes these two mechanisms is introduced subsequently.

In principle, two different flow systems can be distinguished in karst aquifers, namely, rapid and often turbulent conduit flow and Darcian flow in the fissured porous rock (Shuster and White 1971). Thus, carbonate aquifers can be conceptualized as dual-flow systems consisting of a discrete conduit system embedded in a continuous fissured system. In order to transfer this conceptual model into a numerical flow model, a pipe-network model (Clemens et al. 1996; Liedl et al. 2003), representing the conduit system, was hydraulically coupled to the continuum flow model MODFLOW-96 (Harbaugh and McDonald 1996), representing the fissured system. Assuming a proportional exchange flow rate and head difference between conduit and fissured system, the two models are coupled by a linear exchange term (Barenblatt et al. 1960)

$$Q_{ex} = \gamma\left(h_f - h_c\right) \tag{3}$$

where Q_{ex} = exchange flow rate, h_f = head in the fissured system, h_c = head in the conduit system, and γ = proportionality constant termed exchange coefficient, which is considered here as a parameter that must be adjusted during model calibration.

Conduit flow is simulated using the Darcy-Weisbach equation

$$\Delta h_c = \frac{fL}{2ga}v^2 \tag{4}$$

where Δh_c = head difference along the distance L, a = conduit diameter, v = average flow velocity in the conduit, g = gravitational acceleration, and f = friction factor. Under the conditions considered in this work, conduit flow is always turbulent, and the friction factor is obtained by iteratively solving the implicit Colebrook-White formula

$$\frac{1}{\sqrt{f}} = -2\log\left(\frac{e}{3.71a} + \frac{2.51}{Re\sqrt{f}}\right) \tag{5}$$

where e is roughness height of the conduit wall and Re Reynolds number. This continuum-pipe flow model was initially designed for the simulation of conduit development in carbonate aquifers and thus termed CAVE (Carbonate Aquifer Void Evolution) (Birk et al. 2003; Liedl et al. 2003; Bauer et al. 2003).

In order to be able to simulate tracer transport in the conduit system, an explicit upwind finite-difference scheme solving the advection-dispersion equation (Equation 1) in the pipe network was implemented in CAVE. Solute concentrations in both flow from the fissured system and direct recharge into the conduit system are specified as boundary conditions for the transport simulation in the pipe network.

As mentioned previously, the dispersion coefficient can be calculated by $D = \alpha v$, where the dispersivity α must be adjusted during model calibration. A more process-based approach developed by Taylor (1953, 1954) attributes dispersion to mass transfer processes arising from velocity differences within the flow cross section. Under turbulent flow conditions, the dispersion coefficient is given by (Taylor 1954)

$$D = 10.1 a v_* \tag{6}$$

where a = conduit diameter and v_* = friction velocity. The friction velocity is given by (Clark 1996):

$$v_* = \sqrt{\frac{ag}{2}\frac{\Delta h}{L}} \tag{7}$$

The finite-difference scheme employed to solve the advection-dispersion equation generally creates numerical dispersion, i.e., an artificial dispersion term is added on the dispersion term in Equation 1. However, the magnitude of the numerical dispersion can be calculated for each pipe a priori (Kinzelbach 1992). Hence, the dispersion coefficient determined by one of the aforementioned methods is accordingly reduced to compensate for the effect of numerical dispersion.

Tracer Experiment

The Gallusquelle catchment situated in southwest Germany was selected for this investigation (Figure 1). This catchment has been characterized with hydrogeological investigations that included piezometric surface mapping, ground water tracing, borehole hydraulic tests, and analyses of spring hydrographs and physicochemical parameters of spring water (Sauter 1992).

The spring catchment covers an area of ~45 km^2 on the Swabian Alb, a northeast-southwest–striking low mountain range composed of Upper Jurassic carbonates. The landscape is characterized by dry valleys, which are interpreted as formerly active water courses that dried up with the advance of karstification. Today's drainage occurs mainly via the subsurface. Based on analyses of ground water level records and regional ground water potentials as well as on the knowledge of the former topographic elevations of the spring, which had been significantly below the present spring level at times during the Quarternary, Sauter (1995) concluded that a highly karstified zone is submerged within today's active aquifer. Thus, subsurface drainage is likely to occur through phreatic (i.e., water filled) karst conduits.

Recharge estimates amount to ~380 mm/a, yielding a total recharge within the spring catchment of ~0.54 m^3/s. The spring discharge varies from <0.1 to 2.5 m^3/s with an average of ~0.5 m^3/s. Part of the outflow from the catchment, however, is likely to occur via diffuse seepage into the river Lauchert southeast of the Gallusquelle catchment. Estimates for this flow component range from <0.05 to 0.2 m^3/s (Sauter 1992).

A tracer test was conducted to provide information about the conduit system of the Gallusquelle catchment. The tracer injection location was a sinkhole, assumed to be well connected to the conduit system, instead of a borehole, which may not be well connected. A sinkhole located 3000 m east-northeast of the spring was selected as injection site for the tracer test, as it was easily accessible and water supply for flushing was available on site. In the past, this sinkhole had been filled up with sediments to facilitate agricultural land use and to improve ground water protection. The sediment filling was excavated to the depth of bedrock, i.e., ~5 m below ground level, and the sinkhole was left open during the experiment.

1.5 kg of sodium fluorescein dissolved in ~1 m^3 of water was injected into the excavated sinkhole on April 29, 2003. The depth of the water table at the sinkhole is not known. Measurements in two boreholes 1.0 and 1.5 km north-northeast of the doline suggest that it might be ~100 m below ground level. It should be noted, however, that this value represents the water level in the fractured porous rock rather than that in the conduit system. In order to obtain temporarily saturated conditions within the thick vadose zone, the sinkhole was flushed with ~91 m^3 of water over a time period of ~5 h prior to tracer injection. Flushing was continued at the same rate for ~4 h after tracer injection, yielding an additional water injection of 73 m^3.

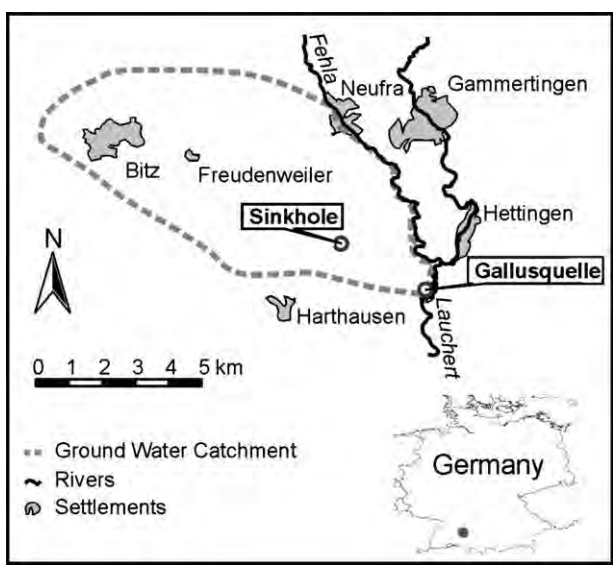

Figure 1. Location of the Gallusquelle catchment (delineation according to Sauter 1992).

The fluorescein concentration at the Gallusquelle was measured using a field spectrofluorometer (GGUN-FL30; Schnegg 2002). The measurement interval varied between 1 and 5 min. In addition, water samples were taken from nearby springs that could potentially drain some water from the injection site and analyzed in the laboratory using high-performance liquid chromatography with fluorescence detector. The Gallusquelle discharge was derived from stream-stage measurements using a stage-discharge relationship provided by the local water authority.

Results

The first arrival of the tracer was detected at the Gallusquelle ~35 h after tracer injection (Figure 2). Forty-two hours after tracer injection, the fluorescein concentration reached its maximum of 132 mg/m^3. After ~1 week, the concentration had returned to the background value. The spring discharge stayed at ~0.43 m^3/s during this time period.

Evaluation of the TBC with the method of moments yielded a mean tracer transit time of ~45 h. The corresponding mean tracer velocity as well as the resulting dispersion coefficient and dispersivity are given in Table 1. The analysis also reveals that ~94% of the injected tracer mass was recovered. While no tracer was detected at nearby springs, the observed mass loss could be caused by seepage into the river Lauchert or retention in the formation. Since the accuracy of the discharge is 5% or greater, the mass loss may be simply a result of discharge measurement errors.

The calibration of both the ADM given by Equation 1 and the nonequilibrium ADM was based on concentration values at regular time intervals of 30 min within a 5-d period after tracer injection in order to make the root mean square error (RMSE) of the resulting model solutions comparable to that obtained with the numerical model. The tracer injection was represented by a Dirac pulse, i.e., it has been assumed that the tracer mass penetrated instantaneously into the aquifer. Two scenarios have been considered for calibration of the ADMs, one with an injected mass equal to the actual injected tracer mass and the other with an injected mass equal to the recovered tracer mass, i.e., 94% of the actual injected tracer mass, thus accounting for the observed mass loss. As both scenarios yield very similar results, only those obtained with the actual injected mass are reported here.

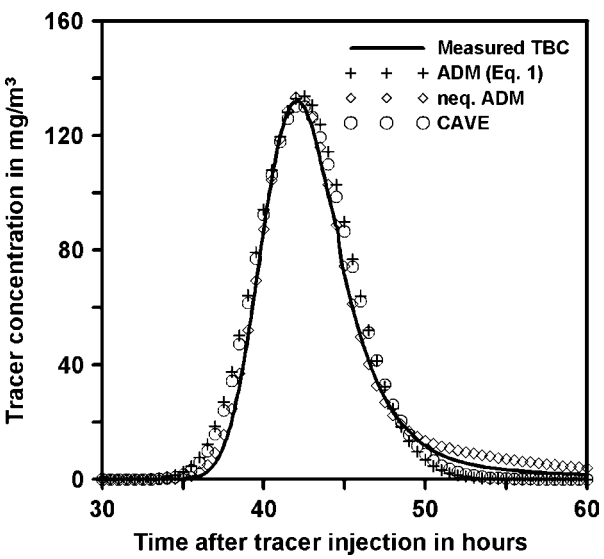

Figure 2. Measured TBC compared to results from the calibrated models (ADM (Eq. 1) = ADM given by Equation 1, neq. ADM = nonequilibrium ADM, CAVE = CAVE model).

In order to account for dilution of the tracer solution by mixing with regional flow, the transformation of the injection mass into a concentration, which is required as boundary condition for the ADM, was based on the measured spring discharge but not on the rate of injection. Thus, it has been implicitly assumed that dilution occurs instantaneously at the injection site.

Figure 2 compares the result from the ADMs to the measured TBC. All calibrated models match the measured TBC reasonably well. The ADM given by Equation 1 does not account for the tail of the measured TBC and therefore yields shorter travel times than the method of moments, which evaluates the whole TBC. Thus, the ADM yields slightly higher velocities than the method of moments (Table 1). Moreover, a higher dispersivity value has to be used in the ADM given by Equation 1 to improve the model fit in the tailing part of the TBC. Nevertheless, this model clearly fails to account for the skewness of the measured TBC, i.e., the tail of the curve is not adequately reproduced.

Field and Pinsky (2000) demonstrated that nonequilibrium ADMs are able to produce better fits of the tails of TBCs. This is also apparent in the modeled TBC (Figure 2) as well as in the residuals (observed minus fitted concentrations) plotted in Figure 3. The RMSE of this model fit is significantly lower than that resulting from the pure ADM given by Equation 1 (Table 1). Dispersion coefficient and dispersivity agree fairly well with the parameter estimates from the method of moments and thus are significantly lower than those resulting from the pure ADM. In contrast, the flow velocities resulting from both types of ADMs are nearly equal (Table 1). Inserting flow distance, spring discharge, and the calculated velocities in Equation 2 yielded estimates for the conduit volume, which were transformed to the corresponding diameter of a circular conduit (Table 1). Volume and diameter from the ADMs and the method of moments agree fairly well.

In addition to the parameters listed in Table 1, the calibration of the nonequilibrium ADM yields a mobile fraction of water of 0.95 as well as mass transfer coefficients of 1.9×10^{-6} 1/s. The mobile fraction of water is greater than and the mass transfer coefficient is less than the corresponding parameter values calculated by Field and Pinsky (2000) for each of five tracer tests in carbonate aquifers.

In order to verify the numerical implementation of Equation 1 in CAVE, transport was numerically simulated in a single conduit decoupled from the continuum using the parameter values identified with CXTFIT for the ADM given by Equation 1 (Table 1, ADM (Eq.1)), i.e., a conduit diameter of ~5.3 m and a dispersivity of 6.9 m.

Table 1
Parameter Estimates from Different Evaluation Techniques

Parameter	Method of Moments	ADM (Eq. 1)	Nonequilibrium ADM	CAVE
Velocity (m/s)	0.018	0.020	0.019	0.032–0.002
Dispersion coefficient (m^2/s)	0.082	0.14	0.086	0.14–0.010
Dispersivity (m)	4.4	6.9	4.6	4.4
Conduit volume (m^3)	7.0×10^4	6.6×10^4	6.9×10^4	4.2×10^4
Conduit diameter(m)	5.5	5.3	5.4	4.2
RMSE (mg/m^3)	—	3.9	1.4	3.1

ADM (Eq.1) = ADM given by Equation 1.

The 3000-m distance between injection site and spring was subdivided into 150 successive pipes of 20-m length each, and the flow rate was set to the spring discharge of 0.43 m^3/s. The result from the numerical simulation was in good agreement with that from the analytical solution provided by CXTFIT (RMSE = 0.6 mg/m^3).

In addition, the model was run in a mode where the dispersion coefficient is calculated using Taylor's approach given by Equations 6 and 7. The hydraulic gradient in Equation 7 is determined by the flow calculation and thus depends on the roughness height of the conduit wall as demonstrated by Equations 4 and 5. The roughness height was adjusted in a model calibration using the parameter optimizer PEST (Doherty 2002). A roughness height of ~0.25 m provided the best fit to the measured TBC. Both methods employed for the calculation of the dispersion coefficient perform equally well. Yet, calibration of the model that uses Taylor's approach yields the roughness height of the conduit wall instead of the physically less meaningful dispersivity. The roughness height is not only involved in the transport calculation but also in the flow calculation and thus could, in principle, be verified if both hydraulic gradient and flow rate were known accurately. Taylor's approach, therefore, provides a more process-based interpretation of dispersion as requested by one of the aforementioned criticisms of the standard techniques for tracer-test analysis.

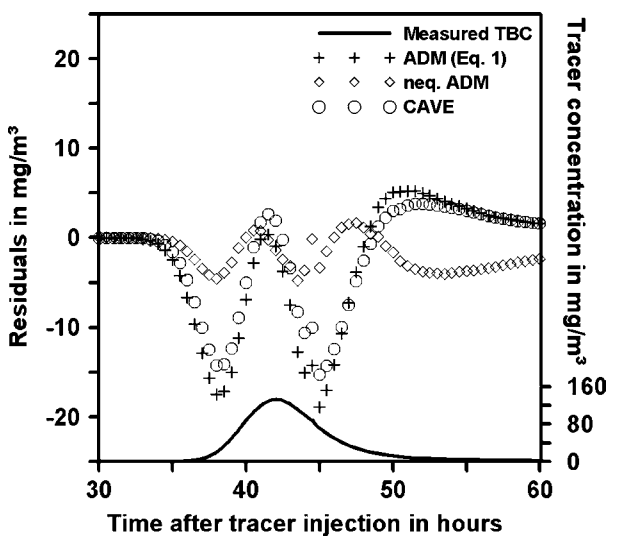

Figure 3. Residuals (observed minus fitted concentrations) from the calibrated models (ADM (Eq.1) = ADM given by Equation 1, neq. ADM = nonequilibrium ADM, CAVE = CAVE model).

The other criticism concerns the source of the large water volume discharged at the spring and its mixing with the injected, tracer-bearing water, which is not explicitly accounted for by the standard techniques. Since there are no stream sinks within the Gallusquelle catchment, the distributed recharge to the catchment area must provide the source of water discharged at the spring. Part of this water is most likely mixed with the injection water somewhere between injection site and spring rather than directly at the injection site. It was attempted to account for these processes in a highly simplified numerical model of the Gallusquelle catchment. To this end, the above conduit model, comprising 150 pipes that represent a karst conduit connection between injection site and spring, was coupled to the continuum model, which simulates regional flow in the catchment. For lack of better knowledge, the diameter was held constant along the length of the conduit.

The model domain is a rectangle of 11,000 m in length and 5500 m in width that is approximately aligned with the longitudinal axis of the actual catchment (Figure 4). Sauter (1992) provides estimates of hydraulic aquifer parameters in the area that vary depending on both investigation site and method (e.g., spring hydrograph analysis, slug tests, injection tests) employed. In order to keep the model simple, approximate average values of 10^{-4} m/s and 0.01 were uniformly assigned to hydraulic conductivity and storativity of the unconfined aquifer. The spring discharge measured during the tracer experiment amounts only to 86% of the average spring discharge. The estimated average recharge was correspondingly reduced and uniformly applied to the model domain. The model domain is drained across one of the narrow sides of the rectangle with a fixed head equal to the spring water level of 633 m a.s.l., while all other sides are no-flow boundaries. Note that the area covered by the model domain is larger than the actual catchment area because outflow from the continuum across the fixed-head boundary does not contribute to spring discharge. Conceptually, this outflow corresponds to the aforementioned diffuse seepage into the river Lauchert.

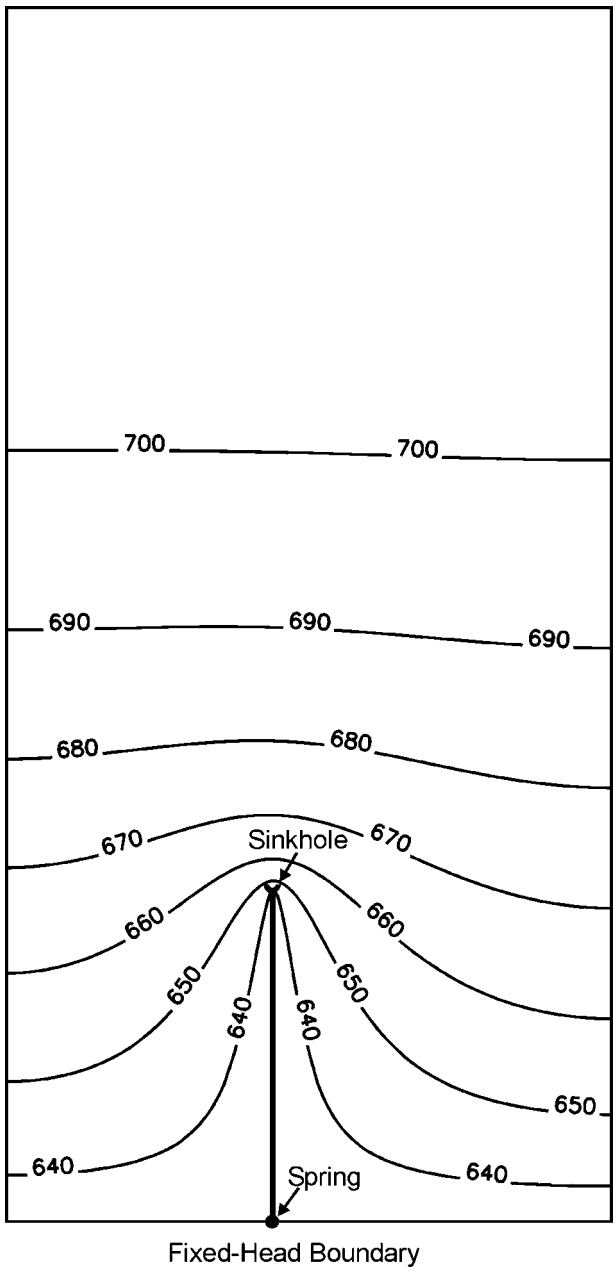

Figure 4. Model domain with a single conduit (thick line) linking the injection site (sinkhole) to the spring. Labeled thin lines represent the initial hydraulic-head distribution (values in m a.s.l.) of the calibrated model.

The steady-state flow field (Figure 4) determined by the aforementioned model parameters and boundary conditions as well as by the exchange coefficient γ and the conduit parameters a and e provided the starting heads for the transient tracer-test simulation. Initial concentrations were zero in the entire model domain. Flushing of the sinkhole was represented by a point injection of 5 L/s into the conduit over a time period of 9 h. After 5 h, a tracer mass of 1.5 kg was added to the injection water within 1 s. The tracer concentration in the injection water was zero at any other time. As before, the parameter optimizer PEST was employed to calibrate the model.

Exchange coefficient, conduit diameter, and roughness height were calibration parameters, while dispersion was quantified using Taylor's approach given by Equations 6 and 7. Changing the given calibration parameters affects both simulated spring discharge and TBC. Hence, as opposed to the standard techniques employed before, not only the measured TBC but also the measured spring discharge had to be matched by the model. The calibrated model yields a spring discharge of ~0.44 m^3/s, i.e., ~2% greater than the measured discharge and thus well within the range of the measurement error. The TBC resulting from the calibrated model is shown in Figure 2, the residuals (observed minus fitted concentrations) are plotted in Figure 3. The RMSE of 3.1 mg/m^3 (referring to the TBC only) is close to that of the ADM given by Equation 1 (Table 1). The calibration approximately yields a conduit diameter of 4.2 m, corresponding to a conduit volume of 4.2×10^4 m^3, a roughness height of 0.067 m, and an exchange coefficient of 5.8×10^{-3} m^2/s. Diameter and volume, thus, are significantly lower than predicted by the standard methods (Table 1). The roughness height in the calibrated dual-flow model is lower by almost a factor of four compared to the model without a coupled continuum.

In order to allow comparison with the dispersivities resulting from the standard techniques, the model was also run in a mode with $D = \alpha v$ (Table 1; CAVE). The dispersivity α was adjusted, while exchange coefficient, conduit diameter, and roughness height were kept constant, yielding a dispersivity of ~4.4 m. The dispersivity obtained is comparable to those resulting from the methods of moments and the nonequilibrium ADM but is significantly less than that from the ADM given by Equation 1.

Discussion

All models presented in the previous sections provide reasonable fits to the measured TBC. Yet, the nonequilibrium ADM is the only model that is capable of reproducing the weak tailing apparent in the measured TBC. In addition to velocity and dispersivity, which are the only calibration parameters in the pure ADM, this model type includes two other fitting parameters to account for first-order mass transfer into immobile-fluid regions. The physical nature of this process, however, is not entirely clear. Results from process-based numerical simulations of tracer transport in turbulent flow at meter-length scale suggest that the tailing of TBCs is caused by flow reversal due to turbulent eddies in pools (Hauns et al. 2001).

The flow velocity resulting from the nonequilibrium ADM is not much different from those obtained with the method of moments and the pure ADM given by Equation 1. Consequently, estimates for conduit diameter and volume are also nearly identical (Table 1). Together with the aforementioned parameter comparison among other carbonate aquifers (Field and Pinsky 2000) the results suggest that retention in immobile-fluid regions is relatively unimportant here. It should be noted, however, that the dispersivity required to match the measured TBC is significantly less for the nonequilibrium ADM than for the pure ADM (Table 1). Thus, part of the dispersion

apparent in the TBC can possibly be explained by retention in immobile-fluid regions.

The dispersion coefficient included in the advection-dispersion equation is commonly calculated by $D = \alpha v$, where the dispersivity a is determined by model calibration. With a more process-based approach, which quantifies the dispersion coefficient depending on flow conditions and geometric properties of the conduit (Taylor 1954), the model calibration yields the roughness height of the conduit wall instead of the dispersivity. In principle, the roughness height could be independently determined if both flow rate and hydraulic gradient were known. Thus, it provides a link between flow and transport modeling. In this work, a transport model based on the advection-dispersion equation is built on the flow model CAVE, which accounts for a dual-flow system in a carbonate aquifer. The calibration of this numerical flow and transport model is entirely based on an adjustment of flow and conduit parameters, which can be constrained by hydraulic field data, such as spring discharge and hydraulic heads.

In order to illustrate this process-based approach to tracer-test interpretation in carbonate aquifers, a highly simplified model of the Gallusquelle catchment has been presented in this work. Both spring discharge and TBC were simultaneously used as calibration targets that had to be matched by the model. Calibration results suggest that the conduit volume is smaller than that predicted by standard techniques because part of the water discharged at the spring is derived from regional flow through the fissured porous rock and thus wrongly attributed to the conduit system if the fissured system is ignored in the analysis. The dispersivity value corresponding to the calibrated flow and conduit parameters is also smaller than that resulting from an equivalent transport model neglecting the effect of the fissured system. Thus, part of the dispersion apparent in the TBC appears to be caused by mixing of regional flow and tracer-marked conduit water.

Conclusions

The techniques employed for tracer-test analysis in this work are based on different conceptual models of flow and transport in carbonate aquifers. With respect to the number of parameters involved in the calibration, the one-dimensional ADM represents the simplest model. It yields reasonable fits to the measured TBC and thus should be considered an adequate standard technique unless there is good reason to apply more complex approaches.

Such reason could be the demand for a better model fit, in particular, in the tailing part of the measured TBC. In principle, a nonequilibrium ADM appears to be suitable for this purpose. Another reason is the wish for a tracer-test interpretation consistent with the knowledge of the flow system. A process-based numerical flow and transport model, such as the CAVE model presented here, can be employed to accomplish this task.

The model application illustrating this approach to a process-based interpretation of tracer tests is based on a highly simplified conceptual aquifer model, which is found to be adequate for presenting the basic methodology. Quantitative results, however, should be interpreted with caution at the present stage of model development because the model calibration did not consider measured hydraulic heads. More reliable parameter estimates will be obtained if the model is built on detailed information gained from a thorough hydrogeological site investigation and if, in addition to spring discharge and tracer concentrations, measured hydraulic heads are used to calibrate the model. Design and calibration of such a model is subject of ongoing research.

Recovering Fresh Water Stored in Saline Limestone Aquifers

by Michael L. Merritt[a]

ABSTRACT

Numerical modeling techniques are used to examine the hydrogeologic, design, and management factors governing the recovery efficiency of subsurface fresh-water storage. The modeling approach permitted many combinations of conditions to be studied. A sensitivity analysis was used that consisted of varying certain parameters while keeping constant as many other parameters or processes as possible. The results show that a loss of recovery efficiency resulted from: (1) processes causing mixing of injected fresh water with native saline water (hydrodynamic dispersion); (2) processes or conditions causing the irreversible displacement of the injected fresh water with respect to the well (buoyancy stratification and background hydraulic gradients); or (3) processes or procedures causing injection and withdrawal flow patterns to be dissimilar (dissimilar injection and withdrawal schedules in multiple-well systems). Other results indicated that recovery efficiency improved considerably during the first several successive cycles, provided that each recovery phase ended when the chloride concentration of withdrawn water exceeded established criteria for potability (usually 250 milligrams per liter). Other findings were that fresh water injected into highly permeable or highly saline aquifers would buoy rapidly with a deleterious effect on recovery efficiency.

INTRODUCTION

Injection of surplus fresh water into saline aquifers for later recovery and use during periods of water scarcity is a concept of particular significance for regions where the natural water supply tends to shift seasonally between surplus and deficit relative to public supply requirements. South Florida provides a typical example of such a hydrologic regime. The climate is characterized by a usually pronounced seasonal cycle of wet and dry periods. To prevent flooding during wet periods, large quantities of water are flushed through canals to the ocean. The waters exit through control structures that are closed during dry periods to maintain water levels sufficiently high to prevent salt-water intrusion in the vicinity of coastal well fields.

The flat topography of south Florida and high cost of land inhibit enlargement of the surface reservoir system, which includes Lake Okeechobee and the three water-conservation areas. However, subsurface reservoirs exist in the form of artesian aquifers that occur within 1,000 to 1,500 feet of land surface. Throughout most of the region shown in Figure 1, these aquifers contain water sufficiently saline to be considered nonpotable (more than 250

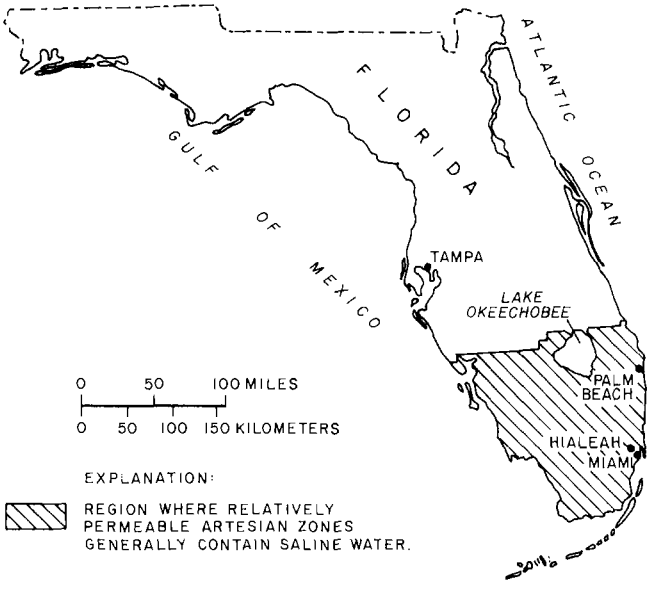

Fig. 1. Map showing region of Florida where relatively permeable artesian zones generally contain saline water.

Discussion open until January 1, 1987.

mg/l chloride) according to published standards of the U.S. Environmental Protection Agency (1976). Where these aquifers contain water of low to moderate salinity (500 to 2,000 mg/l chloride), they would be suitable receptacles for the temporary storage of amounts of water equivalent to part of the fresh water that is presently released to the ocean during the wet season. Various aspects of this water-conservation technique related to south Florida are discussed by Merritt and others (1983). A statistical analysis of coastal and inland fresh-water discharge in the south Florida area, suggesting available amounts of seasonal surplus, is presented by Sonntag (1984).

Experimental fresh-water injection and recovery systems in saline aquifers at several locations in central and south Florida (Black, Crow, and Eidsness, Inc., 1974; Tibbals and Frazee, 1976; J. J. Plappert, Florida Department of Environmental Regulation, written commun., 1977; F. W. Meyer, U.S. Geological Survey, oral commun., 1980; and D. J. Fitzpatrick (1985) have demonstrated varying degrees of success, as summarized by Merritt and others (1983). An operational system to inject fresh water into a high sulfide/sulfate aquifer for later recovery was described by Reynolds and Pyne (1983) and CH_2M HILL (1984). Recovery efficiencies (the volume of potable water recovered expressed as a percentage of the volume of fresh water injected) have ranged from 0 to 75 percent in the saline aquifer tests. This variation has been attributed mainly to differences in the hydraulic characteristics of the receiving aquifers and in the chemical characteristics of their native water, and possibly to the technique or schedule of injection and withdrawal (length of storage period, volume, and rate of injection).

At substantial cost, the injection tests generally have indicated the nature of some of the factors governing the success of subsurface fresh-water storage. As part of a recent study by the U.S. Geological Survey in cooperation with the U.S. Army Corps of Engineers, digital modeling techniques were used to better explain the relation of recovery efficiency to various hydrogeologic, system design, and management parameters. The digital modeling approach permitted many combinations of conditions in a generalized prototype to be studied in a relatively inexpensive manner. There is a trade-off between cost and results, however. The simulation of the transport of solute in secondary-porosity limestone aquifers is a research problem with results subject to various qualifications, particularly when a porous media flow model is used. Operational test results, on the other hand, are direct field evidence, despite their substantially greater cost and the often challenging problem of interpreting them for an understanding of causal processes.

As presented in this paper and others (Merritt, 1982, 1983), the relations developed in the analyses are not all mutually independent, as various physical processes affect one another. Nevertheless, a sensitivity analysis approach was considered best, which was to study the effect of varying each parameter while keeping constant as many other parameters or processes as possible. The hypothetical prototype aquifer designed for the analyses was generally based upon the injection zone at the fresh-water injection test site at Hialeah, Florida (F. W. Meyer, U.S. Geological Survey, oral commun., 1980). This site is considered representative of potential limestone injection zones in Florida. Generally, such zones are permeable, confined limestone strata occurring within 2,000 feet of land surface that contain brackish water of less than 2,000 mg/l chloride. Deeper or more saline strata could be used, but less fresh-water recovery would be anticipated.

The present study follows earlier efforts to study subsurface fresh-water storage in a quantitative manner. Kimbler and others (1975) addressed many of the same problems with different modeling techniques. Grove and Konikow (1976) were the first to use the approach of the present study, and Khanal (1980) also studied the process with other methods. Results of a single small-volume injection test cycle in St. Lucie County, Florida (Wedderburn and Knapp, 1983) were extended to some degree by the author based on various hypothetical assumptions and using modeling techniques similar to those described in this paper.

The model-based study was broad in scope and of short duration. Results of the analyses were briefly summarized (Merritt, 1982) and presented in detail (Merritt, 1983). The purpose of this paper is to describe basic concepts related to the subsurface fresh-water storage alternative. A brief description of the simulator is followed by a discussion of the concept of hydrodynamic dispersion, its representation in the computer model, and its relation to the choice of a finite-difference solution algorithm. These topics are presented in some detail in order to help in evaluating results of the recovery efficiency analyses and to illustrate the conceptual development and selection of appropriate modeling techniques that were found necessary for accomplishment of the goals of the study.

MATHEMATICAL SOLUTION AND COMPUTATIONAL ASPECTS

Basic Equations and Computer Code

The generic digital simulator used in the study was developed under sponsorship of the U.S. Geological Survey (INTERCOMP Resource Development and Engineering, Inc., 1976; INTERA Environmental Consultants, Inc., 1979). The model solves equations in three spatial dimensions for the pressure (p, P/L^2) field [equation (1)] and for the transport of dissolved solute [equation (2)] represented as a constituent fraction (C), taking unitless values that represent the relative proportions of two fluids (represented by C = 0 and C = 1) in a mixture which varies spatially and temporally. A third equation may also be solved for temperature (T) to represent the transport of thermal energy. Solution of either the solute or thermal transport equations is optional. The equations pertinent to this study are:

$$\nabla \cdot \frac{\rho \underset{\sim}{k}}{\mu} (\nabla p - \rho \nabla z) = \frac{\partial}{\partial t} (\phi \rho) + q' \qquad (1)$$

$$\nabla \cdot \frac{\rho C \underset{\sim}{k}}{\mu} (\nabla p - \rho \nabla z)$$

$$+ \nabla \cdot (\rho \underset{\sim}{D} \cdot \nabla C) = \frac{\partial}{\partial t} (\phi \rho C) + Cq + \Sigma C_i q_i \qquad (2)$$

$$\phi = \phi_0 (1 + C_r [p - p_0]) \qquad (3)$$

$$\rho = \rho_0 (1 + C_w [p - p_0] + C_T [T - T_0] + \frac{\partial \rho}{\partial C} [C - C_0]) \qquad (4)$$

$$\mu = \mu (T, C) \qquad (5)$$

$$\underset{\sim}{D} = \underset{\sim}{D} (v, \alpha_\ell, \alpha_t, D_m) \qquad (6)$$

where

ρ is density (P/L^3);

$\underset{\sim}{k}$ is the intrinsic permeability tensor (L^2);

μ is dynamic viscosity (PT/L^2);

q' is the sum of sources and sinks of fluids, expressed as mass flux per unit volume (P/L^3T);

$\underset{\sim}{D}$ is the hydrodynamic dispersion tensor (L^2/T);

q is a sum of fluid sinks (P/L^3T);

q_i is a fluid source (P/L^3T) of constituent concentration C_i;

ϕ is porosity (unitless);

C_r is compressibility of the aquifer solid matrix (LT^2/P);

C_T is the coefficient of thermal expansion (reciprocal temperature units);

C_w is compressibility of water (LT^2/P);

α_ℓ, α_t are longitudinal and transverse dispersivity parameters (L);

D_m is molecular diffusivity (L/T^2); and

P, L, T indicate pound-force, length, and time units.

Equation (3) shows that porosity is considered to be a function of pressure depending upon the compressibility of the aquifer matrix. Equation (4) shows fluid density to be a function of pressure, temperature, and constituent fraction that depends upon the compressibility of water, the coefficient of thermal expansion, and upon its variation with constituent fraction ($\partial \rho / \partial C$). Reference values of porosity and density (ϕ_0, ρ_0) are model inputs corresponding to reference conditions of pressure, temperature, and constituent fraction (p_0, T_0, C_0). Equation (5) shows that dynamic viscosity is considered to depend upon temperature and solute fraction. Several types of functional dependence may be selected as a user option. Equation (6) indicates the assumed functional dependence of dispersion that will be discussed later.

Coordinate directions are assumed to be aligned with the principal axes of the permeability tensor ($\underset{\sim}{k}$) so that directional components of permeability may be specified. These components and the initial value of porosity (ϕ_0) may vary spatially as specified by the user. Values of fluid density are associated by the program user with the extreme values of constituent fraction (0 and 1). The code permits solution of the equations in Cartesian or cylindrical coordinates, depending upon the type of geometric symmetry (or lack of it) which characterize the application problem. Solution of each equation is by a three-dimensional, finite-difference method (INTERCOMP Resource Development and Engineering, Inc., 1976).

Hydrodynamic Dispersion and Its Representation

Flow from wells in secondary-porosity limestone aquifers probably does not occur as the spatially uniform displacement of native water by injected water. It is usually assumed that flow is through a network of solution channels that vary in size and tortuosity, and that the velocity of flow

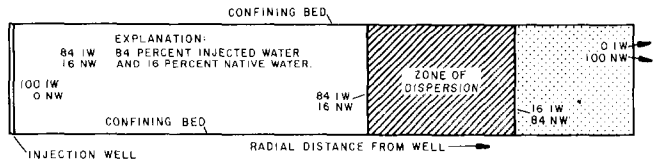

Fig. 2. Diagram showing conceptual model of mixing caused by mechanical dispersion.

may vary over the cross section of each channel. A well drilled near the outer limit of water moving outward from an injection well would penetrate many flow paths containing injected water, native water, or a mixture of the two waters. This situation is usually conceived as occurring within some radius beyond which little injected water has penetrated the aquifer and outward of some smaller radius within which virtually all native water has been flushed by injected water. The volume between the limiting radii, referred to as the "transition zone" or "zone of dispersion," is described mathematically as a spatially averaged concentration mix of the two waters that varies from nearly that of the injected water near the inner boundary to nearly that of the native water near the outer boundary. Figure 2 is a schematic of the "zone of dispersion." This cylindrical section arbitrarily depicts the zone as the region occurring between radii to the 84 and 16 percent concentrations of injected water. The concentration gradient is greatest in the center of this region. The process just described is referred to as "mechanical dispersion." If molecular diffusion effects are included, the term "hydrodynamic dispersion" is used.

The mathematical representation of dispersion [second term, equation (2)] is based upon a diffusion model that suggests the migration of solute from locations of higher to lower concentration at a rate dependent upon a set of dispersion coefficients (D) and the concentration gradient. The functional dependence of the dispersion coefficients is indicated by equation (6). The elements of the dispersion tensor are trigonometric projections of the parametric coefficients longitudinal and transverse dispersivity (α_ℓ and α_t), which relate to dispersion in the direction of flow (α_ℓ) and in the plane perpendicular to the direction of flow (α_t). The relative magnitude of the projections is a function of the net speed (v) and direction of flow. This characterization assumes that flow can be approximated as a spatially continuous process within an isotropic medium (Scheidegger, 1961), and that actual small-scale flow heterogeneities are represented by the dispersion terms. The directional components of dispersion are encoded in the finite-difference model as:

$$A_{i+1,i}\,C_{i+1} - A_{i+1,i}\,C_i - A_{i,i-1}\,C_i + A_{i,i-1}\,C_{i-1} \quad (7)$$

where the internodal mass-flux term $A_{i+1,i}$ contains the dependence upon the dispersivity coefficients, the velocity of flow, the concentration gradient, and molecular diffusion. C_i is the concentration value at node i. This writing suggests a conceptualization of the dispersion process as an interchange of equal amounts of fluid across the interface between two grid cells with the fluid received by each cell having the concentration fraction of the node center of the other cell. The cell with lower concentration receives the greater amount of constituent; thus, an alternative conceptualization is that of constituent moving in the direction of decreasing concentration. Molz and others (1983) describe the concept of "macrodispersion" in which a scale-dependent convective term dominates a term related to "local hydrodynamic dispersivity." The latter term is analogous to the model representation of dispersion by longitudinal and transverse dispersivity coefficients. The scale-dependent component is a result of vertical nonuniformities in the permeability of the aquifer and the resulting different rates of solute movement at various depths.

In the hypothetical perfectly stratified aquifer used as a prototype for this study, the effect of layering was explicitly represented in the spatial design of the model by discrete layers of uniform permeability. Local hydrodynamic dispersion occurred within each discrete layer to a degree determined by the dispersivity coefficients chosen by the model user. The concentration fraction of water arriving at a pumping well was computed as a weighted multizone composite of water from individual zones. This modeling approach as applied to field studies might not fully account for the effect of layering; representation of aquifers by layers of uniform hydraulic characteristics is only a generalization. Given any conceptual subdivision of an aquifer into discrete layers, the dispersion process in each layer might still be characterized by some degree of scale dependence.

The numerical techniques used to approximate the advective flow terms [first term, equation (2)] can affect the apparent degree of dispersion portrayed by the model. If the user specifies upstream weighting for the advective terms, then the concentration of the component of mass advective flux between nodes i and i + 1 ($C_{i+1,i}$)

takes the value of the upstream node. This backward difference method introduces "numerical dispersion" (Lantz, 1971), the degree of which is a function of the grid spacing. The effect is indistinguishable from the simulation of physical dispersion by the specification of dispersivity coefficients, so that the apparent degree of dispersion portrayed in the solute-transport computation can be much greater than is realistic if the grid spacing is too coarse. Backward differencing the time derivative has the same effect to a degree depending upon the time step size (Lantz, 1971).

If the user selects spatially centered differencing, $C_{i+1,i}$ is computed by linear interpolation to be the concentration value at the cell interface as a function of the values at nodes i + 1 and i. This scheme greatly reduces numerical dispersion, as does use of central differencing (Crank-Nicholson) in approximating the time derivative, so that the apparent degree of dispersion in model computations is primarily dependent upon local flow velocity, to a degree under user control through the specification of dispersivity coefficients.

The degree of dispersion as fresh water flowed from the well into the aquifer matrix during injection and subsequently back toward the well during recovery was of major importance in most analyses. Therefore, it was considered advantageous to minimize numerical dispersion by using space and time centered differences. The central difference approach, however, has a drawback in that the size of grid cells and the length of time steps must be controlled to prevent oscillatory behavior ("overshoot" and "undershoot") near the interface between the fluids (Price and others, 1966). The criteria to control oscillations (INTERCOMP Resource Development and Engineering, Inc., 1976) become more restrictive with lower specified degrees of mechanical dispersion (the dispersivity coefficients). However, for the 2- to 30-foot range of longitudinal dispersivity values used in this study, these criteria were satisfied to a sufficient degree that the oscillatory behavior that did occur did not hamper interpretation of results.

Few field studies have been performed to determine the degree of dispersion occurring in carbonate aquifers. In northwest Florida, Ehrlich and others (1979) estimated 30 feet for ("local") longitudinal dispersivity by measuring the increasing concentration of a conservative tracer at an observation well located about 1,000 feet from a waste injection well. Their computational method was based upon assumptions that the permeability and porosity of the injection zone were vertically

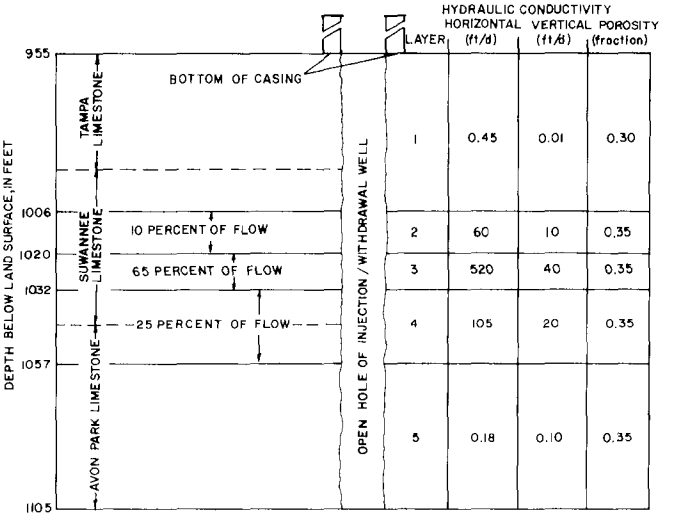

Fig. 3. Sketch of hypothetical aquifer resembling the Tertiary limestone injection zone at the Hialeah test site, Dade County.

uniform throughout a 60-foot aquifer thickness and that permeability was laterally isotropic (within the plane of flow). Implicit in these assumptions is the further assumption that the measured dispersivity would not be scale-dependent. Other carbonate injection zones at sites where detailed geophysical data have been obtained, the Hialeah, Florida site being such an example (F. W. Meyer, U.S. Geological Survey, oral commun., 1980), depart substantially from assumptions of permeability uniformity within such a large interval. The measured value could be considered an estimate of scale-dependent "macrodispersion" if it is understood to be valid only for the distance scale of the test.

The molecular diffusion component (D_m, L^2T) of the hydrodynamic dispersion tensor [equation (6)] is usually considered to be of negligible magnitude compared to mechanical dispersion in large-scale field situations of fluids moving at appreciable velocities (Ren Jen Sun, 1976). An estimate of 1×10^{-5} cm^2/s (0.13 ft^2/d) was used by Hoopes and Harleman (1967) in analyzing results of tests with their sand model.

DESIGN OF A HYPOTHETICAL AQUIFER FOR MODEL ANALYSES

A hypothetical aquifer was designed that was considered representative of a brackish artesian limestone aquifer. The hydraulic characteristics of this prototype (Figure 3) were based upon those estimated from aquifer tests and geophysical

logging of the injection zone at the U.S. Geological Survey fresh-water injection and recovery test site at Hialeah (Figure 1) in Dade County, Florida. The hydraulic conductivity estimates were based on the measured transmissivity of the injection interval and the contributions of flow from various depth intervals as indicated by flowmeter logs. Porosity estimates were based on a correlation of neutron, sonic, and caliper logs (F. W. Meyer, U.S. Geological Survey, oral commun., 1980). The 150-foot interval shown in Figure 3 is divided into five hydraulically distinct, vertically uniform layers. The outer layers are relatively impermeable and act as confining layers receiving very little flow from the injection wells. The 12-foot middle layer is the most permeable, receiving 65 percent of the injected water. As shown in Figure 3, the most permeable layer at the Hialeah site was about 12 feet thick and occurred within the Oligocene Suwannee Limestone from 1,020 to 1,032 feet below land surface. The permeable layer was surrounded by much less permeable limestone of the Suwannee Limestone, the overlying Miocene Tampa Formation, and the underlying Eocene Avon Park Limestone. The injection zone was found to have a static head of 42 feet above mean sea level, or 33 feet above land surface (F. W. Meyer, U.S. Geological Survey, oral commun., 1980). A more complete description of the Floridan aquifer system in south Florida is included in Merritt and others (1983).

The Hialeah site data seemed to show a vertical variation from 800 to 2,000 mg/l in chloride concentration, but native-water chloride concentration and density were considered vertically uniform at various values in the hypothetical aquifer because none of the results of the sensitivity analyses would have benefitted from a spatial density variation. The chloride concentration of injected water was considered to be 65 mg/l.

The hypothetical aquifer was simulated in various ways depending upon the requirements of the problems considered. Analyses in which the injection and recovery processes were characterized by radial symmetry were simulated with a cylindrical coordinates (r, z) model design with each layer represented as one or two layers in the model. Analyses in which radial symmetry did not apply (regional flow and multiple wells) required three-dimensional Cartesian-coordinate simulations. To reduce costs, and taking advantage of the vertical hydraulic uniformity of layers in the hypothetical aquifer, the 12-foot, most permeable layer was represented in Cartesian coordinates with a two-dimensional areal model design. The cylindrical coordinate models were discretized into 27 annuli, with the outer radius at 30,000 feet, where constant pressure and concentration boundary conditions could be specified without affecting the simulated flow of fresh water near the well. Annuli widths ranged from less than 2 feet near the well (and should have been larger for better stability) to 10,000 feet near the outer radius, but were less than 60 feet in the area containing the fresh-water mass. The areal grids were symmetric, and boundary edges were more than 20,000 feet from the center. Grid cells in the vicinity of fresh-water movement were less than 200 feet on a side.

In some analyses of buoyancy stratification, it was found advantageous to design an entirely different prototype 170 feet thick with uniform hydraulic characteristics similar to the five-layer model, except that nominal horizontal and vertical hydraulic conductivities were 100 and 10 ft/d. The model of this prototype was discretized into 17 10-foot layers in cylindrical coordinates.

As the Hialeah site data did not support any estimates of the degree of hydrodynamic dispersion, various dispersion models [choices of longitudinal (α_ℓ) and transverse (α_t) dispersivity coefficients] were used. The one most often used was: $\alpha_\ell = 4$ feet, $\alpha_t = 0$. Assigning a α_ℓ value of 4 feet assumes that the value from Ehrlich and others (1979) was scale-dependent, and that a reasonable estimate of "local" hydrodynamic dispersivity would be smaller. Longitudinal dispersivity was assigned other values in some analyses. Setting $\alpha_t = 0$ assumes no transverse dispersion ("interlayer dispersion" when flow is predominantly in the lateral direction). Transverse dispersivity was assigned nonzero values in some analyses discussed in Merritt (1983).

RELATION OF RECOVERY EFFICIENCY TO HYDROGEOLOGIC CHARACTERISTICS

Buoyancy Stratification

If a substantial amount of injected fresh water buoys upward about the well during injection, storage, or withdrawal, the amount which is recoverable will be reduced. Native salt water will tend to migrate inward toward the bottom of the well, and the injected fresh water will tend to migrate outward in upper intervals of the injection zone. During withdrawal, salt water will reach the bottom of the well and contaminate withdrawn water even while fresh water remains around the well bore in the upper part of the zone. One objective of the computer analyses was to deter-

Table 1. Relation of Recovery Efficiency to Permeability

100.0	21.9	–

[K_r and K_z (feet per day) are radial and vertical hydraulic conductivity values.]

mine the degree to which the magnitude of this process was related to the density contrast between injected and native waters and to the permeability of the aquifer material.

Table 1 shows results of two series of runs with the five-layer cylindrical coordinates model in which both horizontal and vertical hydraulic conductivities varied from the Hialeah site prototype values by the same multiple. Values in the second column are for a native-water density of 62.57 lb/ft^3, similar to the Hialeah site injection zone, and values in the third column are for a native-water density of 64.0 lb/ft^3, about that of sea water. Simulated injection was for 53 days, followed immediately by withdrawal. The five-layer model was not considered to provide a detailed representation of buoyancy stratification but was used to establish general quantitative relations.

Where recovery efficiency changes little with successive multiples, little stratification is portrayed by the simulations. A comparison of results from the two sets of runs shows native-water density to be an important factor affecting the degree of buoyancy stratification. Results indicate that for a given native-water density there seems to be a certain range of permeability in which virtually no stratification occurs during time periods comparable to those of the simulation. This permeability range is lower for higher values of native-water density. As simulated permeability values increase beyond this range for each density value, an increasing degree of stratification occurs, apparently because of a decrease in the frictional retarding force opposing upward (buoyant) flow for the prevailing density contrast and outward flow in upper layers.

These observations were consistent with results of runs of the 17-layer model of the hypothetical prototype with spatially uniform hydraulic characteristics, which showed the stratification pattern in greater detail. Of particular interest is a run in which horizontal (radial) hydraulic conductivity was increased by a factor of 100 while vertical hydraulic conductivity was not increased. In this scenario, the aquifer initially contained water of sea-water density (64.0 lb/ft^3). At the end of injection (Figure 4A), considerably more fresh water is present in the top layer than in lower layers, and considerably less is present in the lowest layer. Intervening layers were relatively uniform in volumes of fresh water, and the model computed a relatively uniform vertical fluid particle velocity of 0.86 ft/d in the fresh-water region around the well bore. Withdrawal followed immediately, and Figure 4B shows fresh water remaining in the injection zone when sufficient saline water reached the well in lower layers to cause the mix of withdrawn water to exceed the 250-mg/l chloride concentration limit. Runs in which longitudinal

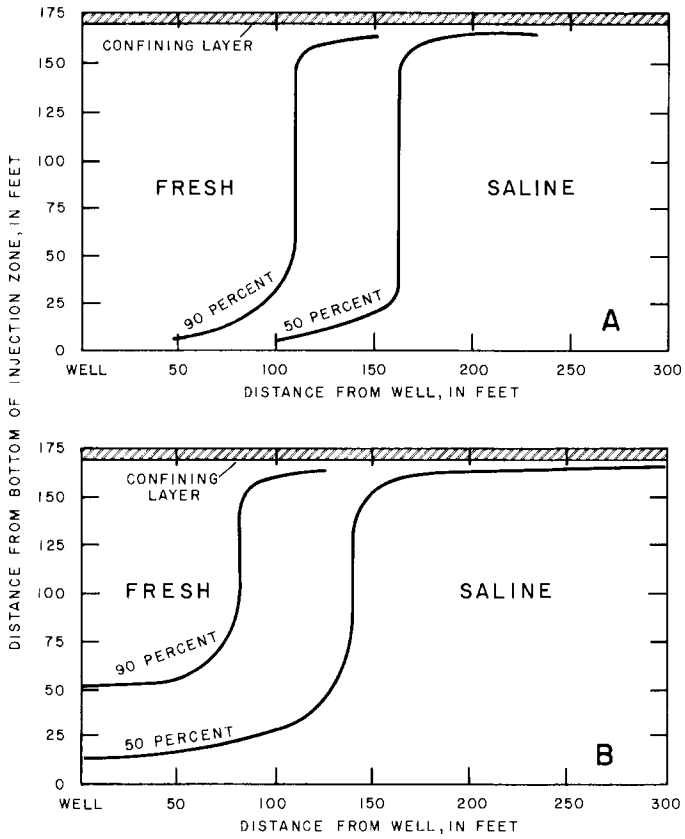

Fig. 4. Diagrams showing vertical and radial distribution of fresh water resulting from buoyancy stratification during injection and withdrawal.

dispersivity was increased show a decrease in buoyancy stratification, perhaps because waters of contrasting density are more widely separated by a broader zone of dispersion.

Evidently, aquifers of high permeability containing highly saline water are a worst case for successful recovery of injected fresh water. Because carbonate injection-zone hydraulic and chemical characteristics typically vary regionally and even locally, it is appropriate to evaluate the possibility that some degree of buoyancy might occur on a site-by-site basis.

Hydrodynamic Dispersion

When the upper limit of the concentration of some constituent considered acceptable in recovered water is less than half the average of the concentrations in the injected and native aquifer waters, hydrodynamic dispersion is a deleterious process that reduces recovery efficiency. If the upper limit is greater than the average, hydrodynamic dispersion works to the benefit of the injector, and recovery efficiencies greater than 100 percent can be realized. In the hypothetical test cases posed in this study, the acceptable limit for chloride (250 mg/l) was less than the average of the injected water (65 mg/l) and native aquifer water (2,000 to 19,000 mg/l) concentrations.

Although part of the water within the zone of dispersion may be potable, the total amount of recoverable water is lower when the volume of the zone of dispersion is larger relative to the volume injected, a result of a higher degree of hydrodynamic dispersion. In a series of tests with the five-layer model of the Hialeah prototype to observe the simulated effect upon recovery efficiency, longitudinal dispersivity was varied from 2 to 30 feet, while the volume injected was kept constant. Recovery efficiency decreased as the dispersivity value increased. Results are shown in Figure 5 for three different values of native-water density. Transverse dispersivity was assumed to be zero. When α_ℓ = 4 feet, the native-water chloride concentration was 2,000 mg/l, and the acceptable limit for chloride was raised to 1,300 mg/l, the computed recovery efficiency was 108 percent, demonstrating that dispersive mixing is a beneficial process when the native-water concentration does not greatly exceed the acceptable limit in recovered water.

Native-Water Salinity

The greater the salinity of the native water, the greater will be the range of salinity across the zone of dispersion, and the proportion of potable

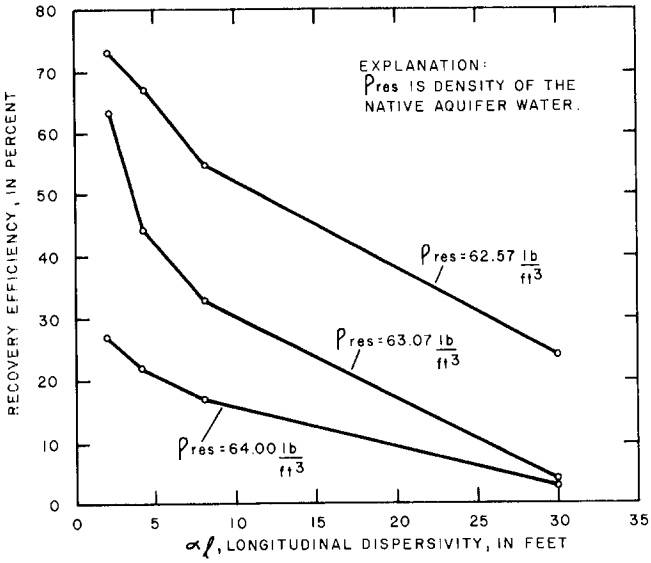

Fig. 5. Graph showing relation between recovery efficiency and the degree of dispersion.

water within the zone will be smaller. The inverse relationship between recovery efficiency and aquifer-water salinity, computed by the model as a recovery efficiency-density relation, is shown in Figure 6 for a range of longitudinal dispersivity coefficients (α_t). α_ℓ was zero in the analyses illustrated (no interlayer dispersion). No effort was made to isolate the deleterious effect of buoyancy stratification at higher values of native-water density.

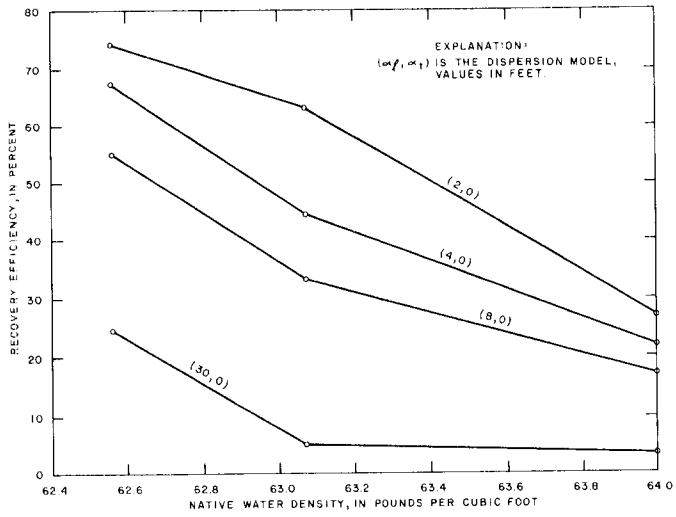

Fig. 6. Graph showing relation between recovery efficiency and native-water density.

Aquifer Storativity

The aquifer storage coefficient is modeled as an algebraic combination of values of porosity, native-water density, layer thickness, and compressibility of the aquifer material and of water (Lohman, 1979). Of the parameters other than density, porosity and layer thickness were considered to have the greatest possible range of variation in the class of aquifers with potential as receptacles for injected fresh water. Therefore, these two parameters were varied in model tests to determine the relation between recovery efficiency and aquifer storativity.

This relation is less obvious conceptually than others tested with the model. For a given volume of injected fresh water, a thicker receiving layer will have a zone of dispersion which is smaller in lateral dimension because of the reduced distance of radial outflow from the well but greater in vertical dimension because of the increased thickness of the receiving zone. Given greater porosity, the zone of dispersion will be reduced in lateral dimension but will contain a greater amount of water per unit volume. The question posed is whether the relative volumes of water within the unmixed fresh-water zone and mixed fresh and native saline water within the zone of dispersion would change if the layer thickness or porosity were different. If the relative volume of the zone of dispersion were to increase, which would mean a reduction in the volume of unmixed fresh water, recovery efficiency would be reduced because only part of the water in the zone of dispersion is potable.

Results of model runs (Figure 7) for a dispersion model in which α_ℓ = 4 feet and α_t = 0 (no interlayer dispersion) indicate that recovery efficiency is lower for larger values of layer thickness and porosity. Indicated recovery efficiency decreases with increasing porosity and layer thickness are not dramatic. An assumption underlying analyses with the model was that hydraulic conductivity and the degree of hydrodynamic dispersion are unrelated to changes in porosity.

Background Hydraulic Gradients and Length of Storage Period

Of major interest relative to the potential feasibility of fresh-water injection is the effect of delaying recovery of the injected fresh water until it is needed. The length of a storage period can be a significant factor if natural or man-made background hydraulic gradients move the injected fresh water downgradient from the injection well. If the shift is appreciable, the well will no longer be near the center of the fresh-water mass during recovery. After recovering part of the potable water, further pumping would then draw saline water from the upgradient direction while appreciable amounts of fresh water remain in the downgradient direction. When the saline contribution becomes substantial enough that the salinity of withdrawn water exceeds the limit established for potability, the remaining fresh water is lost as such unless downgradient wells are available for its recovery.

The degree to which a mass of injected water will shift during a given storage period with respect to the well used for injection will vary depending upon the diameter of the fresh-water mass and the rate of background flow. If the diameter of the fresh-water mass is relatively large, a relatively large amount of downgradient movement can occur before the degree of the shift is sufficient to appreciably affect recovery efficiency, because the injection and recovery well would be closer to the center of the larger fresh-water mass. The diameter of the fresh-water mass is a function of its volume and the thickness and porosity of the injection zone. This dependence upon diameter was not tested with the model, but the length of the storage period was varied in model tests assuming a given injection volume, aquifer dimensions and hydraulic characteristics, and rate of background flow.

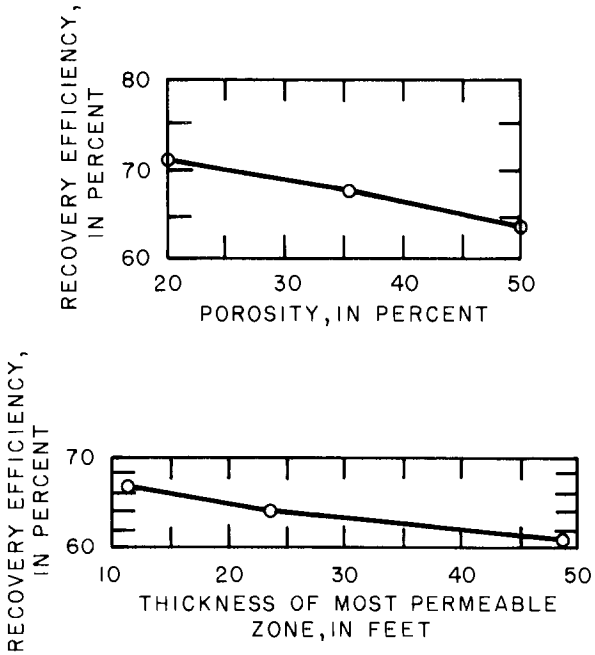

Fig. 7. Graph showing relation between recovery efficiency and aquifer storativity parameters.

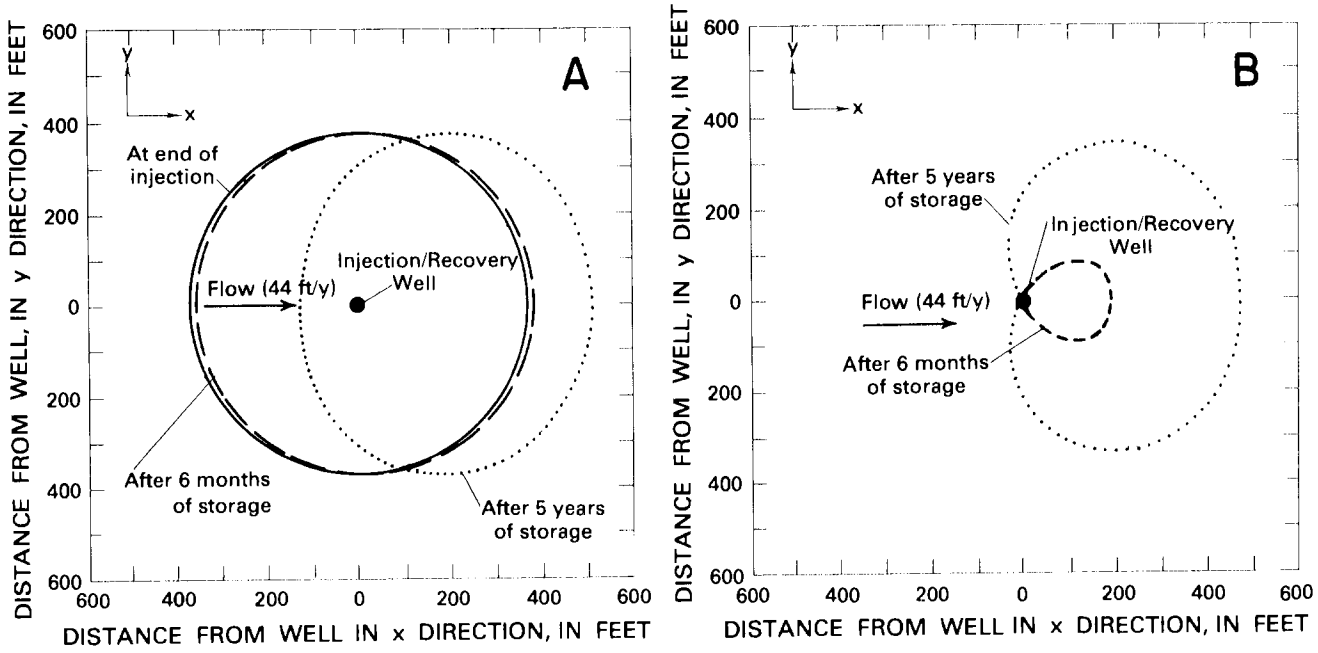

Fig. 8. Diagrams showing effect of regional flow upon the position and recoverability of potable water.

The single-layer Cartesian representation of the 12-foot, most permeable layer at Hialeah was used for the analysis. Background flow, caused by a natural hydraulic gradient in the aquifer, was assumed to be 44 ft/yr along the x-axis of the grid, and was simulated by compatible initial and boundary pressure specifications. The native-water salinity was insufficient to cause appreciable buoyancy stratification. Results (Figure 8A) show the nearly circular fresh-water mass at the end of the injection period (solid line) shifted slightly after six months of storage (dashed line) and shifted substantially after five years of storage (dotted line). In the latter case, appreciable movement downgradient has caused additional hydrodynamic dispersion which has compressed the 250-mg/l chloride profile. Recovery efficiencies when recovery began immediately following injection, after six months of storage, and after five years of storage, were 60.9, 59.9, and 21.8 percent. Figure 8B shows fresh water remaining when recovery ended because withdrawn water became saline following storage periods of six months (dashed line) and five years (dotted line).

As the specified hydraulic conductivity and rate of flow in a layer of high permeability are probably not atypical of potential limestone injection zones, the analysis indicates that the possible deleterious effects of background flow need assessment on a site-by-site basis, taking into consideration aquifer characteristics, the likely volumes to be injected, and the likely storage period prior to recovery.

RELATION OF RECOVERY EFFICIENCY TO DESIGN AND MANAGEMENT PARAMETERS

Rates of Injection and Recovery

It is of interest relative to the feasibility of recovering injected fresh water to ascertain whether certain ranges of injection and recovery rates will favor high recovery efficiencies. The five-layer model was used to simulate the injection and withdrawal of a fixed volume at various rates. In one series of tests, injection at different rates with the time period of injection adjusted to maintain the fixed volume was followed by withdrawal at a fixed rate. In the second series of tests, injection at a fixed rate for a fixed time period was followed by withdrawal at different rates until the concentration of withdrawn water reached 250 mg/l.

No variation in recovery efficiency was observed in the tests. The zone of dispersion at the end of injection was virtually unchanged when the injection rate varied, demonstrating that the model represents the dispersion process in radial flow from a well as a function of the extent of fluid movement to a new position and not of the rate of movement to that position, despite the functional dependence upon flow velocity. This is consistent with other analytical formulations describing the

concentration variation within the zone of dispersion (Hoopes and Harleman, 1967; Ren Jen Sun, 1976).

Volume of Water Injected

The five-layer model was used to show the relation of recovery efficiency to the volume of fresh water injected. From a theoretical standpoint, the problem actually considered is whether the volume of the zone of dispersion varies in proportion to the injection volume. If not, there would be a variation in recovery efficiency as the injection volume changes.

The rate of injection for a fixed time period was varied in model tests from 1,000 to 250,000 ft^3/d, as results of the previous analysis had shown that recovery efficiency was independent of rate in model simulations. The dispersion model (α_ℓ = 4 feet, α_t = 0) represented the assumption that no interlayer dispersion occurred. Results of this analysis (Figure 9) show that there is a large increase of recovery efficiency with increasing volume for small volumes, but that the rate of increase is small at large volumes. Zero recovery efficiency would occur for a sufficiently small injection volume because of the effect of hydrodynamic dispersion. Evidently, operational tests performed with small injection volumes cannot be expected to yield encouraging results. Results of this analysis apply to a single cycle of injection and recovery; whether the relation with volume continues in successive cycles was not established.

Well Not Open to Full Thickness of Injection Zone

For various reasons, operational injection wells might be constructed to be open only to part of a permeable receiving zone, instead of being open to an entire permeable zone and to sections of overlying and underlying confining layers, as was the case at the Hialeah test site used as a prototype in this study. To investigate this type of situation, the five-layer model was modified so that the well was open only to the lower 77 feet of the 150-foot Hialeah site interval; that is, to the lower 4 feet of the most permeable layer, to the next underlying relatively permeable layer, and to a section of the lower confining layer. Simulated conditions did not permit any appreciable buoyancy effect.

Virtually no change in recovery efficiency was observed. Injected fresh water flowed upward near the well to fill permeable zones, but there was virtually no vertical flow at radii greater than 300 feet. The concentration gradient of the zone of dispersion at the end of the injection phase was quite similar to that of the fully penetrating case, in which very little vertical flow occurred during either injection or withdrawal. Results are of significance relative to the design of operational injection systems in that they suggest that partial well penetration of a permeable unit might not affect the recoverability of potable water.

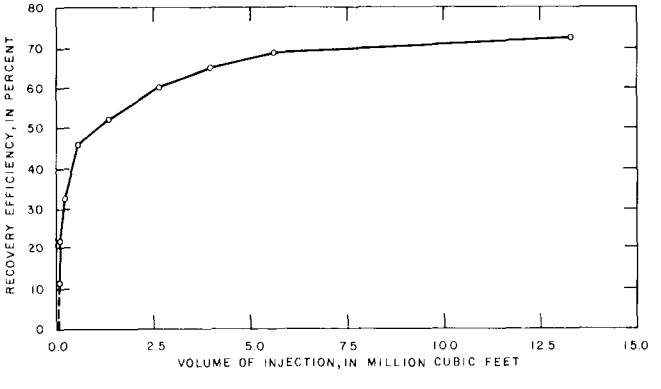

Fig. 9. Graph showing relation between recovery efficiency and volume of fresh water injected.

Successive Cycles of Injection and Recovery

If implemented as a water-conservation practice in regions with an annual wet- and dry-season climatic cycle, fresh-water injection and recovery would likely be done on a seasonal schedule. The recovery efficiency of the first cycle of injection and recovery is not a good indicator of the potential of the system, as recovery efficiency tends to improve in subsequent cycles. Such improvement was observed to some extent in several short-duration operational tests in south Florida (Tibbals and Frazee, 1976; J. J. Plappert, Florida Department of Environmental Regulation, written commun., 1977; and F. W. Meyer, U.S. Geological Survey, oral commun., 1980) though the tests were not specifically designed to measure it.

A conceptual explanation for the improvement of recovery efficiency is that it is caused by changes in the zone of dispersion. If withdrawal were to end when withdrawn water exceeded potability (250 mg/l chloride), the chloride distribution in the aquifer at that time would become the initial distribution for the next injection phase. This mix of injected fresh water and saline native water about the well would mix with additional fresh water during the next injection to form a new zone of dispersion. Thus, with each successive injection, the zone of dispersion would progressively increase

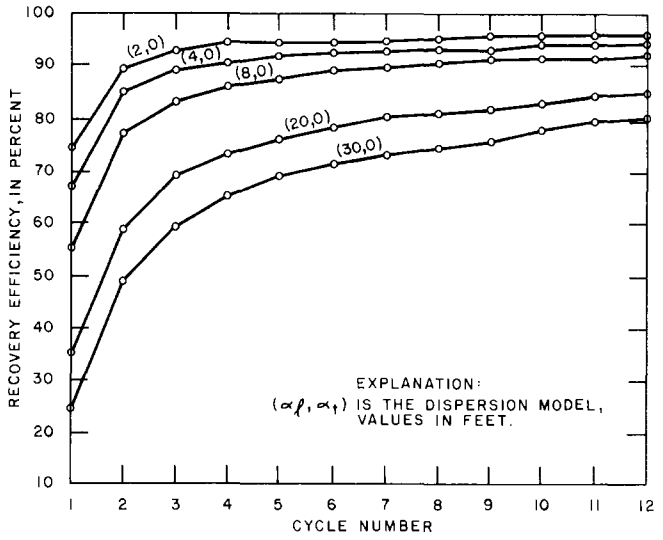

Fig. 10. Graph showing improvement of recovery efficiency with successive injection and recovery cycles.

in volume from accretion of residual fresh water from previous injections and contain greater quantities of mixed water that is potable. This would lead to a progressive increase in recovery efficiency even if the volumes of injected fresh water did not increase. Because the cost of the fresh-water storage alternative is most realistically based upon the recovery efficiency obtainable after initial cycles, and because operational tests have not clearly established what the degree of improvement will be, the model was used to assess the possible degree of improvement.

Twelve similar cycles of injection and recovery were simulated in the five-layer model, and each recovery was terminated when withdrawn water exceeded potability (250 mg/l chloride). Results for various dispersion models (Figure 10) indicate major improvement in the first several cycles. Improvement continues at a reduced rate in later cycles. It is of interest that even when recovery efficiency is 35 percent in the first cycle (α_ℓ = 20 feet, α_t = 0), the model indicates that it could improve to 70 percent in the third cycle and to 80 percent in the seventh cycle.

Multiple-Well Configurations

Operational fresh-water injection and recovery systems may require more than one well if the volumes to be injected and the required inflow rate exceed the capacity of a single well, or if the pressure must be distributed to avoid fracturing the aquifer or damaging the well. The recovery efficiency of a group of wells depends upon the extent and nature of their interaction. Model analyses were designed to compare the recovery efficiencies of groups of wells arranged in various geometries. A single-well simulation was also performed for further comparison.

As most of the simulated cases were not radially symmetric, the single-layer Cartesian representation of the most permeable layer of the Hialeah site prototype was used. The dispersion model was α_ℓ = 4 feet, α_t = 0. Analyses assumed approximately uniform flow in an isotropic aquifer with no background hydraulic gradient and insufficient density contrast to cause appreciable buoyancy. Wells were arranged so that adjacent wells were 500 feet apart. The total volume injected was the same in most of the runs and was apportioned equally among wells in operation at a particular time.

Centered configurations (a central well surrounded by peripheral wells at a 500-foot radius) of three, four, five, seven, and nine wells were tested. Noncentered configurations tested included a two-well arrangement and triangular and square arrangements. A simultaneous injection schedule (injection at equal rates at all wells for the entire time period of the injection) was tested in the noncentered configurations and in the five-well centered configuration. A sequential injection schedule (injection at the center well until fresh water reached peripheral wells, followed by injection at equal rates at all wells) was tested in centered configurations and in the two-well arrangement (with one well serving as the "center"). Generally, withdrawal schedules consisted of equal-rate withdrawals with various wells being shut down when pumped water exceeded a salinity limit corresponding to 250 mg/l chloride. In one test, a sequential injection schedule in a five-well centered configuration was followed by withdrawal solely from the center well.

There were no major variations in recovery efficiency in any configurations or for any schedules when the volume injected remained constant. Sequential injection schedules in the centered configurations followed by equal-rate withdrawals generally had the highest recovery efficiencies, nearly that of the single-well test. Simultaneous injection and equal-rate withdrawal in noncentered configurations produced recovery efficiencies less than the single-well simulation by factors of 3 to 4 percent. Variations in the volume showed the same type of relation to recovery efficiency, and variation in rate showed the same lack of relation, as in the single-well analyses.

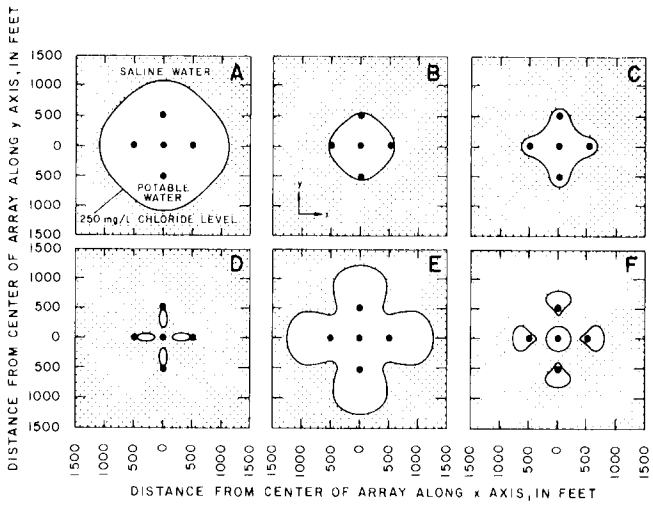

Fig. 11. Diagrams showing the distribution of potable water resulting from various schedules of injection and withdrawal in a centered configuration of five wells.

The five-well centered configuration serves as a useful test case for comparing various types of injection and withdrawal schedules. Figure 11A shows the fresh-water mass at the end of sequential injection in the five-well configuration, and Figure 11B shows the fresh-water mass at the point during recovery when saline water had just reached the peripheral wells. When the sequential injection was followed by withdrawal from only the central well, the fresh-water distribution (Figure 11C) after the same volume of recovery as in Figure 11B was different. When all wells became saline, some fresh water remained (Figure 11D), and recovery efficiency was less than the equal-rate withdrawal (Figure 11B) by a factor of 6 percent.

Simultaneous injection in the five-well centered configuration produced a cloverleaf distribution of fresh water (Figure 11E). The water remaining (Figure 11F) after the same volume of withdrawal (at equal rates) as the other examples is in five distinct masses. When recovery ended, small amounts of fresh water remained outside the peripheral wells, and recovery efficiency was less than the sequential injection and equal-rate withdrawal case (Figure 11A-B) by a factor of 10 percent.

The basic principle illustrated by the multiple-well analyses seemed to be that recovery efficiency is somewhat enhanced when flow patterns during injection and recovery are similar (though reversed), as in the sequential injection and equal-rate withdrawal case.

CONCLUSIONS

Generally, the study shows that a loss of recovery efficiency resulted from: (1) processes causing mixing of injected fresh water with native saline water (hydrodynamic dispersion); (2) processes or conditions causing the irreversible displacement of the injected fresh water with respect to the well (buoyancy stratification and background hydraulic gradients); and (3) processes or procedures causing injection and withdrawal flow patterns to be dissimilar (dissimilar injection and withdrawal schedules in multiple-well systems). A significant result is the theoretical demonstration that recovery efficiency should improve considerably in initial successive cycles, provided that each recovery phase ends when the chloride concentration of withdrawn water increases to some prescribed value less than that of the more-saline native water. Other results show that a high degree of aquifer permeability or high salinity of the native water, or a combination of these factors, would permit rapid buoyancy stratification and bring about a substantial loss of recovery efficiency.

ABSTRACT: Interpretation of pumping test and tracer test data allowed for the evaluation of capture areas of discharge wells as well as important hydraulic parameters of a multi-layered aquifer system such as longitudinal dispersivity, hydraulic conductivity, effective porosity and leakage flow. Evaluation of the tracer breakthrough curves was realized using an analytical solution of the mass transport equation for radial symmetric flow patterns induced by the forced gradient tracer test. The results of the tracer test yielded important input parameters for subsequent calculations of pollution spreading with a numerical groundwater model to optimize the location and necessary pumping rates of future discharge wells as part of hydraulic remediation measures.

1 INTRODUCTION

In order to design future remediation measures on a contaminated site the hydraulic characteristics of the fractured aquifer were investigated using a forced gradient tracer test. In the focus of interest were the capture areas of future discharge wells, the quantification of groundwater flow from different directions as well as the quantification of vertical leakage into the underlying siltstone.

2 SITE HYDROGEOLOGY

The subsurface consists of fractured sedimentary rocks of the Middle Buntsandstein formation (Triassic Sandstone). The sequence of sand, clay- and siltstones forms a complex multi-layered aquifer system. The upper sandstones are partially weathered and form a hydraulic unit with the underlying sandstones, i.e. the interbedded thin clay- and siltstone band does not seem to act as a hydraulic barrier. The lower sandstones though are hydraulically separated from each other by layers of clay and siltstones. The groundwater table is about 3-4 m below surface level. The thickness of the upper aquifer is about 8-10 m. Hydraulic conductivities as derived from previous pumping tests are in the order of $1x10^{-4}$ m/s. The groundwater flow from the site in the upper aquifer is in the order of 8 m^3/h. The aquifer thickness of the underlying sandstone is about 10 m, due to a lower hydraulic conductivity of about $1x10^{-5}$ m/s, the groundwater flow from the site in the underlying aquifer is about 5 m^3/h. As a consequence of the higher hydraulic heads in the upper aquifer vertical leakage downwards the lower aquifer was assumed.

3 TRACER TEST

The hydraulic parameters were investigated by a long-term forced gradient tracer test which was subdivided in three main pumping phases.

3.1 *First pumping phase*

Groundwater was pumped from two wells screened in the first/second aquifer for a total time of 18 weeks. At a constant discharge rate of about 4 m^3/h a forced gradient towards the pumped wells was superimposed on the natural gradient of groundwater flow. During pumping five fluorescent and chemical tracers were injected simultaneously into different observation wells spread around the pumped wells.

Table 1. Tracers, tracer mass injected and distances from the injection well to the pumping well in the first /second aquifer

Tracer substance	Tracer mass	Distance
Na-Naphthionate	2.0 kg	64 m
Sulforhodamine B	0.5 kg	25 m
Uranine	0.2 kg	50 m
Strontium Chloride	3.0 kg	90 m
Lithium Chloride	2.0 kg	42 m

These injection wells are screened in the first/second aquifer too. At the same time a mass of 2,0 kg of Ammonium Bromide was injected into an observation well screened in the third aquifer, located about 16 m from the pumping wells.

3.2 *Second pumping phase*

With a duration of 5 weeks groundwater was pumped from a well screened in the third aquifer in addition to the ongoing extraction from the first/second aquifer. The discharge rate from the third aquifer was kept constant at about 6 m^3/h. Similar to the first pumping phase 4 fluorescent and chemical tracers were now injected into observation wells screened in the third aquifer.

Table 2. Tracers, tracer mass injected and distances from the injection wells to the pumping well in the third aquifer

Tracer substance	Tracer mass	Distance
Na-Naphthionate	3.0 kg	56 m
Sulforhodamine B	2.0 kg	110 m
Uranine	1.0 kg	80 m
Lithium Chloride	6.0 kg	47 m

To make sure that tracer concentrations in the third aquifer are not influenced by the previous injection in the first/second aquifer, tracer injection in the third aquifer was repeated 2 weeks later using identical tracer substances and masses at the same injection wells.

3.3 *Third pumping phase*

For another 3 weeks the groundwater abstraction from the third aquifer was continued whereas the extraction from the first/second aquifer was stopped. No additional tracers were injected in this pumping phase.

3.4 *Sampling*

Tracer concentrations were monitored by sampling the pumped groundwater from the discharge wells and from selected observation wells.

3.4.1 *Discharge wells*

Representative samples were taken from the extracted groundwater assuming constant tracer concentrations over the thickness of the aquifer. During the first week of pumping samples were taken at intervals of 4 hours. In the second week sampling was realized at intervals of 6 hours. Sampling at intervals of 12 hours started in the third week of groundwater extraction.

3.4.2 *Observation wells*

In order to control time depending tracer concentrations in the nearby surrounding, especially in observation wells located down gradient of the natural flow direction a number of 10 observation wells were sampled in weekly intervals during the tracer test. Water extraction and sampling was accomplished by pumping the observation wells with a rate of up to 5 m^3/h for 1 to 2 hours. Analogous to sampling the pumping wells, all samples were taken assuming constant tracer concentrations over the thickness of the aquifer.

3.5 *Trace analysis*

In order to protect the fluorescent tracers from UV-radiation all groundwater samples were filled in small bottles (250 mL) of brown glass. Except bromide ion, all tracers were simultaneously analyzed from one sample but with different analytical methods to enable cost-effective analysis of the tracers simultaneously injected (Käss 1993). The feasibility of this analytical procedure was tested with groundwater samples from the site, which additionally proved no substantial interference of the analytical methods by organic contaminants such as PAH or phenols in the water.

Table 3. Analytical methods and lowest tracer detection limits

Tracer substance	Method	Detection Limit
Na-Naphthionate	Fluorescence spectroscopy	0.1 µg/L
Sulforhodamine B		0.02 µg/L
Uranine		0.002 µg/L
Strontium Chloride	Atomic absorption	2.0 µg/L
Lithium Chloride		0.2 µg/L
Ammonium Bromide	Flame spectroscopy	100.00 µg/L

4 RESULTS

4.1 *First/second aquifer*

4.1.1 *Discharge wells*

The best results were received from Strontium Chloride which could be detected at the pumping well after a travel time of 16 days. The first concentration peak appeared about 18 days after injection with two smaller peaks following about 28 and 45 days later (see figure 1). The total recovery rate of Strontium Chloride was approximately 51 %. A good result as

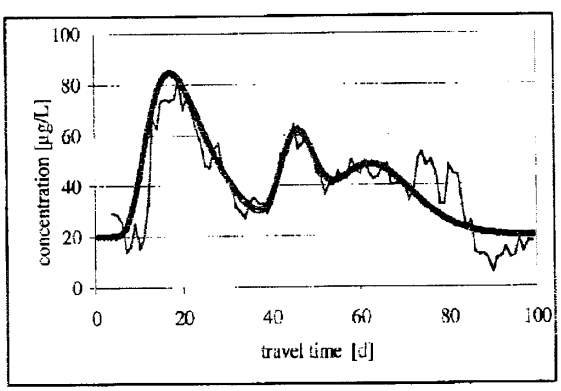

Figure 1. Strontium Chloride concentration during the tracer test, normal line = measured concentration, bold line = calculated concentration

well was received from Sulforhodamine B which was detected after a travel time of 59 days with the concentration peak 5 days later (see figure 2). The total recovery rate was 43 %. Uranine proved a travel time of 49 days and a total recovery rate of 9.5%. Concerning Uranine a concentration peak was not observed because tracer concentrations detected were still increasing until the end of the tracer test. In contrast to that, the tracers Na-Naphthionate and Lithium Chloride were impossible to detect throughout the complete tracer test.

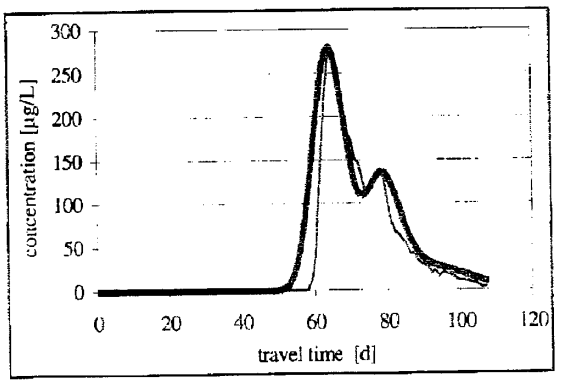

Figure 2. Sulforhodamine B concentration during the tracer test, normal line = measured concentration, bold line = calculated concentration

Bromide although injected into the third aquifer showed travel times of only 9 days with a long term peak concentration of about 20 days and a total recovery rate of more than 50 %.

4.1.2 *Observation wells*
Except Bromide all tracer substances injected were detected at least in one of the sampled down gradient observation wells with travel times between 7 days and up to 63 days. That means the tracers Na-Naphthionate and Lithium Chloride although not found in the pumping wells could be detected in some down gradient observation wells. The tracers registered at the pumping wells also drifted with the natural groundwater gradient to some extent, the concentrations found in the down gradient observation wells in most cases being much smaller than the concentrations detected at the pumping wells.

4.2 *Third aquifer*

4.2.1 *Discharge well*
Results received from the two identical tracer injections in an interval of two weeks nearly proved to be identical concerning travel times and recovery rates. Na-Naphthionate could be detected at the pumping well after a travel time of 1 day with a concentration peak 4 day after the injection (see figure 3). The total recovery rate of Na-Naphthionate was approximately 20 %. Uranine arrived at the pumping well 2

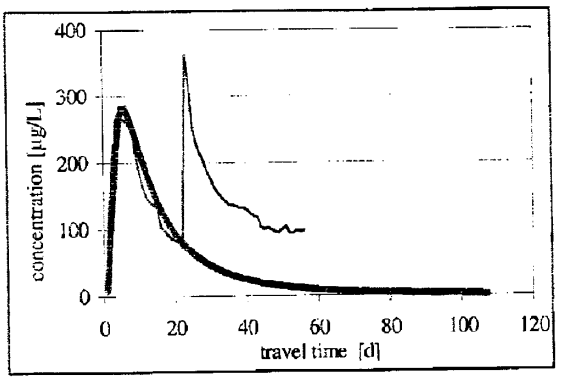

Figure 3. Na-Naphthionat concentration during the tracer test, normal line = measured concentration, bold line = calculated concentration (first injection)

days after the injection with a concentration peak another 2 days later. The recovery rate was 6 %. Lithium Chloride could be detected after a very short travel time of less than 1 day with the concentration peak 1 day after the injection and a total recovery rate of 16 %. Although providing an ideal breakthrough curve with a travel time of 2 days and the concentration peak 11 days later, the recovery rate of Sulforhodamine B was in the order of 1 %.

4.2.2 *Observation wells*
The concentration peak of Sulforhodamine B could be detected in one of the down gradient observation wells sampled approximately 7 days after the injection. The maximum concentration in this observation well exceeded the maximum concentration at the pumping well by a factor of 50. The other tracers injected could not be registered in the down gradient observation wells.

5 EVALUATION

The resulting concentrations of the tracer-substances previously injected into the observation wells allowed for the construction of corresponding breakthrough curves. Interpretation of the breakthrough curves in combination with the interpretation of different draw-down rates lead to the evaluation of the dominating fluid pathways within the multi-layered aquifer system. Assuming radial symmetric flow patterns induced by the constant groundwater extraction, the breakthrough curves at the pumping wells were calculated using Equation 1, which is an analytical solution of the mass transport equation published by Kinzelbach et al.:

$$c(r,t) = \frac{M}{2Q\sqrt{\pi a_L v_a t^3}} \exp\left(-\frac{(r - v_a t)^2}{4 D_L t}\right) \quad (1)$$

where M = injected tracer mass; Q = pumping rate; a_L = longitudinal aquifer dispersivity; v_a = average groundwater velocity; t = flow time; r = radial distance from injection to pumping well; D_L = longitudinal dispersion coefficient = $a_L * v_a$.

Fitting of measured and calculated breakthrough curves varying the input parameters allowed for the calculation of average groundwater velocity and aquifer dispersivity as well as an estimation of the effective porosity. Assuming breakthrough curves with more than one concentration peak to be a superimposition of tracer spreading on different flow paths, modeling of these breakthrough curves could be performed calculating a superimposition of up to three independent layers within one aquifer (see figures 1-3). Each layer is characterized by a specific dispersivity and a specific average groundwater velocity.

6 INTERPRETATION

6.1 *First/second aquifer*

The registered tracer signals from different injection wells located around the pumping well proved a clear anisotropy of the hydraulic characteristics. The results show a dominating groundwater flow direction towards the NE with an average groundwater velocity of 1.4 - 4 m/d and a longitudinal dispersivity in the range of 5 to 10 m. In contrast to that the average groundwater velocity calculated from tracer injections NNE of the pumping wells is less than 0.5 m/d and shows a longitudinal dispersivity in the order of 1 m. In addition no signals were registered from tracer substances injected into wells located N and NW at a distance of less than 30 m from the pumping wells. Due to a strong anisotropy of the hydraulic properties a well defined anisotropy of the capture area is obvious. The hydraulic anisotropy is also confirmed by the strong elliptical shape of the depression cone in the NE direction. The values calculated, especially longitudinal dispersivity and average groundwater velocity, hint at an aquifer with mixed properties. Fluid flow seems to occur through both the porous medium and through rock fractures.

Another important conclusion of the tracer test in the first/second aquifer is drawn from the observed travel times and recovery rates of Uranine and Sulforhodamine B compared to those of other tracers injected in analogous directions from the pumped wells. Whereas the average groundwater velocity from the other tracers is in the range of about 1–2 m/d, results of less than 0.4 m/d were calculated from Sulforhodamine B. Due to increasing tracer concentrations until the end of the test, the average groundwater velocity could not be calculated for Uranine. Both tracers are assumed not to be conservative but to some extent reactive tracers. That means both tracers are affected by significant reactions especially with organic contaminants found in the aquifer in residual concentrations. The travel times observed therefore are thought to be characterised by adsorption and chemical reactions with organic contaminants such as PAH and phenols. Though these substances did not significantly interfere the analytical methods of tracer detection, they are assumed to be responsible for a significant retardation of the fluorescent tracers Uranine and Sulforhodamine B. Travel times of these tracers in this case are not representative for the average groundwater velocity. As a consequence salt tracers are thought to be the best tracers to investigate aquifers with significant organic contamination.

6.2 *Third aquifer*

The average groundwater velocity calculated from all tracer substances injected is up to 10 m/d, the longitudinal dispersivity is in the order of 10 – 50 m. As regards the longitudinal dispersivity and the depression cone received from the pumping test a strong anisotropy of the hydraulic characteristics is also obvious. In the third aquifer, the depression cone also has an elliptical shape in the NE direction too. In contrast to that the calculated average ground water velocity received from the tracer substances injected does not depend on the flow direction.

Results obtained for the third aquifer are significantly different from the results of the first/second aquifer and allow for the identification of a distinct aquifer type. The high longitudinal dispersivity and average groundwater velocity calculated for this aquifer represent typical values for a fractured rock aquifer with an exclusively fluid flow within the fracture system. Though not proved by the tracer test in the third aquifer, the anisotropy of hydraulic characteristics observed in both aquifers indicates to a fracture system with a main direction towards the NE. This conclusion suits very well with the spreading of the contaminant plume previously observed.

6.3 *Vertical leakage*

Bromide tracer, injected into the third aquifer, and recovered in the pumped wells of the first/second aquifer is a clear proof of vertical ground water flow. As an important result of the tracer test, the layers of clay and siltstones, although representing an effective hydraulic separation of the two aquifers, do still allow for significant vertical leakage of contaminants.

7 SUMMARY

Interpretation of pumping test and tracer test data allowed for the evaluation of capture areas of discharge wells as well as important hydraulic parameters such as hydraulic dispersivity, hydraulic conductivity and anisotropy. In addition vertical ground water flow from the first/second aquifer to the third aquifer was identified. These parameters provided a basis for further groundwater modeling studies. With the numerical groundwater model calculations of pollution spreading were performed and the model calculations helped to optimize the location and necessary discharge rates of future discharge wells as part of hydraulic remediation measures. Due to the strong anisotropy of the capture area the total contaminated area is not contained by the pumping wells used for the tracer test, which was evident measuring tracer substances in down gradient observation wells too. As a result the remediation wells were placed at other sites than previously planned.

Simulation of Subsurface Storage and Recovery of Effluent Using Multiple Wells, St. Petersburg, Florida

By Dann K. Yobbi

Abstract

The potential for subsurface storage and recovery, otherwise called aquifer storage and recovery, of effluent in the uppermost producing zone of the Upper Floridan aquifer in St. Petersburg, Florida, was studied by the U.S. Geological Survey, in cooperation with the city of St. Petersburg and the Southwest Florida Water Management District. The success of subsurface storage and recovery depends on the recovery efficiency, or the quantity of water, relative to the quantity injected, that can be recovered before the water that is withdrawn fails to meet salinity limits. The viability of this practice will depend upon the ability of the injected zone to receive, store, and discharge the injected fluid.

A three-dimensional numerical model of ground-water flow and solute transport, incorporating available data on aquifer properties and water quality, was developed to evaluate the effects of changing various operational factors on recovery efficiency. The reference case for testing was a base model considered representative of the aquifer system underlying the Southwest St. Petersburg Water Treatment Facility. The base simulation used as a standard for comparison consisted of a single cycle of 90 days of simultaneous injection of effluent in three wells at a rate of 4.0 million gallons per day and then equal rate withdrawal of 4.0 million gallons per day until the pumped water in each well reached a dissolved-solids concentration of 1,500 milligrams per liter. A recovery efficiency of 14.8 percent was estimated for the base simulation. Ten successive injection and recovery cycles increased recovery efficiency to about 56 percent. Based on model simulations for hypothetical conditions, recovery efficiency (1) increased with successive injection and recovery cycles; (2) increased when the volume of injectant increased; (3) decreased when storage time increased; (4) did not change significantly when the injection rate or recovery rate increased, or when the ratio of recovery rate to injection rate increased, and (5) was not significantly affected by any particular geometric arrangement of wells or by the number of wells when the volume of water injected remained constant. Recovery efficiency from multiple wells was nearly the same as from a single well. Recovery efficiency ranged from about 7 to 56 percent, in several tests.

Sensitivity of recovery efficiency to variations in selected parameters such as dissolved-solids concentration of the injection zone, permeability, vertical anisotropy, longitudinal and transverse dispersivities, and effective porosity was tested. Changes in the dissolved-solids concentration of the injection zone produced the greatest change in recovery efficiency. Uniform changes in dispersivity values produced the second greatest change in recovery efficiency. Generally, recovery efficiency increased when the above parameter values were decreased and recovery efficiency decreased when these parameter values were increased.

Density difference between native and injected waters was the most important factor

affecting recovery efficiency in this study. For the base simulation, sensitivity tests indicated that recovery efficiency increased from about 15 to 78 percent when the dissolved-solids concentration of the native water decreased from about 7,800 to 500 milligrams per liter.

Dispersivity is another important factor affecting recovery efficiency. For the base simulation, sensitivity tests indicated that recovery efficiencies from about 9 to 24 percent can be obtained for different dispersivity values. A field determination of dispersivity was not made as part of this study, and values used may not be representative of the actual dispersive characteristics of the aquifer system at the study site. However, dispersivity values tested are within the range of values used in previous studies.

INTRODUCTION

The city of St. Petersburg owns and operates one of the largest urban reclaimed water reuse systems in the world. In 1995, approximately 21 Mgal/d of advanced secondary-treatment plant effluent was piped from the city's four water reclamation facilities (WRF's) through a 260-mi irrigation system to water residential, recreational, and commercial properties.

Demand for reclaimed water is seasonal. There is a deficiency of effluent for irrigation in the dry months (generally fall and spring) and an excess in the wet months (generally summer and winter). The excess is disposed of through deep underground injection wells into the lowermost zones of the Upper Floridan aquifer (a highly-fractured dolomite zone saturated with saltwater). The injected water from these deep permeable zones cannot be effectively recovered because of excess mixing occurring in the disposal zone (Hickey and Ehrlich, 1984).

Developing alternate methods for augmenting water supplies is a major priority for water managers. For this reason, the U.S. Geological Survey (USGS), in cooperation with the city of St. Petersburg and the Southwest Florida Water Management District (SWFWMD), began a study in 1994 to assess the feasibility of subsurface storage and recovery (SSR), otherwise known as aquifer storage and recovery, of effluent in a shallow, moderately transmissive limestone aquifer underlying St. Petersburg that is slightly to moderately saline.

The objective of this study was to provide an assessment of the potential for SSR in St. Petersburg. The study included two phases:

(1) development and testing of a prototype cylindrical numerical model to assess the recovery efficiency for injected water of a typical single well system in St. Petersburg; and,

(2) development and testing of a three-dimensional numerical model to assess the recovery efficiency for injected water using multiple wells at one of the four St. Petersburg's WRF's.

The phase 1 single-well cylindrical model was described by Yobbi (1996). That model was devised to evaluate recovery of injected water at a typical SSR well and to assess the relation between recovery efficiency and uncertainties in values of physical properties and operational variables. For practical ranges of hydraulic and fluid properties in the study area, the model analysis indicated that (1) the greater the density contrast between injected and resident formation water, the lower the recovery efficiency, (2) recovery efficiency decreased significantly as dispersion increased, (3) high permeability produced low recovery efficiencies, and (4) recovery efficiency increased as anisotropy increased and as porosity decreased. The recovery efficiency ranged from about 4 to 76 percent in several hypothetical tests performed with the single-well cylindrical model.

An implementation of SSR would probably require more than one well to handle the required inflow rates and wellhead pressures. Operational field tests of this size are generally too expensive for preliminary assessments. Modeling is a cost-effective approach for preliminary evaluation of the feasibility of SSR since many combinations of conditions can be investigated with relatively inexpensive computer simulations.

Purpose and Scope

This report presents the results of the development of the phase 2, three-dimensional numerical model and the results of an assessment of the potential for SSR using multiple wells at the Southwest St. Petersburg WRF. Specifically, the model was used as a simulation tool to assess: (1) recovery efficiencies for injected water for multiple-well configurations,

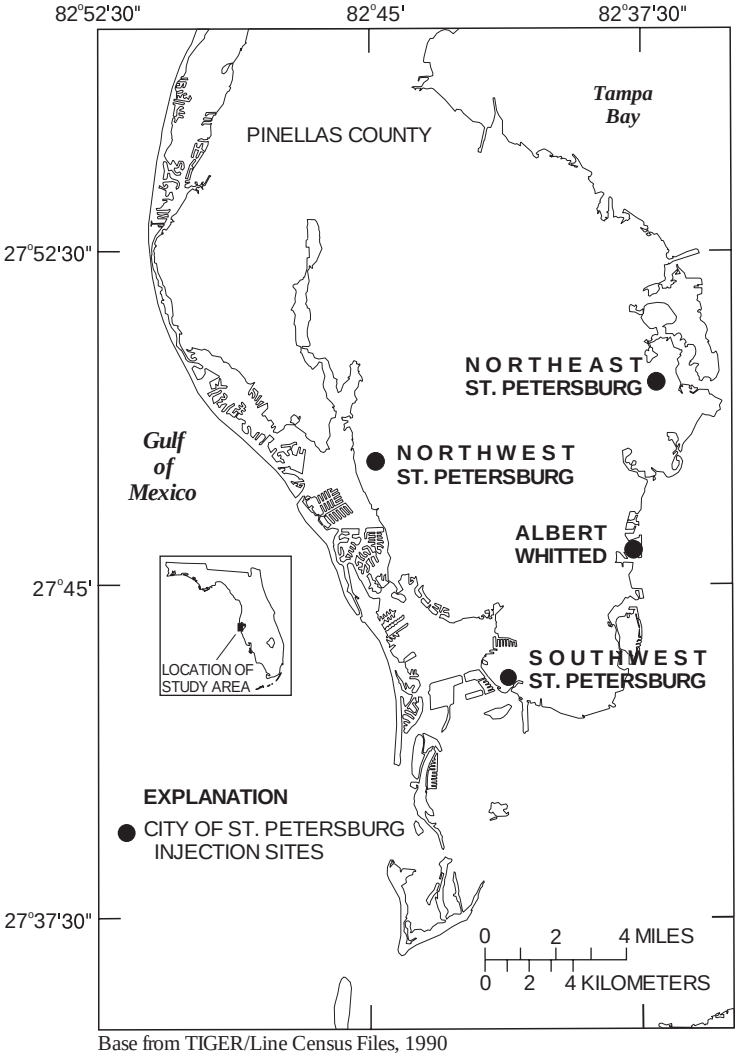
injection and recovery rates, volumes of injected water, injection/recovery ratios, length of storage times and background hydraulic gradients, and repeated cycles, and (2) the relation between recovery efficiency and the uncertainty in values for physical properties. This report also presents numerical analysis of hydraulic properties using the model. Data were obtained from published reports and from files of the USGS.

A finite-difference model, HST3D (Kipp, 1987, as modified), for simulating heat and solute transport in three dimensions was used for the simulations. The model is used to simulate a hypothetical injection and recovery operation at the Southwest St. Petersburg WRF. Approximately 75 simulations were run and recovery efficiencies were calculated for various SSR tests. Hydrologic properties of the aquifer system also were estimated using numerical simulation of data collected during a previous study at the Southwest St. Petersburg WRF.

Description of Study Site

The Southwest St. Petersburg WRF is located in southern Pinellas County, Florida (fig. 1). The study site is underlain by a thick sequence of honeycombed and fractured limestone and dolomite of Tertiary age overlain by a sequence of clastic deposits. Land altitudes range from about 6 to 10 ft above mean sea level.

Rainfall in the area averages about 53 in/yr, of which about 34 in. falls during the 5-month period May through September. August is the wettest month and April is the driest. The mean annual temperature



Base from TIGER/Line Census Files, 1990

Standard parallels 29° 30' and 45° 30', central meridian -83° 00'

Figure 1. Location of study area and the city of St. Petersburg injection sites.

is about 74 °F, and monthly means range from about 83 °F in August to about 62 °F in January (National Oceanic and Atmospheric Administration, 1995).

Three deep injection wells comprise the injection system at the Southwest St. Petersburg WRF. The injection zone at the site is within the most productive of the identified permeable zones, with a transmissivity of about 1,200,000 ft^2/d, and about 1,000 ft below land surface. The injection wells were put into continuous operation in 1979 and were designed to accept about 15.2 Mgal/d each of highly treated wastewater. In 1995, the wells were permitted for 9 Mgal/d each.

Subsurface Storage and Recovery Concept

Subsurface storage and recovery is a strategy of water-supply augmentation by which effluent is injected underground, by one or more wells, for storage during wet periods when demand is low, and then recovered later for water use during dry periods when demand is high. SSR is especially appropriate for areas like St. Petersburg where there is (1) seasonal variation in reclaimed water and demand, and (2) a moderately permeable aquifer near land surface that contains water of low to moderate salinity.

The feasibility of a SSR system depends upon the ability of the injected zone to receive, store, and discharge the injected effluent. Recovery of the stored effluent is dependent upon the effective emplacement of a relatively stable, thick lens of low-density effluent during the injection phase. To form this lens, enough effluent must be injected to displace a large volume of saline water; the mixing of the effluent and native waters must not be significant; and confinement must be sufficiently tight to prevent rapid vertical migration of the less dense effluent (Rosenshein and Hickey, 1977). The lens of effluent formed must have sufficient aerial extent and thickness to be tapped by a system of recovery wells.

The success of a SSR system is measured by the quantity of water that can be recovered relative to the quantity injected, or the recovery efficiency. Recovery efficiency, usually expressed as a percentage per cycle of injection, storage, and recovery, is defined as the quantity of water, relative to the quantity injected, that can be recovered before the water that is withdrawn fails to meet some prescribed salinity standard. In this report, the standard is a dissolved-solids (DS) concentration of 1,500 mg/L (about 600 mg/L chloride).

Throughout this report, statements are made concerning the salinity of water. The terminology used to describe the salinity is modified slightly from a USGS-classification system of water based on dissolved solids (Heath, 1989, table 2, p. 65), as follows:

Classification	Dissolved-solids concentration (mg/L)	Percent seawater
Freshwater	<500	<1.5
Slightly saline (brackish water)	500 to 3,000	1.5 to 8.6
Moderately saline (brackish water)	3,000 to 10,000	8.6 to 29
Very saline (saltwater)	10,000 to 35,000	29 to 100
Briny	>35,000	>100

Freshwater meets the DS concentration limit for potable water. Slightly saline water is generally nonpotable, but it may be suitable for irrigation. Moderately saline water is suitable for desalinization plant feed, and very saline water and briny water are considered unusable.

Factors Affecting Recovery Efficiency

Two primary physical processes affect the recoverability of the injected water: (1) mixing by molecular diffusion and hydrodynamic dispersion, and (2) density stratification. Unfavorable physical and solute properties of the aquifer system also can reduce the recoverability of injected water.

When two fluids of different composition are in contact, a transfer of molecules occurs. As time passes, the random movement of molecules creates a mixed zone where the two fluids have diffused into one another (molecular diffusion). When one fluid miscibly displaces another fluid in a porous medium, the mixed zone will be greater than that formed due to molecular diffusion alone. The additional mixing, primarily dependent on pore geometry, results from variations in the velocity field and the constant intermingling of flow paths as displacement progresses. This additional mixing, known as mechanical dispersion, occurs both longitudinally (in the direction of gross fluid movement) and transversely (in the direction normal to the gross fluid movement). Mechanical dispersion is caused by mixing of solutes due to variations in fluid velocities

resulting from local differences in hydraulic conductivity (Skibitzke and Robinson, 1963, p. B3). At the relatively large fluid velocities during injection and recovery cycles, the effects of mechanical dispersion are generally greater than those of molecular diffusion.

Density stratification describes the tendency for a lighter fluid to rise above a denser fluid. When fluids of unequal densities are in contact in a porous medium, gravity causes the less dense fluid to rise relative to the more dense fluid. Density stratification is controlled by several factors, including: (1) the density contrast between native and injected waters, (2) permeability of the injection zone, and (3) the thickness of the injection zone (Merritt, 1985). Stratification in porous media can be separated into two cases, static and dynamic (Kimbler and others, 1975). The static case involves no bulk flow of fluids except that arising from convective currents attributable to gravity. Dynamic stratification occurs in the presence of bulk flow of fluids caused by the displacement of a native fluid by an injected fluid of different density.

HYDROGEOLOGIC FRAMEWORK

The hydrogeology of the St. Petersburg area has been described by Hickey (1982). The hydrogeologic units beneath St. Petersburg consist of a thick sequence of carbonate rock overlain by clastic deposits (fig. 2). The upper 1,100 ft includes the unconfined, surficial aquifer and the confined, Upper Floridan aquifer (UFA). The units are separated by the intermediate confining unit (ICU).

The surficial aquifer is the uppermost water-bearing formation and consists of sand and shell of Pleistocene age. The surficial aquifer underlying the study area is about 85 ft thick. The aquifer is a source of recharge to the Upper Floridan aquifer and is mainly used as a source of water for lawn irrigation in St. Petersburg.

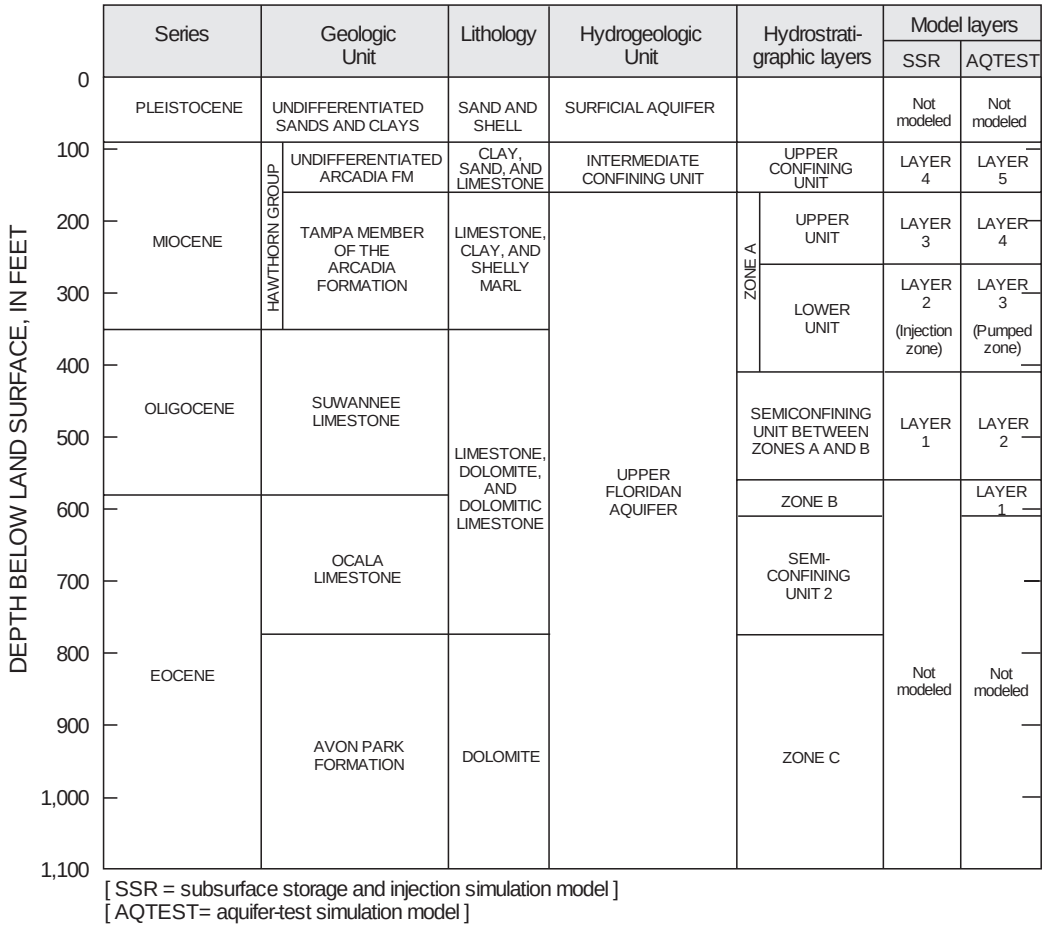

Figure 2. Generalized stratigraphic and hydrogeologic section, St. Petersburg, Florida. (Modified from Hickey, 1982.)

The low-permeable ICU lies between the surficial aquifer and the UFA. The unit coincides with the undifferentiated Arcadia Formation of the Hawthorn Group and at the study site consists of clay, sand, shell, and some limestone (Black, Crow and Eidsness, 1978). The ICU at the study site occurs at about 85 ft below land surface and is about 75 ft thick. Vertical hydraulic conductivities of the ICU range from about 3×10^{-3} to 7×10^{-5} ft/d, and average about 8×10^{-4} ft/d, as reported by Sinclair (1974). Vertical hydraulic conductivity of the ICU at the study site determined from laboratory tests is 6.9×10^{3} ft/d, as reported by Black, Crow and Eidsness (1978).

The UFA is a thick, regionally extensive sequence of limestone and dolomite. The upper part consists of, in ascending order, the Avon Park Formation, Ocala Limestone, Suwannee Limestone, and the Tampa Member of the Arcadia Formation of the Hawthorn Group. Identification of three permeable zones separated by two semiconfining beds within the UFA have been listed by Hickey (1982) and include permeable zones alphabetically labeled with increasing depth from A to C. The upper part of zone A is utilized on a limited basis for irrigation and municipal water supply and zone C is used as a repository for injected treated effluent. Zones B and C contain very saline water throughout southern Pinellas County and are not utilized for any supply purposes.

Zone A is the shallowest and freshest of the producing zones and is the most promising potential receiving zone for SSR in St. Petersburg. This zone comprises the Tampa Member of the Arcadia Formation of the Hawthorn Group and the upper part of the Suwannee Limestone. Zone A occurs at about 160 ft below land surface and is about 250 ft thick at the study site. Data collected during drilling, aquifer testing, and geophysical logging indicate that zone A contains two different permeability units. The upper 100 ft of zone A is a poorly-transmissive sequence of interbedded limestone, clay, and shelly marl. The lower 150 ft of zone A is a moderately-transmissive limestone (Black, Crow, and Eidsness, 1978). Transmissivity of zone A determined analytically from data collected from an aquifer test conducted at the study site is 29,000 ft^2/d (Hickey, 1982). The estimated storage coefficient of zone A (calculated from compressibility of cores and an estimated thickness of 250 ft) is 7.75×10^{-4} based on a specific storage value of 3.1×10^{-6}.

Underlying zone A is the first of a series of poorly transmissive carbonate rocks that act as semiconfining units that separate the permeable zones (Hickey, 1982). The semiconfining unit below zone A (SCU A/B) is part of the Suwannee Limestone. Thickness of the semiconfining unit at the study site is about 150 ft. The leakance coefficient of this semiconfining unit interpreted from the zone A aquifer test is 2.9×10^{-3} d^{-1} (Hickey, 1982).

Permeable zone B is composed of dolomite, dolomitic limestone, and limestone and includes the lower part of the Suwannee Limestone and the upper part of the Ocala Limestone. Zone B at the study site occurs at about 560 ft below sea level and is about 60 ft thick. The transmissivity, determined from specific capacity tests conducted on wells completed in zone B, is 5,000 ft^2/d (Hickey, 1982).

Underlying zone B is the Ocala Limestone that acts as a semiconfining unit. This semiconfining unit at the study site occurs at about 620 ft below sea level and is about 160 ft thick. Cores from this semiconfining unit indicate that the beds have closed fractures; consequently, the unit retards the vertical movement of water between zones B and C (Hickey, 1982). Calculated vertical hydraulic conductivities range from 0.1 to 1 ft/d (Hickey, 1982).

Permeable zone C is the present repository for injected effluent. The zone is composed of dolomite, dolomitic limestone, and limestone and includes the upper part of the Avon Park Formation (Hickey, 1982). Zone C is about 320 ft thick and occurs at about 780 ft below sea level. Zone C contains the most productive water-producing intervals within the Floridan aquifer in Pinellas County. The transmissivity of zone C, based on aquifer-test analysis, is 1,200,000 ft^2/d (Hickey, 1982). The storage coefficient, based on aquifer-test analysis, is 3.3×10^{-4} (Hickey, 1982). Effective porosity of zone C, determined from transport-model simulation, is 10 percent (Hickey, 1989).

NUMERICAL ANALYSIS OF HYDRAULIC PROPERTIES

A numerical ground-water flow and solute-transport model was developed to test and refine the conceptualization of the hydrogeologic system underlying the Southwest St. Petersburg WRF. Data from Hickey (1982) and interpretation of geophysical logs

and aquifer-test data were used to define the hydrostratigraphic units and to provide initial model input. The USGS computer code HST3D (Kipp, 1987, as modified) was applied using a cylindrical coordinate system. Backward-in-space and backward-in-time finite-difference equations were used in the numerical model. A brief discussion of the model is included in a subsequent section of this report.

Data were obtained from the aquifer test performed during the period of March 28 to April 1, 1977 (Hickey and Spechler, 1979) for three observation wells (B-9, B-5, and B-4, in fig. 3). A constant flow rate of 650 gal/min was maintained during the test. Results of the aquifer test indicate that water levels in well B-9 (zone A upper unit) began to decline 60 minutes after pumping of well B-8 began and the decline in water level after 3.45 days of pumping was 1.64 ft. Water levels in well B-5 (zone A lower unit) began to decline less than one minute after pumping began and drawdown in well B-5 after 3.45 days of pumping was 1.65 ft. Water levels in well B-4 (SCU A/B) began to decline 10 minutes after pumping began and the decline after 3.45 days was 1.04 ft. The delayed response in water-level drawdown in wells B-9 and B-4 and the presence of low permeable units in the depth intervals 95-250 ft and 396-520 ft indicate the existence of semiconfining beds between producing zones (Black, Crow and Eidsness, 1978).

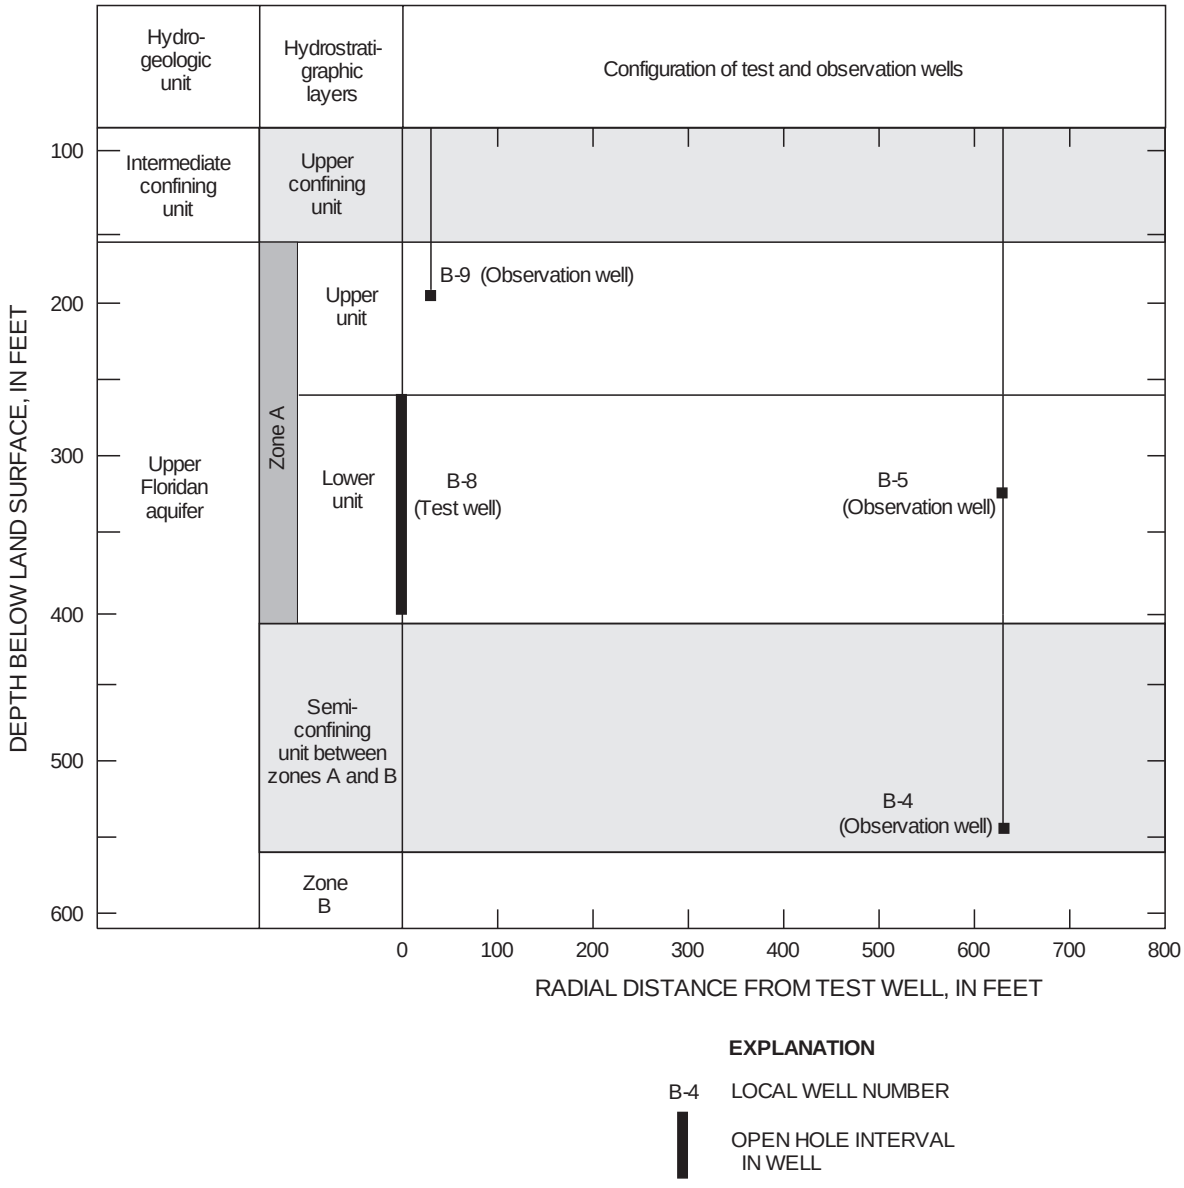

Figure 3. Generalized hydrogeologic section and configuration of test and observation wells.

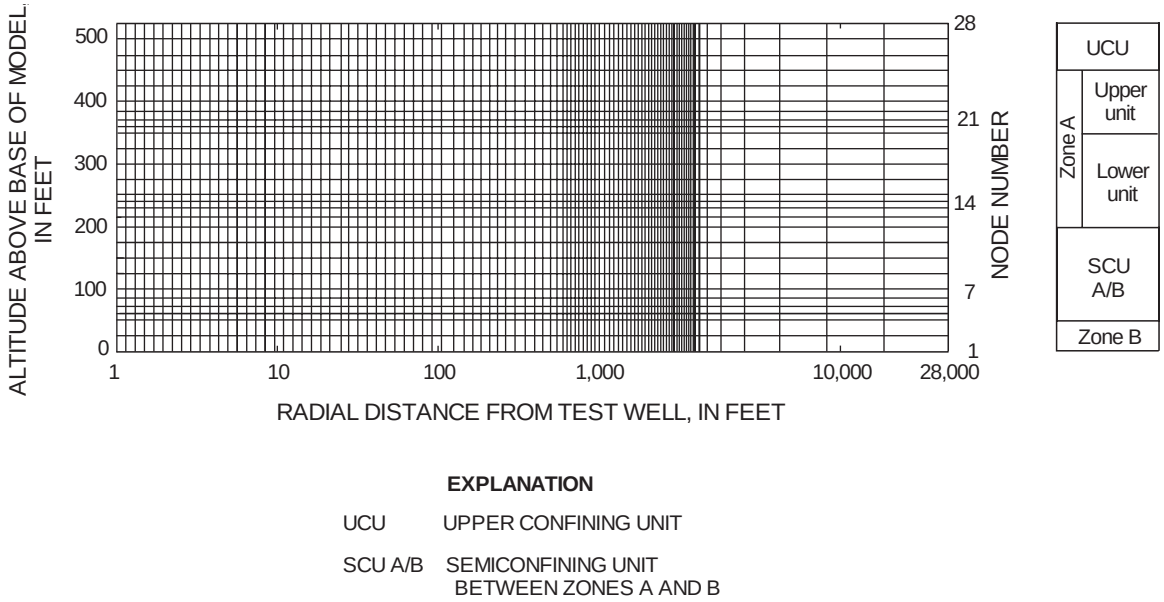

Figure 4. Cylindrical-model grid used for the simulation of hydraulic properties of the aquifer system at the Southwest St. Petersburg Water Reclamation Facility.

Model Grid and Boundary Conditions

The conceptual model consists of five layers including, from top to bottom, the upper confining unit, zone A upper unit, zone A lower unit, SCU A/B, and zone B. The model consists of 28 variable-width node spacings in the vertical direction and 97 variable-width node spacings in the radial direction (fig. 4). The model dimensions represent 28,000 ft horizontally and 675 ft vertically. The vertical spacing ranges from 10 to 25 ft. The radial grid spacings out to a distance of 105 ft present a very gradual logarithmic expansion from 0.14 ft at the well up to a maximum of 13.5 ft. With the exception of several radial grid spacings adjusted to fit the location of monitor wells, the radial dimensions of the grid from a distance of 105 ft to 2,500 ft show a constant spacing of 50 ft. The radial dimensions from a distance of 2,500 to the edge of the grid at 28,000 ft show an expansion from 100 ft to 12,800 ft.

A no-flow boundary condition was assumed at the top, bottom, outer radial edge, and the cased interval above and below the modeled withdrawal well. The no-flow boundary at the bottom of the model was deemed reasonable, because permeability is very low below the lower layer. The no-flow bounday at the top of the model was deemed reasonable, because of the distance from the withdrawal source and, because the intermediate confining bed has a hydraulic conductivity that is three orders of magnitude less than the overlying permeable zone. The outer radial edge boundary was intentionally located far from the withdrawal source to prevent any effect that it may have on determination of pressures in the aquifer segment affected by the withdrawal. One advantage of setting this type of boundary condition (no flow at the top, bottom, and outer edge) is that it restricts model computations to effects caused by withdrawal within a confined radially symmetrical cylinder and approximates the major flow processes during withdrawal. Both the pressure and concentration equations in the model were solved during the simulations, but only the pressure results were analyzed during calibration. Initial pressures were assumed to be hydrostatic and set on the basis of a column of water having dissolved-solids concentration specified as a function of depth. Initial solute concentrations were set equal to solute concentrations in the native water.

Calibration

Hydraulic properties of the hydrostratigraphic units were estimated from these drawdown data by using the numerical model to match simulated head changes to measured water-level changes in observation wells above, below, and within the pumped zone (zone A lower unit). The calibration focused on obtaining a satisfactory match between observed and

model-generated head change data. The model was calibrated by systematically adjusting:

(1) hydraulic conductivity of the various units.

(2) rock compressibility of the various units.

The time increments used to step through the model runs during calibration were gradually expanded from 1 minute to 0.54 days. A total of 16 time steps were used in the calibration. The total simulated time of pumping was 82.8 hours. The simulated well corresponds to an open hole interval from about 260 to 400 ft below land surface.

Measured drawdowns in observation wells B-4, B-5, and B-9 and the simulated drawdowns at the corresponding model nodes are shown in figure 5. Simulation results indicate that the model matched the measured responses reasonably well.

Late-time data were matched by varying hydraulic conductivity, specified in ft/d. Values of 0.0008, 0.01, 180, 0.04, and 150 ft/d for hydraulic conductivity for the upper confining unit, zone A upper unit, zone A lower unit, SCU A/B, and zone B provided the best match for late-time data.

Early-time data were matched by varying rock compressibility, specified in in^2/lb. This procedure is similar to varying storage coefficient in a hydraulic model because storage coefficient (S) is considered to be a linear function of rock compressibility (C_r) according to the following formulation (Merritt, 1994):

$$S = n\rho b(C_w + C_r) \qquad (1)$$

where: S is storage coefficient (dimensionless);
n is porosity (dimensionless);
ρ is fluid density (lb/ft^3);
b is layer thickness (ft);
C_w is water compressibility (3.03×10^{-6} in^2/lb); and
C_r is rock compressibility (in^2/lb).

Values of 5.5×10^{-5}, 3.4×10^{-5}, 3.4×10^{-6}, 3.4×10^{-6}, and 3.4×10^{-6} in^2/lb for rock compressibility of the intermediate confining unit, zone A upper unit, zone A lower unit, SCU A/B, and zone B, respectively, provide the best match for early-time data.

A vector representation of the flow field generated by the model is shown in figure 6. Flow was nearly lateral in the permeable zones and nearly vertical in the semiconfining units.

Sensitivity Analysis

A sensitivity analysis was done to evaluate the response of the model to changes in input parameters

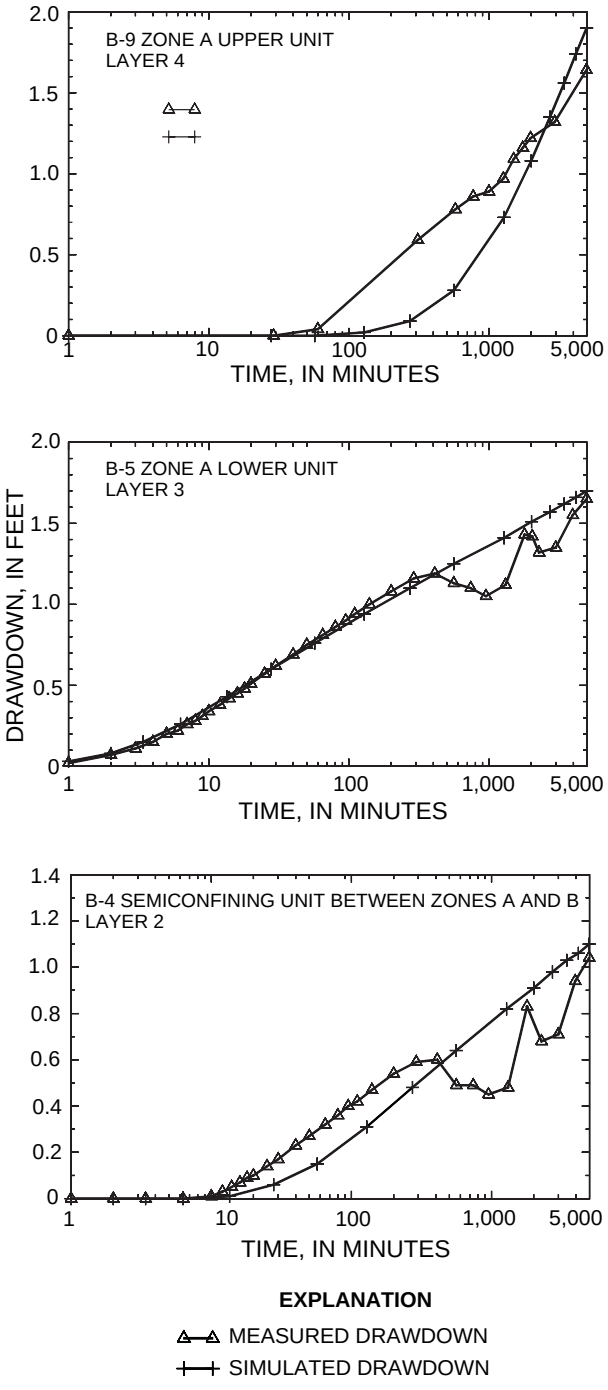

Figure 5. Simulated and observed drawdowns in wells B-9, B-5, and B-4.

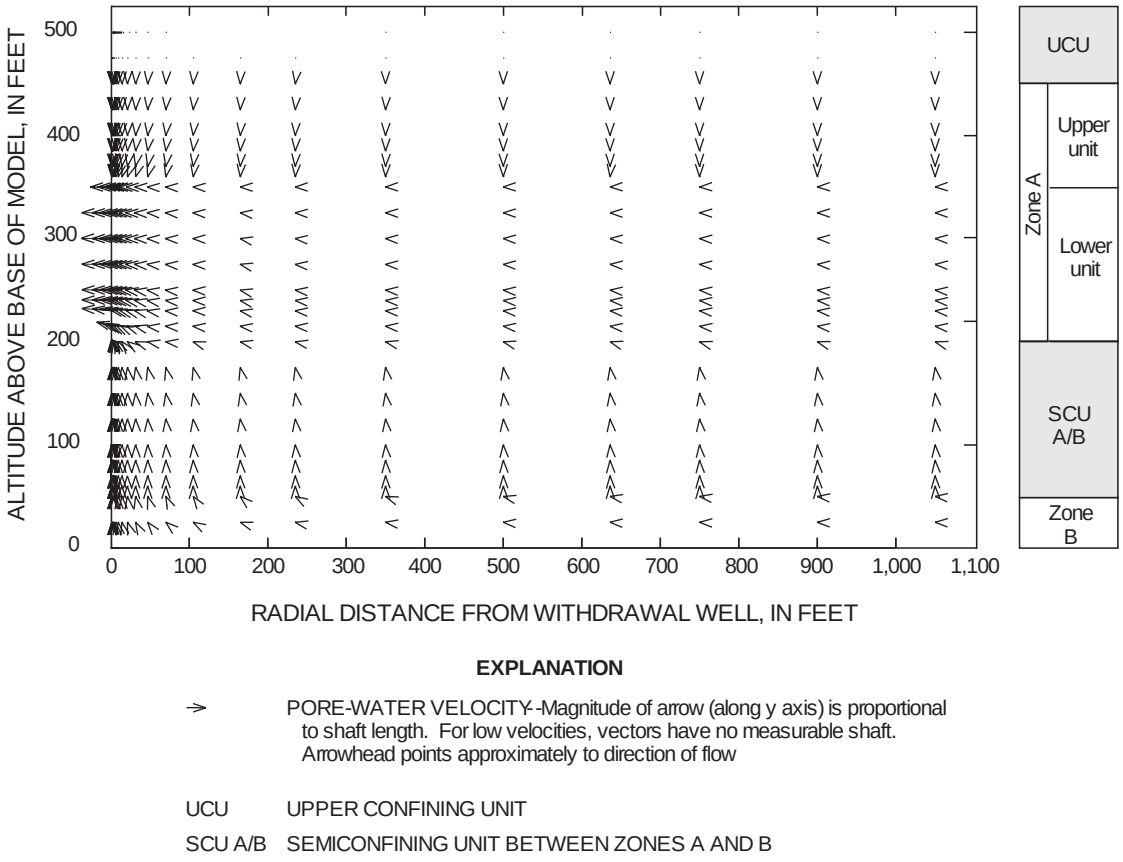

Figure 6. Simulated flow field at the end of the 3.45 day aquifer test.

and to gain an understanding of how much error could result by overestimating or underestimating the parameter values. The sensitivity analysis consisted of uniformly increasing or decreasing values of one model input parameter while others remained at calibration levels, then noting the change in drawdown as a result of the change. Hydraulic conductivity and compressibility of layers 2, 3, and 4 were increased and decreased by a factor of 10. The computed drawdowns are shown in figures 7 and 8. The tests show substantial variation from observed and simulated drawdowns at both early and late times for most of the changes.

Hydraulic Conductivity

Results of the sensitivity analysis indicate that changes in hydraulic conductivity of layer 3 (pumped zone) produced the greatest change in water levels. Generally, small changes in simulated drawdown occur when hydraulic conductivity values are increased while substantial changes in simulated drawdown occur when hydraulic conductivity values are decreased.

If layer 2 (SCU A/B) had a much higher hydraulic conductivity than the calibrated values, hydraulic response to pumping from layer 3 would be greater than otherwise would be observed in wells B-4 and B-5 and would be smaller than otherwise would be observed in well B-9. Maximum drawdown in wells B-4 and B-9 would be about 0.3 and 0.2 ft, respectively, more than observed drawdown, and maximum drawdown in well B-5 would be about 0.1 ft less than observed drawdown.

If layer 3 (zone A lower unit) had a much higher hydraulic conductivity, water-level changes would occur much slower than observed. Hydraulic response to pumping from layer 3 in each well would be considerably more sluggish compared to the observed response. Maximum drawdowns only would be about 0.3 ft in each well, compared to 1.10, 1.70, and 1.61 ft for wells B-4, B-5, and B-9, respectively, for the calibration.

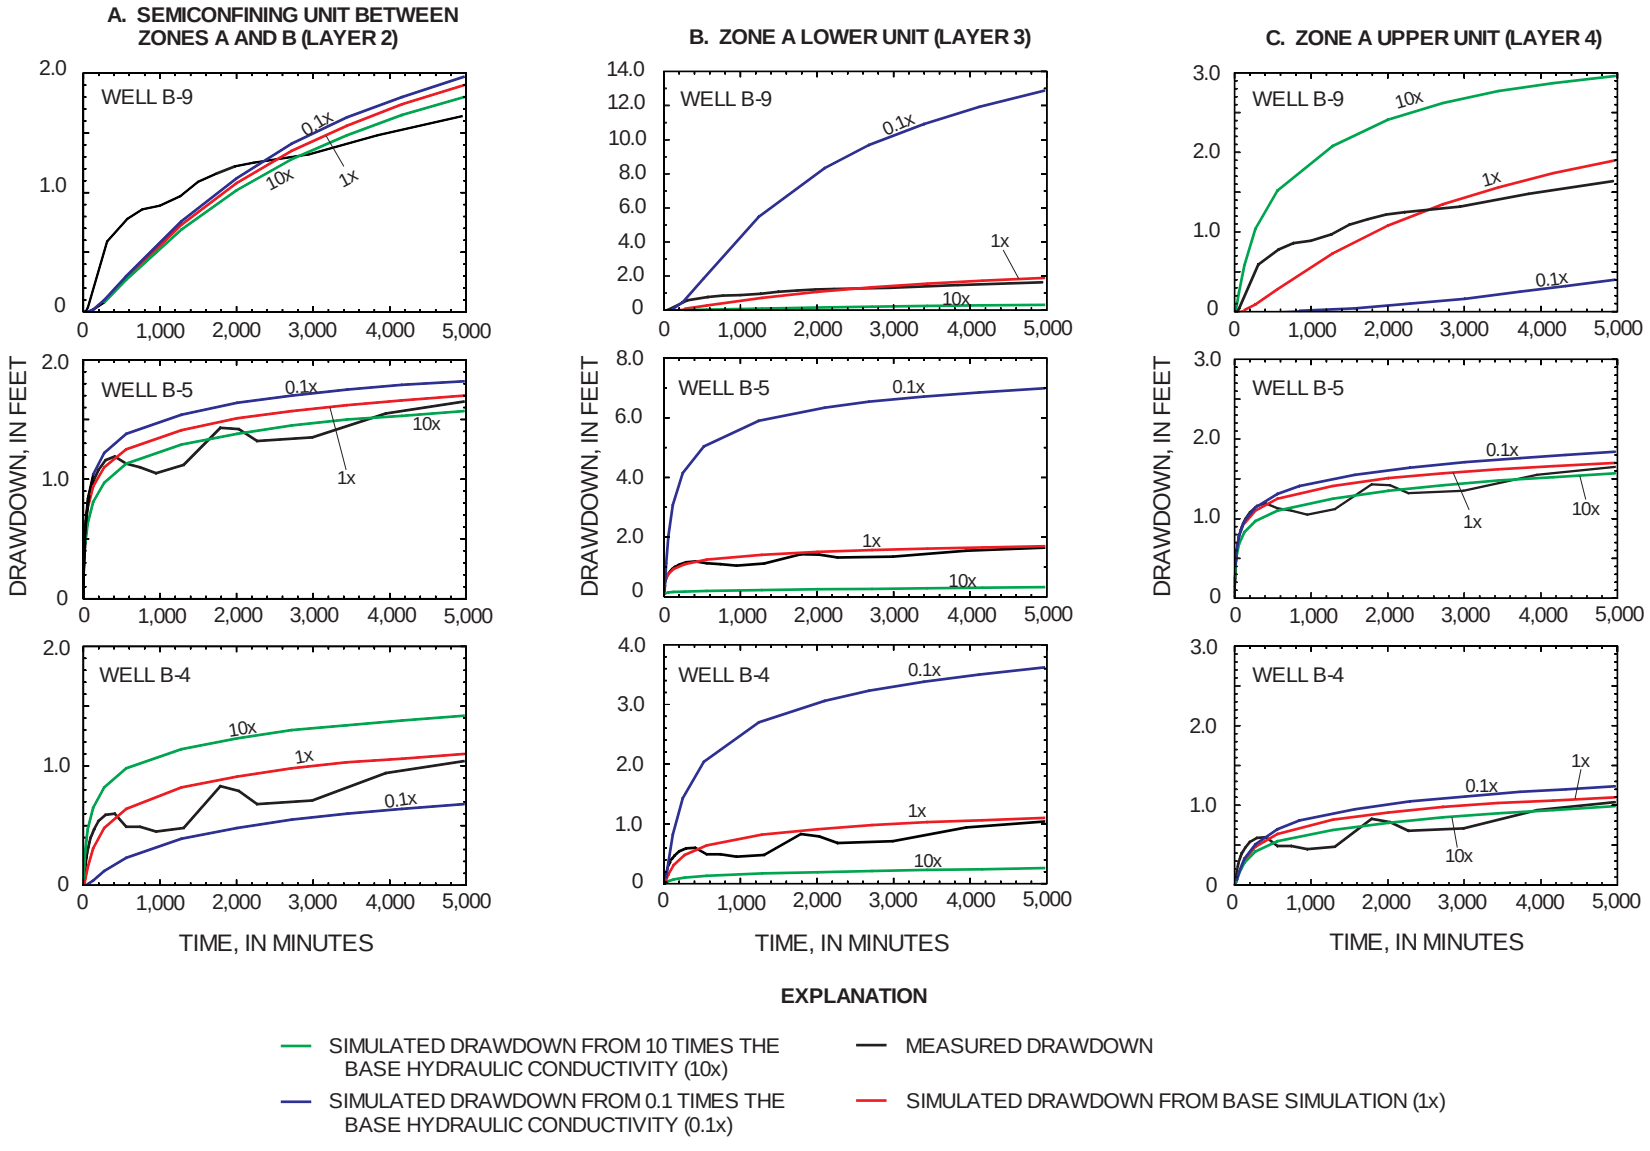

Figure 7. Effects of varying hydraulic conductivity on the simulated drawdowns in (A) semiconfining unit between zones A and B, (B) zone A lower unit, and (C) zone A upper unit.

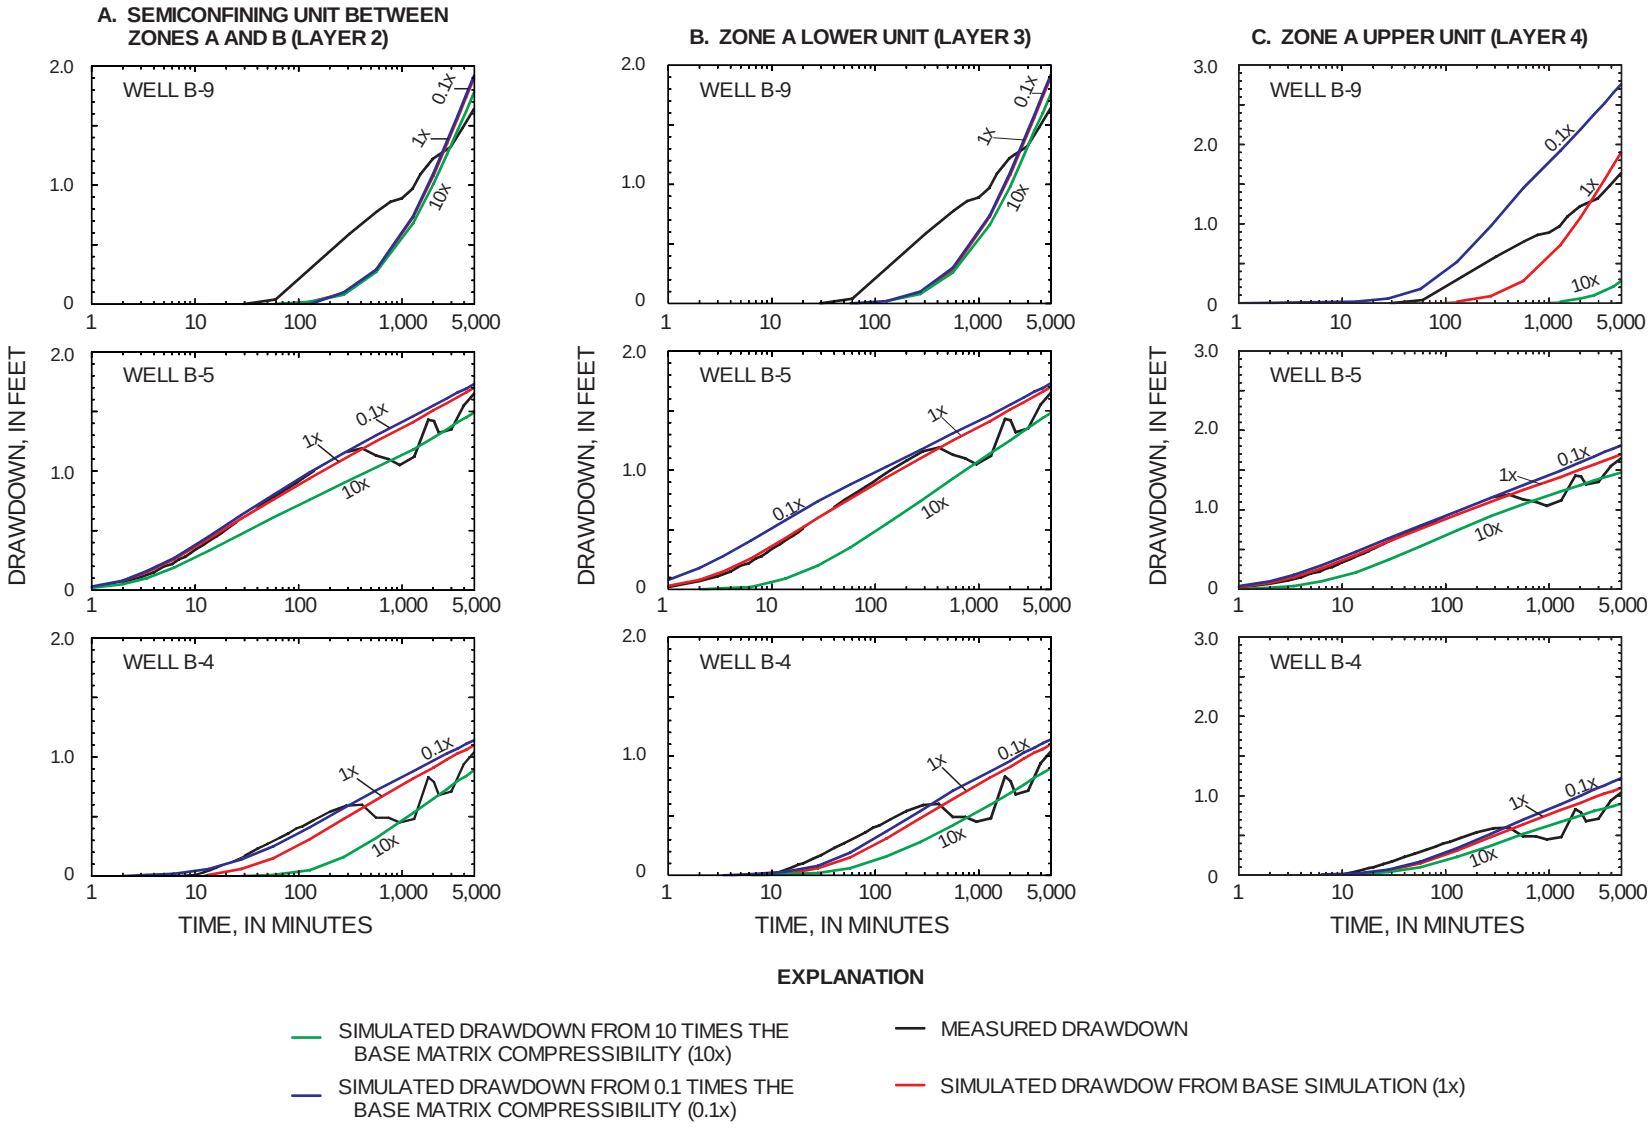

Figure 8. Effects of varying matrix compressibility on the simulated drawdowns in (A) semiconfining unit between zones A and B, (B) zone A lower unit, and (C) zone A upper unit.

If layer 4 (zone A upper unit) had a much higher hydraulic conductiviy, the hydraulic response to pumping from layer 3 would be slightly less than otherwise would be observed in well B-4 and B-5 and much greater than otherwise would be observed in well B-9. Maximum drawdowns in wells B-4 and B-5 would be about 0.1 ft less than observed drawdown in each well, and maximum drawdown in well B-9 would be about 1.3 ft greater than observed drawdown.

A contrasting hydraulic response is observed when much lower hydraulic conductivity values are simulated. A tenfold decrease in hydraulic conductivity of layer 2 would result in a more responsive hydrograph than was observed in wells B-5 and B-9 and a slightly less responsive hydrograph than was observed in well B-4. Maximum drawdowns in wells B-5 and B-9 would be about 0.2 ft higher than observed, and maximum drawdown in well B-9 would be about 0.4 ft lower than observed.

A much lower hydraulic conductivity of layer 3 would result in a considerably more responsive hydrograph than was observed in each well. Maximum drawdowns would be about 2.6, 5.3, and 11.2 ft, respectively, more than was observed in wells B-4, B-5, B-9 and water-level changes would occur much faster than observed.

If layer 4 had a much lower hydraulic conductivity, the hydraulic response to pumping layer 3 would result in a slightly more responsive hydrograph for wells B-4 and B-5, and a significantly less responsive hydrograph for well B-9. Maximum drawdowns in well B-4 and B-5 would be 0.1 ft more than was observed. Maximum drawdown in well B-9 would be about 1.2 ft lower than observed, and water-level changes would occur much slower than observed.

Matrix Compressibility

Compressibility of the limestone for each layer was increased and decreased by one order of magnitude. Substantial disagreement occurred in the early-time range when this value was increased while only slight disagreement occurred in the early-time range when this value was decreased. At later times, observed and simulated data are offset to a degree that seems to change only slightly with increasing time.

If layer 2 had a much higher matrix compressibility, water-level changes would occur much slower than observed in well B-4 and slightly slower in wells B-5 and B-9. If layer 2 had a much lower matrix compressibility, hydraulic response to pumping from layer 3 in each well would be slightly quicker compared to the simulated response.

If layer 3 had a much higher matrix compressibility, water-level changes would occur much slower than observed in wells B-4 and B-5 and only slightly slower in well B-9. If layer 3 had a much lower matrix compressibility, hydraulic response to pumping from layer 3 shows only slight discrepancies with observed data at early times.

If layer 4 had a much higher matrix compressibility, the hydraulic response to pumping layer 3 would result in a significantly less responsive hydrograph than would be observed in well B-9, and only a slightly lower response than would be observed in wells B-4 and B-5. If layer 4 had a much lower matrix compressibility, water-level changes in well B-9 would occur much faster than observed while water-level changes in well B-4 and B-5 would occur only slightly faster than observed.

SIMULATION OF SUBSURFACE STORAGE AND RECOVERY OF EFFLUENT USING MULTIPLE WELLS

A finite-difference three-dimensional variable-density ground-water flow and solute-transport model was used to simulate injection and recovery from a multiwell hypothetical SSR system open to a moderately transmissive, slightly to moderately saline aquifer, underlying the Southwest St. Petersburg WRF. The specific question to be answered is: In what quantitative fashion will operational and physical variables influence recovery efficiency from multiple wells? The recovery efficiency was defined as the volume of water recovered below a dissolved-solids concentration of 1,500 mg/L (about 600 mg/L chloride), divided by the volume injected, and expressed as a percentage.

To answer this question, the USGS model HST3D (Kipp, 1987, as modified) was used to simulate the hypothetical SSR system. The analysis implemented a conceptual modeling approach (Merritt, 1985), rather than a calibration and predictive approach (Merritt, 1994), because no injection and recovery data exist for comparison with model results. This type of analysis permitted many combinations of conditions to be studied. The input values are hydraulic and native chemical characteristics of the aquifer system underlying the Southwest St. Petersburg WRF.

The rate of ground-water flow is assumed to be governed by Darcy's law, which when written in terms of fluid pressure (rather than piezometric head) is:

$$q = -k (\nabla p + \rho g z) / \mu \quad (2)$$

where,

- q is specific discharge vector (flow rate per unit cross-sectional area) [L/T];
- k is the intrinsic permeability vector of the aquifer materials [L^2];
- ∇ is the gradient operator [1/L];
- p is the fluid pressure [M/LT^2];
- ρ is fluid density [M/L^3];
- g is gravitational acceleration vector [L/T^2];
- z is the unit vector in the vertical direction [dimensionless]; and
- μ is the dynamic viscosity of the fluid [M/LT].

Using Darcy's law and the principle of conservation of fluid mass, the transport of a conservative solute can be written as:

$$\partial (n\rho) / \partial t = -\nabla (\rho q) + Q_p \quad (3)$$

where,

- n is aquifer porosity (dimensionless);
- t is time (T);
- ∇ (ρq) denotes the divergence of the specific discharge mass flux [$M/(TL^3)$]; and
- Q_p is mass of fluid injected (+) or withdrawn (-) per unit time per unit volume of aquifer [$M/(TL^3)$].

Numerical Model

The HST3D model (Kipp, 1987, as modified) is a computer program written in FORTRAN-77 that simulates variable density fluid movement and transport of either dissolved substances or energy in the subsurface. The HST3D version used in this report (version 2.0) is a result of several modifications made after version 1.0. In addition to changes made at the programming level to facilitate the handling of data, the main technical modification that pertains to this study is the usage of a new iterative solver (Kenneth L. Kipp, written communication, 1995). The model, as used here, solves for two interdependent variables; pressure and mass-fractional concentration in Cartesian coordinates under isothermal conditions. Backward-in-space and backward-in-time finite-difference equations are used for solution of ground-water flow and the solute-transport equations in the numerical model. The reader is referred to Kipp's (1987) report for a complete discussion of the model code and numerical methods.

Two changes were made to the HST3D code (version 2.0). The first change was made to simulate the shutdown of the production well when the solute fraction of the withdrawn water reached 0.05769, corresponding to a DS concentration of 1,500 mg/L (about 600 mg/L chloride). The second change to the code was made to suppress the cross-derivative dispersive terms. This change was made to eliminate the nonradial spatial distribution of injectant caused by inaccuracies of the mathematical solution for radial flow in Cartesian coordinates.

Design of Base Model

The base model used as a standard for comparison for subsequent simulations was designed to be representative of the slightly to moderately saline aquifer system underlying the Southwest St. Petersburg WRF. The physical properties of the aquifer system were selected as the best possible representation of the actual field values at the study site. The chemical properties of the aquifer system were estimated values of the native formation waters prior to the start of deep well injection into zone C (about 1977). Initial pressures for the simulation were calculated by the solute-transport model on the basis of the boundaries and properties of the aquifer system.

Several simplifying assumptions are made in the conceptualization and simulation of the flow system:

1. The aquifer system is homogeneous and isotropic in all directions.
2. Hydrostatic conditions initially prevail.
3. A uniform native fluid density exists within each model layer.
4. The water-quality profile is laterally homogeneous throughout the model area.
5. The viscosity of the injected and native fluids is the same.
6. Dispersivity is constant throughout each model layer, and
7. Injection and recovery wells are 100 percent efficient.

Data from the numerical simulation discussed in the previous section were used to define the hydrogeologic system and to provide the basis for estimating the hydraulic characteristics for the aquifer system underlying the Southwest St. Petersburg WRF. The conceptual model consists of four layers representing,

from top to bottom, the upper confining unit, zone A upper unit, zone A lower unit, and the semiconfining unit between zones A and B (fig. 2).

Grid Design

To apply the HST3D model, the hydrologic and hydrogeologic characteristics of the aquifer system underlying the study site was discretized using a Cartesian coordinate system (fig. 9). The model area dimensions are 5,000 by 5,000 horizontal ft and 475 vertical ft. The horizontal grid consists of 31 rows by 31 columns. Grid dimensions range from 100 by 100 ft at the center of the grid to a maximum of 200 by 200 ft at the four corners of the grid. The vertical grid consists of 19 intervals each 25-ft thick (20 equally spaced nodes).

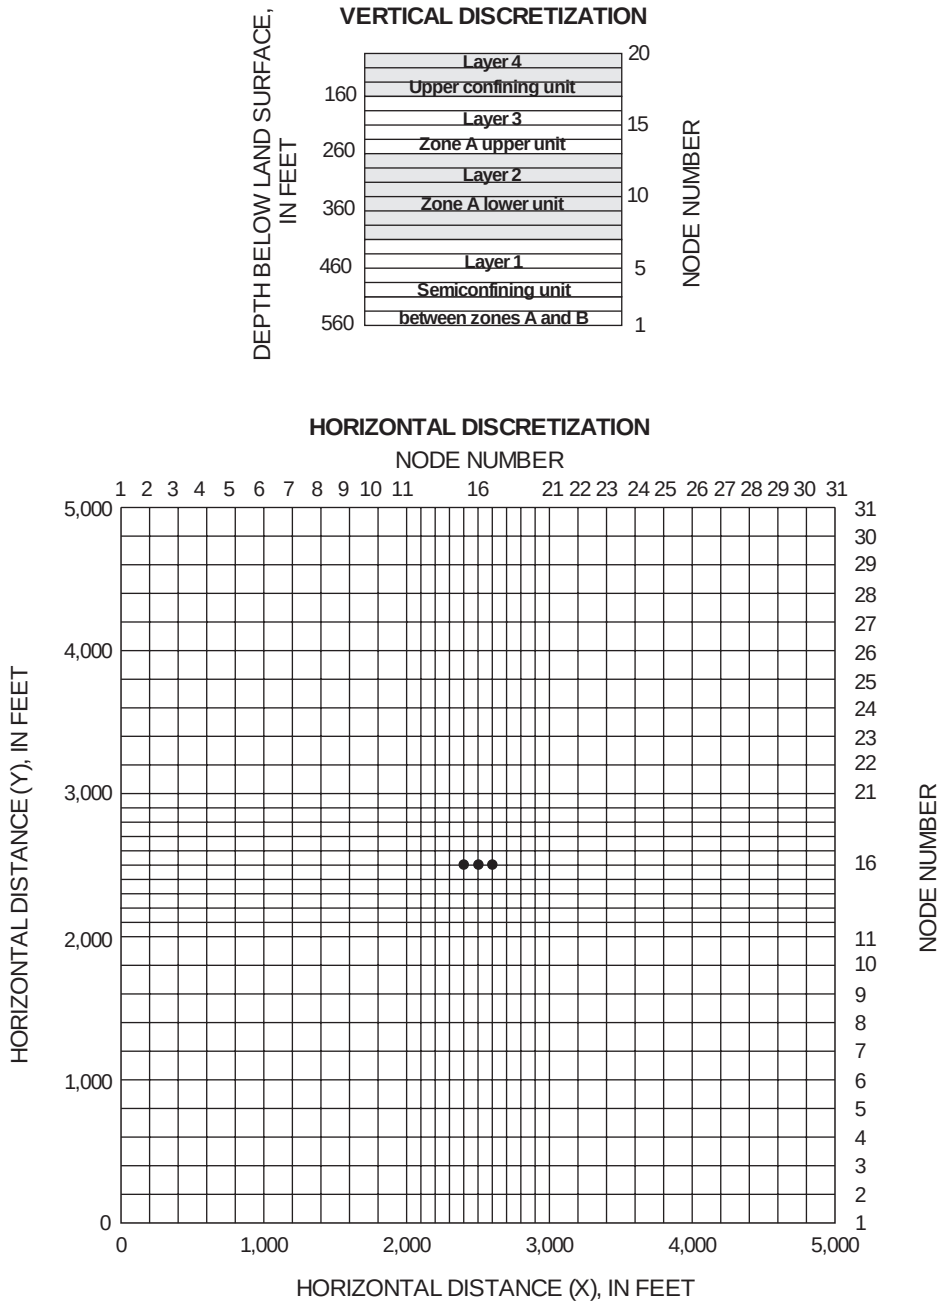

Figure 9. Vertical and horizontal discretization of the model grid used for the simulation of subsurface storage and recovery. (Position of injection/recovery wells used in the base simulation model is indicated by heavy dots.)

Boundary Conditions

Boundary conditions are used to constrain the lateral and vertical extent of the simulated flow system providing a simplified representation of the flow and transport processes at the model limits. The top and bottom boundaries of the model are specified pressure boundaries. The pressures were set equal to the hydrostatic pressures at the specific depths where the boundaries were located. Pressure on the upper boundary is set at 36.760 lb/in^2, equivalent to the pressure exerted from an overlying 85-ft column of freshwater presumed to exist in the overlying surficial aquifer. Pressure on the lower boundary is 243.465 lb/in^2, equivalent to the pressure exerted from a 560-ft column of freshwater and saline water presumed to exist in the overlying formations. One limitation of setting this type of boundary condition is that if injected or mixed water passes across these boundaries, the model would be unable to consider it during the recovery pumping. For this study, this boundary condition yielded the best representation of the actual aquifer and yielded more conservative estimates of recovery efficiency.

The lateral extent of the model is represented by leakage boundaries used to simulate flow into or out of the model at these locations. Representation of leakage-boundary conditions is based on the approach of Prickett and Lonnquist (1971, p. 30-35), which has been generalized to include variable-density and variable-viscosity flow (Kipp, 1987). The leakage-boundary employed in the HST3D code accounts for permeability and thickness of the confining unit, fluid density in the outer aquifer and at the simulation-region boundary, viscosity in the confining layer, and elevation of the simulation-region boundary and the elevation at the top of the confining layer. The reader is referred to Kipp's (1987) report for a complete discussion of this boundary condition.

Fluid Properties

The fluid properties of the native formation waters assumed for the simulations are listed in table 1 and include temperature, viscosity, fluid compressibility, molecular diffusivity, and DS concentration expressed as scaled-solute mass fraction (SSMF). Isothermal conditions at 75 ^oF were assumed to prevail. Fluid densities assigned to injected and native waters were based on the measured or estimated concentrations of DS concentrations in each fluid. Viscosity of the injected and native formation waters vary with temperature and solute fraction. Because isothermal conditions were assumed to prevail and because the viscosity of freshwater and saltwater differ by only 0.06 centipoise, a constant viscosity of 0.8904 centipoise (viscosity of pure water at 75 ^oF) was used. Compressibility of water was held constant at 3.03 x 10^{-6} $(lb/in^2)^{-1}$ (Freeze and Cherry, 1979, p. 52), and molecular diffusivity of the solute in the porous media was set at 9.30 x 10^{-5} ft^2/d (Kimbler and others, 1975). The model SSMF is a term ranging in value from 0 to 1. Any fluids present within or entering the aquifer system in simulation exercises are considered to be a mixture of the two fluids by the appropriate specification of SSMF values. SSMF = 0 was used to represent pure freshwater (0 mg/L), and SSMF = 1 represents the most saline native water (26,000 mg/L) residing within the aquifer system, than at the base of the model. The assigned densities of 62.2690 lb/ft^3 (SSMF = 0) and 63.4582 lb/ft^3 (SSMF = 1) at 75 ^oF and atmospheric pressure were obtained from a standard handbook (Chemical Rubber Company, 1982). The SSMF values of the injected effluent, the water of the aquifer system, and water in mixtures of effluent and native formation waters were assigned values based on their salinity relative to the two extremes. The model was simplified with the assumption of a vertically uniform initial DS concentration distribution assigned to each layer although a vertical salinity gradient has been documented (Hickey and Spechler, 1979; Hickey, 1982). SSMF values of 0.0192 (500 mg/L DS), 0.0769 (2,000 mg/L DS), 0.3005 (7,813 mg/L DS), and 0.6490 (16,874 mg/L DS) represent the composite background water quality in samples from wells at the Southwest St. Petersburg WRF injection site (Hickey and Spechler, 1979). These values were assigned to the upper confining unit, zone A upper unit, zone A lower unit and the SCU A/B, respectively. Measured injected-water DS concentration was about 700 mg/L and was assigned a SSMF value of 0.0269.

Table 1. Fluid properties assumed for simulation

[°F, degrees Fahrenheit; in^2/lb, inch squared per pound; ft^2/d, foot squared per day; mg/L, milligrams per liter; SSMF, solute scaled mass fraction; DS, dissolved-solids concentration]

Model unit	Hydrostratigraphic layer	Tem-peature (^{0}F)	Viscosity (centipoise)	Fluid compressibility (in^2/lb)	Molecular diffusivity (ft^2/d)	SSMF (unitless)	DS (mg/L)	Water classification
Layer 4	Upper confining unit	75	0.8904	3.03×10^{-6}	9.30×10^{-5}	0.0192	500	fresh water
Layer 3	Zone A upper unit	75	0.8904	3.03×10^{-6}	9.30×10^{-5}	0.0769	2,000	slightly saline
Layer 2	Zone A lower unit	75	0.8904	3.03×10^{-6}	9.30×10^{-5}	0.3005	7,813	moderately saline
Layer 1	Semiconfining unit between zones A and B	75	0.8904	3.03×10^{-6}	9.30×10^{-5}	0.6490	16,874	very saline

Matrix Properties

Matrix properties are defined for each of the four hydrogeologic layers of the model (fig. 2, table 2). The matrix properties are intrinsic permeability, matrix compressibility, effective porosity, longitudinal dispersivity, and transverse dispersivity.

Table 2. Matrix properties assumed for simulation

[ft/d, foot per day; ft^2 foot squared; α_L, longitudinal dispersivity; α_T, transverse dispersivity; in^2/lb, inch squared per pound]

Model unit	Hydrostratigraphic layer	Hydraulic conductivity (ft/d)	Intrinsic permeability (ft^2)	Effective porosity (unitless)	α_L (feet)	α_T (feet)	Matrix compressibility (in^2/lb)
Layer 4	Upper confining unit	0.0008	3.102×10^{-15}	0.3	25.0	2.5	5.5×10^{-5}
Layer 3	Zone A upper unit	0.01	3.878×10^{-14}	0.3	25.0	2.5	3.4×10^{-5}
Layer 2	Zone A lower unit	180	6.979×10^{-10}	0.3	25.0	2.5	3.4×10^{-6}
Layer 1	Semiconfining unit between zones A and B	0.04	1.551×10^{-12}	0.3	25.0	2.5	3.4×10^{-6}

Intrinsic permeability is defined as:

$$k = \mu K / \rho g$$

where,

- k is intrinsic permeability [L^2];
- μ is dynamic viscosity of the fluid [M/LT];
- K is hydraulic conductivity, [L/T];
- ρ is fluid density [M/L^3]; and
- g is gravitational acceleration [L/T^2].

Intrinsic permeability was calculated from hydraulic conductivity values given in table 2 and conversion factors obtained from Freeze and Cherry (1979, p. 29). Values of hydraulic conductivity and matrix compressibility were based on simulation of aquifer-test data as previously discussed. The ICU was assumed to be 75 ft thick, have a hydraulic conductivity of 0.008 ft/d, and a matrix compressibility of 5.5×10^{-5} $(lb/in^2)^{-1}$. Zone A upper unit was assumed to be 100 ft thick, have a hydraulic conductivity of 0.01 ft/d, and a matrix compressibility of 3.4×10^{-5} $(lb/in^2)^{-1}$. The injection zone (zone A lower unit) was assumed to be 140 ft thick, have a hydraulic conductivity value of 180 ft/d, and a matrix compressibility of 3.4×10^{-6} $(lb/in^2)^{-1}$. The SCU A/B was assumed to be 150 ft thick, have a hydraulic conductivity of 0.04 ft/d, and a matrix compressibily of 3.4 x 10-6 $(lb/in^2)^{-1}$.

The effective porosity of all layers was set at 30 percent, based on estimates from geophysical logs at the WRF injection sites in St. Petersburg (Hickey, 1982). The values of longitudinal (α_L) and transverse (α_T) dispersivity were not quantified as part of this study and were assumed to be 25 ft and 5 ft, respectively. These values meet gridding stability criteria recommended in Voss (1984, p. 232), where α_L and α_T are greater than one-fourth and one-tenth the spacings along and transverse to the flow direction.

Effects of Operational Factors on Recovery Efficiency

A series of hypothetical SSR tests were made for the aquifer system underlying the Southwest St. Petersburg WRF using the numerical modeling technique. A base simulation was used as the standard to study the effects of changing a series of SSR operational variables and physical properties on recovery efficiency. The effect on recovery efficiency from multiple-well configurations, rates of injection and recovery, volume of water injected, storage time and regional flow, and operational schedules were studied using the numerical model.

The general results from the analysis, which are described in the following sections, indicate that recovery efficiency improves as the volume of injectant increases and improves with successive injection and recovery cycles. Recovery efficiency decreases significantly as storage time increases due to advection and hydrodynamic dispersion. Recovery efficiency was not significantly affected by the rate of injection, by the rate of recovery, by the ratio of recovery to injection rate, by a particular multiple well geometric arrangement, or by the total number of wells used.

Base Simulation

The base simulation used as a standard for comparison consisted of a single cycle of 90 days of simultaneous injection of effluent in three wells at a total rate of 4.0 Mgal/d at a temperature of 75 ^{o}F, and then withdrawal of 4.0 Mgal/d from all wells until the pumped water in each well reached a salinity limit corresponding to 1,500 mg/L DS concentration, at which time the production well was shut off. The wells are centered in the middle of the grid and aligned 100 ft apart on the X-axis. For the base simulation, a DS concentration of 1,500 mg/L was reached in 12.4 days in the two peripheral wells and 15.1 days in the center well. The recovery efficiency calculated for the base simulation is 14.8 percent.

Two simulations were made with the same parameters that were used in the base simulation; one using no-flow/no-transport boundaries at the top and bottom limits of the model, and a second using no-flow/no-transport boundaries at the lateral limits of the model. These simulations were made to test the effect on recovery efficiency of using a constant pressure/constant concentration boundary condition at the top/bottom boundary and a leaky-aquifer boundary at the lateral boundaries to represent interlayer solute mass movement across these boundaries. The simulations yielded recovery efficiencies of 14.5 and 14.7 percent compared to 14.8 percent estimated from the base simulation. This indicates that constant pressure/constant concentration, and leaky-aquifer boundaries have a very small effect on recovery efficiency in the base simulation.

The simulated flow fields at the end of the 90-day injection simulation and at the end of the 12-day recovery phase are shown in figure 10. The general configuration of the flow field at the end of injection is typical of that of buoyant flow, where injectant mixes with and rides over the relatively denser native fluid. Flow of the injectant is along the upper part of the injection zone generally away from the center of the grid where it then is directed strongly downward beyond the leading edge of the injectant front. A similar, but opposite, flow field was generated by the model during the recovery phase.

The distribution of DS concentration associated with the flow field of figure 10 is shown in figure 11. The shape of the injectant mass is highlighted in figure 11, although vertically exaggerated, and provides an illustration of the lateral extent of the injectant mass at the end of injection and at the end of recovery. The DS concentration of the mixture increases outwardly in the transition zone between the injected effluent and native water. Figure 11A shows the upward movement of injectant above the injection wells and inward migration of more saline water in the lower part of the well. After 12 days of recovery (fig. 11B) injectant in the lower part of the wells has been depleted, although considerable injectant remains in the upper part of the wells.

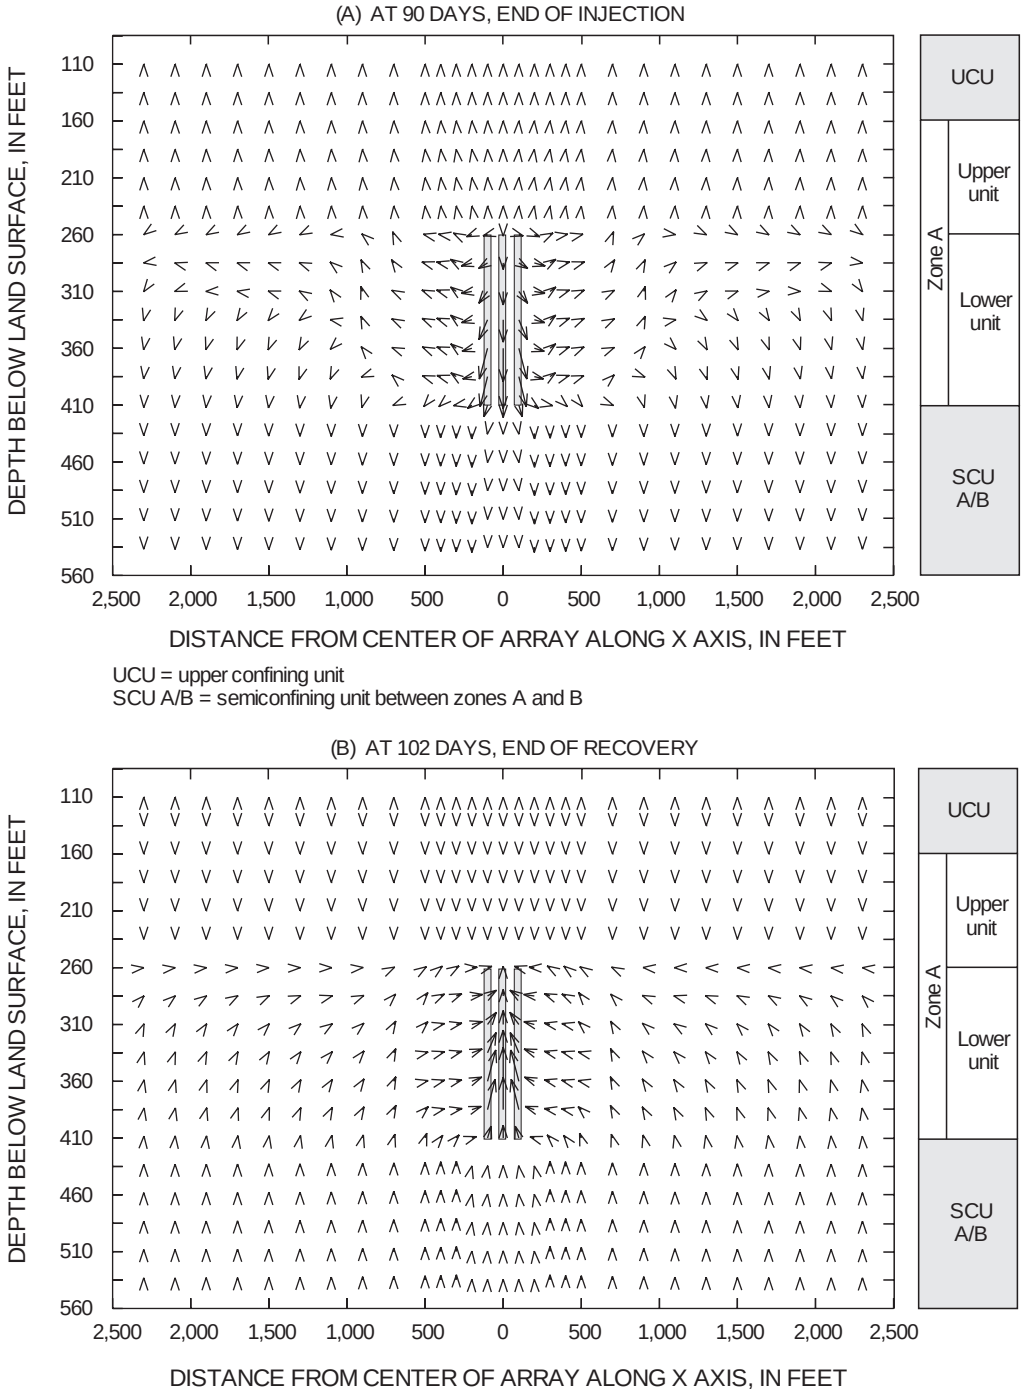

Figure 10. Simulated flow field along vertical plane 16 at the end of the injection and recovery phases of the base simulation.

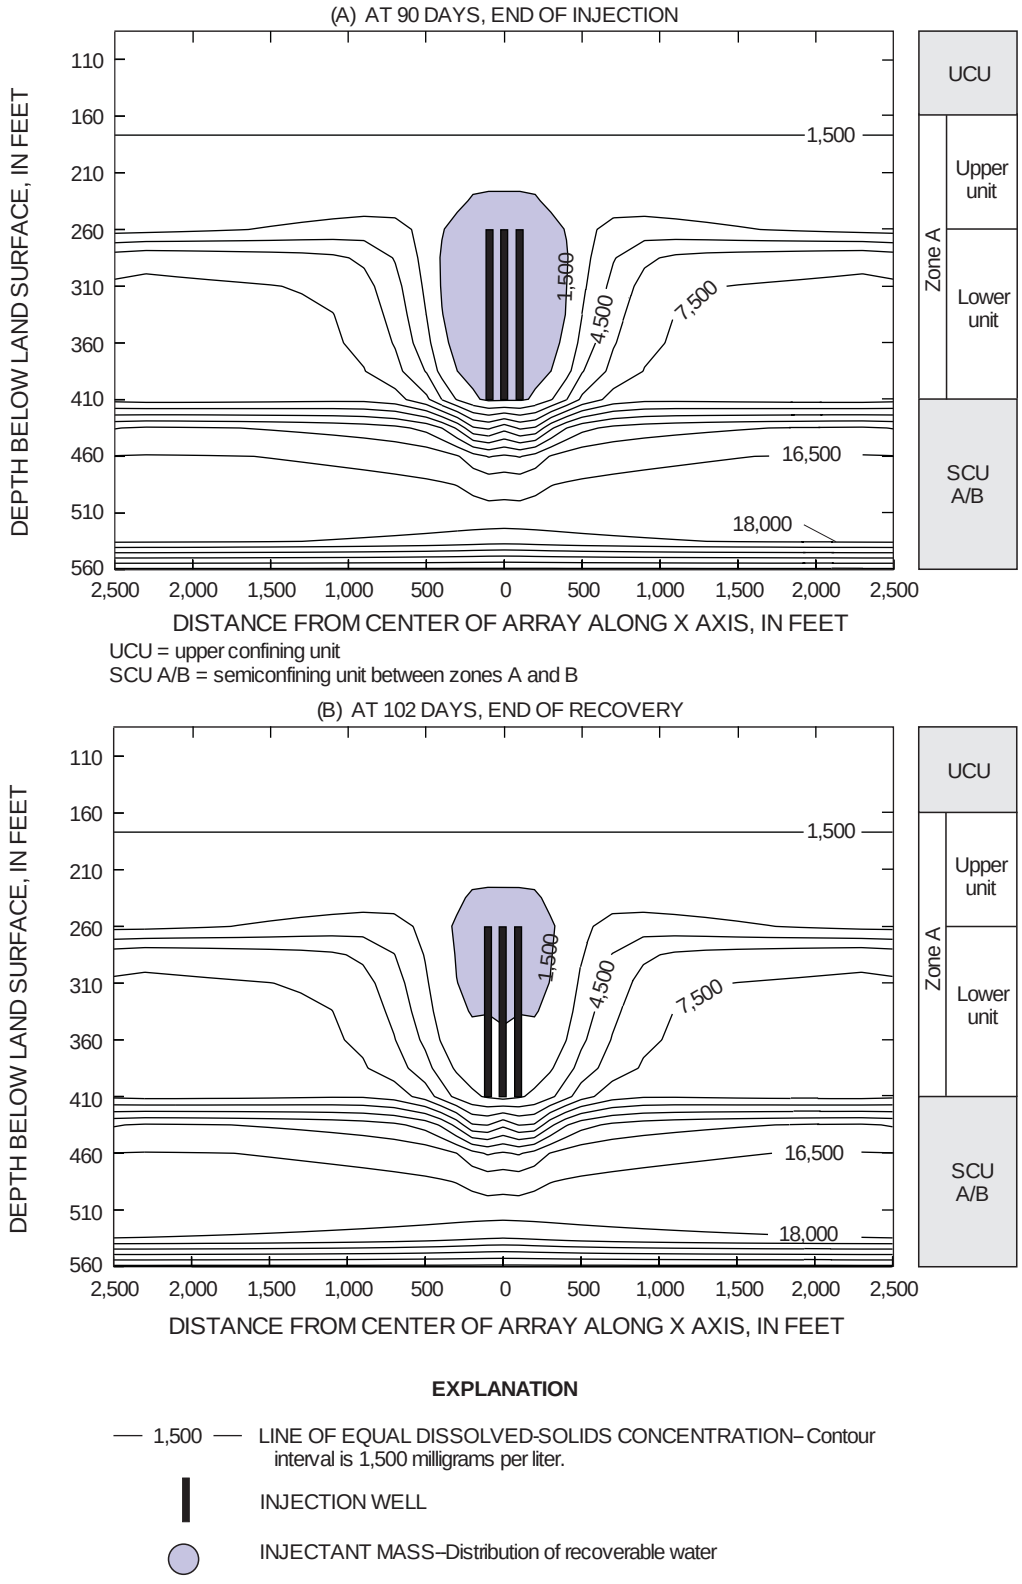

Figure 11. Simulated dissolved-solids concentration along vertical plane 16 at the end of the injection and recovery phases of the base simulation.

Multiple-Well Configurations

The effect of a group of wells on recovery efficiency was examined with ten simulations using different well configurations (fig. 12) and simultaneous equal rate injection of 4.0 Mgal/d for 90 days. Injection and recovery rates were divided equally among all wells operating at a particular time. Withdrawal was from all wells and wells were shut off when the water withdrawn reached 1,500 mg/L. All cases were compared with a control simulation from a single well, in which computed recovery efficiency was 14.7 percent. Results of the simulations are summarized below:

Number of wells	Well configuration	Recovery time (days)					Recovery efficiency (percent)
		Well number					
		1	2	3	4	5	
1	centered in grid	13.2					14.7
2	100 ft apart on x axis	13.1	13.1				14.6
3	100 ft apart on x axis (base)	12.4	15.1	12.4			14.8
3	triangle pattern	11.7	12.4	12.4			13.5
4	square array, 200 ft apart	10.9	10.9	10.9	10.9		12.1
4	square array, 100 ft apart	13.3	13.3	12.9	13.3		14.7
4	triangle array, well in center	11.9	16.1	12.2	12.2		14.6
5	square array, well in center	11.1	11.1	17.0	11.1	11.1	13.6
5	diamond array, well in center	13.4	13.4	15.5	13.4	13.4	15.4

Simultaneous injection and equal-rate withdrawals in the two-, three-, four-, and five-well systems led to no major variations upon recovery efficiency when the volume injected remained constant. Recovery efficiencies for these configurations was nearly the same as if injection and recovery had been from a single-well.

Injection and withdrawal in the square array with wells 200 ft apart produced recovery efficiency less than the base simulation by about one-fifth (from 14.8 to 12.1 percent). In the centered configurations, peripheral wells reached their salinity limit at virtually the same time, but earlier than the center well. Because of stratification and the leaky nature of the aquifer system, appreciable vertical flow of saline water into the injection zone occurred, and therefore, the geometric arrangement of the wells was not important. Model results were similar to those reported by Merritt (1985). Merritt (1985) reported that no major variations in recovery efficiency occurred in multiwell configurations when the volume injected remained constant. The number of wells varied from one to nine in Merritt's study; however, recovery efficiency was nearly the same as the single-well system.

Recovery efficiency from a particular arrangement of wells also may depend on the schedule of withdrawal at each well. Three simulations were used to study the effects of selected operational schedules on recovery efficiency. The base simulation (three-well center configuration) was the test case for comparing the withdrawal schedules. Each test consisted of four consecutive 90-day cycles of simultaneous injections and equal-rate withdrawals at all wells. Withdrawal was from selected wells until the solute fraction of the withdrawn water at any of the wells reached a DS concentration of 1,500 mg/L. Injection and withdrawal rates were the same in all tests (4.0 Mgal/d) and were divided equally among all wells operating at a particular time. The following withdrawal schedules were simulated:

Test 1-- Withdrawal at only the center well until the perimeter wells exceeds salinity limit.

Test 2-- Withdrawal at only the center well until withdrawn water exceeds salinity limit.

Test 3-- Equal rate withdrawal at all wells until the water in the perimeter wells exceeds salinity limit.

Results of the simulations were compared to the base simulation and are summarized below:

Cycle number	Base	Test 1	Test 2	Test 3
	Recovery Efficiency			
1	14.8	13.3	14.3	13.3
2	28.7	31.2	31.2	30.0
3	37.3	40.1	40.1	39.0
4	42.8	45.0	44.8	44.8

With the exception of the first cycle, recovery efficiency for the various schedules of withdrawal was only slightly higher than that of the base simulation. The recovery efficiency increased with each cycle because residual injectant accumulated in the aquifer from previous cycles.

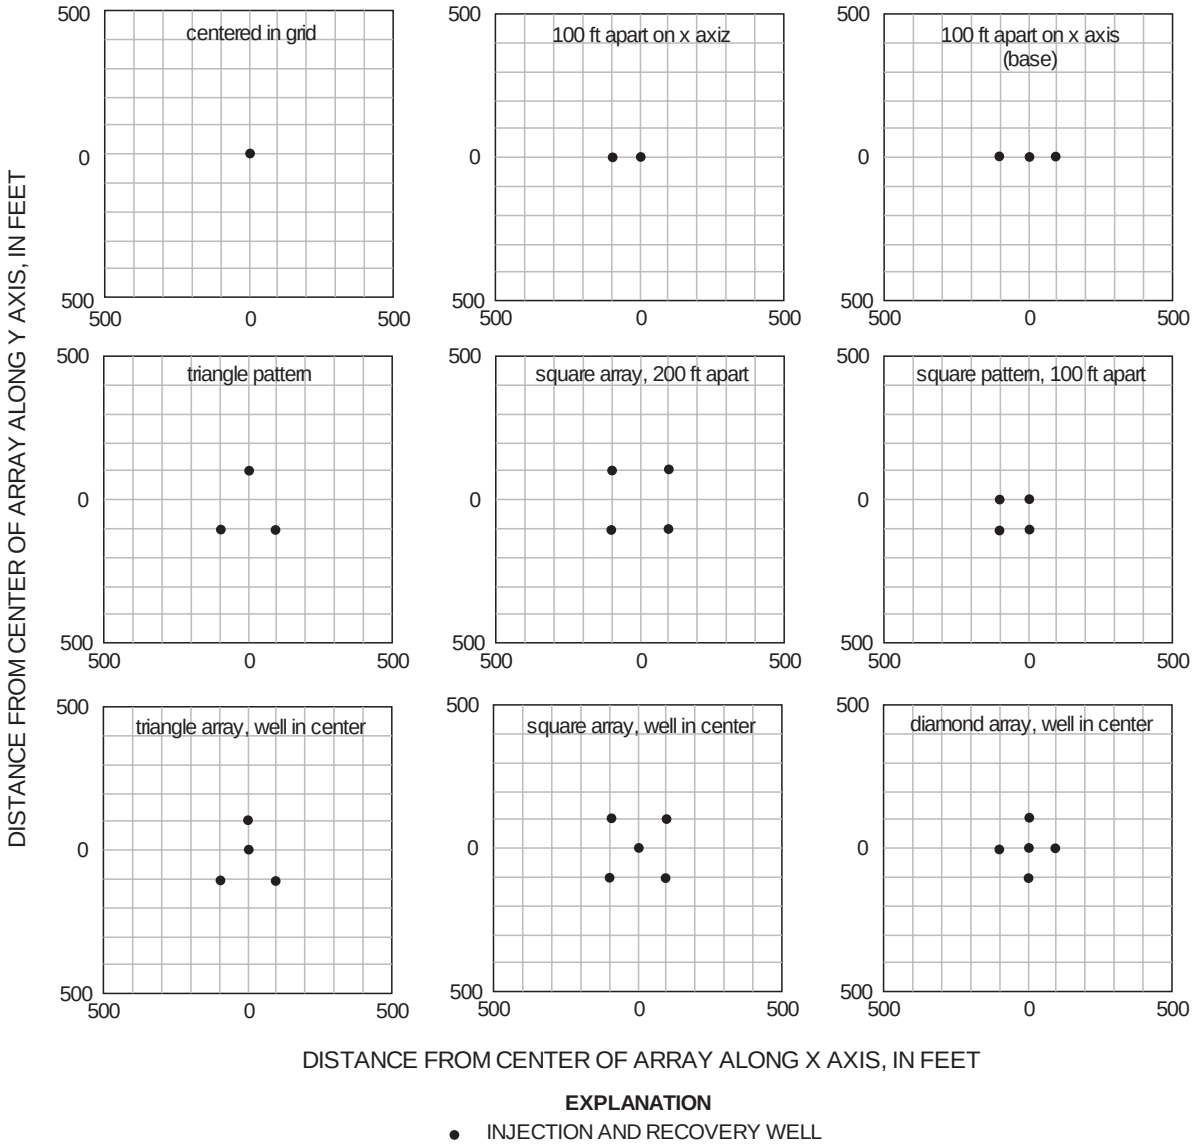

Figure 12. Geometric arrangement of injection and recovery wells.

Rates of Injection and Recovery

The base simulation model was used to simulate the injection and withdrawal of a fixed volume of water at various rates. The rate of injection and withdrawal for a fixed volume of water was varied by 0.25, 0.50, 2.0, and 4.0 times the base value. The duration of injection was adjusted so that the total volume injected remained constant at 360 Mgal. Durations of injection ranged from 22.5 days at 16.0 Mgal/d to 360 days at 1.0 Mgal/d. Results of the simulations are summarized below:

Injection/recovery rate (Mgal/d)	Volume of water injected (Mgal)	Injection time (days)	Recovery efficiency (percent)
16.0	360	22.5	15.0
8.0	360	45.0	13.9
4.0 base	360	90.0	14.8
2.0	360	180.0	14.8
1.0	360	360.0	13.6

Results of the simulations indicate no significant relation between the rate at which a given volume of water was injected or withdrawn and the amount of water that could be recovered. This implies that the

simulated dispersion process is most sensitive to the extent of fluid moment to a new position and not to the rate of movement to that position.

The effects of using different ratios of recovery to injection rates (Q_R/Q_I) also were studied and are summarized below:

Injection rate (Mgal/d)	Recovery rate (Mgal/d)	Q_R/Q_I	Recovery efficiency (percent)
4	1	1/4	14.0
4	2	1/2	14.4
4 (base)	4	1/1	14.8
4	8	2/1	14.9
4	16	4/1	15.1

When Q_R/Q_I ratios were decreased to 1/2 and 1/4, the recovery efficiency decreased slightly from 14.8 (base simulation) to 14.4 and 14.2 percent, respectively. When the Q_R/Q_I ratios were increased to 2/1 and 4/1, the recovery efficiency increased slightly from 14.8 percent (base simulation) to 14.9 and 15.4 percent, respectively. Because the mass of injected water buoys upward, native water generally remains near the bottom of the wells, and therefore, the duration and rate of injection and recovery are not important.

Volume of Water Injected

Various changes in the volume of water injected for a fixed time period were studied in the base simulation model using six simulations in which the injected volume was varied from 0.25 to 2.0 times the base value. This was accomplished by decreasing or increasing the injection rate, while keeping the same injection time (90 days) as used in the base simulation. Zero recovery efficiency would occur for a sufficiently small injection volume because of mixing. Results of the simulations are summarized below:

Volume of water injected (Mgal)	Injection rate (Mgal/d)	Recovery efficiency (percent)
720	8.0	16.9
540	6.0	16.3
450	5.0	15.7
360 (base)	4.0	14.8
270	3.0	13.6
180	2.0	11.4
90	1.0	6.9

Simulations suggest that recovery efficiency is proportional to the injected flow volume. Recovery efficiency increased as the volume of water increased, and conversely, decreased as the volume of water decreased. For injected volumes of 1.25, 1.50, and 2.0 times the base value, recovery efficiency increased from 14.8 percent (base simulation) to 15.7, 16.3, and 16.9 percent, respectively. For injection volumes of 0.75, 0.50, and 0.25, times the base value, recovery efficiency decreased from 14.8 percent (base simulation) to 13.6, 11.4, and 6.9 percent, respectively. Recovery efficiency increased at a greater rate at smaller volumes than at larger volumes, nearly doubling (from 6.9 to 13.6 percent) when the injection volume increased from 90 to 270 Mgal; while only increasing by about one-fifth (from 13.6 to 16.9) when the injection volume increased from 270 to 720 Mgal.

The effect of keeping the same injection rate (4.0 Mgal/d) while decreasing or increasing the injection time used in the base simulation also was tested. Results from these simulations are as follows:

Volume of water injected (Mgal)	Injection time (days)	Recovery efficiency (percent)
720	180.0	17.0
540	135.0	16.2
450	112.5	15.6
360 base	90.0	14.8
270	67.5	13.6
180	45.0	11.6
90	22.5	7.7

Results from these six simulations are similar to the previous six simulations. As discussed earlier, the dispersion process is simulated as a function of the extent of fluid movement to a new position and not the rate of movement to that position, despite the functional dependence upon flow velocity.

Storage Time and Regional Flow

Two series of model simulations were used to illustrate the effect of storage time and the effect of the regional flow in the Upper Floridan aquifer on recovery efficiency. The first series of tests consisted of five simulations using storage times of 0, 30, 90, 180, and 360 days and no regional flow. The second series of tests consisted of five simulations using storage times of 0, 30, 90, 180, 360 days and an assumed hydraulic gradient of 1 ft/mi observed at the study site. Regional flow was represented as occurring along the X-axis of the grid, and specified boundary pressure values were entered to maintain simulated flow. Results of the simulations follows:

Volume of water injected (Mgal)	Injection time (days)	Storage time (days)	Regional gradient 0 ft/mi	Regional gradient 1 ft/mi
			Recovery efficiency (percent)	Recovery efficiency (percent)
360	90	0	14.8 (base)	14.7
360	90	30	13.7	13.6
360	90	90	12.0	11.9
360	90	180	9.2	9.1
360	90	360	4.7	4.6

Simulations indicated that long storage time greatly affects recovery efficiency but shorter times do not. About a two-thirds decrease (from 14.8 to 4.7 percent) in recovery efficiency was simulated when storage time was increased from 0 to 360 days. But the difference between a storage of zero and 30 days was small. If the storage period were lengthened much beyond 360 days the remaining injectant would be nearly lost completely. Simulations also show that a regional gradient of 1 ft/mi had virtually no effect on the recoverability of the injected water, within the storage times simulated.

The simulated flow fields at the end of 30, 180, and 360 days of storage are shown in figure 13. After injection ceases, rapid stratification and upconing occurs. Oscillations of the flow field in the upper unit at 180 days of storage are due to temporal instabilities in pressure. The figures show circular convection throughout a large part of the injection zone, with counter flow of native water toward the injection well in the lower part of the injection zone. The native water then mixes with the injectant, and the mixture flows away from the injection wells in the upper part of the injection zone. Because of the leaky nature of the aquifer system represented in this model, appreciable vertical flow of saline water into the injection layer occurs from adjacent layers. The longer the withdrawal is delayed, the lower the recovery efficiency. This is a major limiting factor for SSR.

Successive Cycles of Injection and Recovery

A series of ten consecutive multicycle model simulations were used to illustrate the effects of successive cycles of injection and recovery on the recovery efficiency. As discussed earlier, the base simulation consisted of a single cycle of 90 days of simultaneous injection of effluent in three wells at a rate of 4.0 Mgal/d and then equal rate withdrawal of 4.0 Mgal/d until the pumped water in each well reached a DS concentration of 1,500 mg/L. Model results from the preceeding cycle were used as initial conditions for simulating the following cycle. Results of the simulations are shown in figure 14.

Model results are similar to those reported by Merritt, (1985), Quinones and Wexler (1995), and Yobbi (1996). Recovery efficiency per cycle increases with the total number of cycles. Recovery efficiency increases very rapidly in initial cycles, increasing from about 15 percent to about 47 percent during the first five cycles, and less rapidly in later cycles, increasing from about 49 percent to about 56 percent during the last five cycles. Results also indicate that recovery efficiency approaches an asymptote after several cycles, where little improvement of recovery efficiency occurs.

Two simulations were made with the same parameters that were used in the multicycle simulation; one using no-flow/no-transport boundaries at the top and bottom limits of the model, and a second using no-flow/no-transport boundaries at the lateral limits of the model. These simulations were made to test the effect on recovery efficiency of using a constant pressure/constant concentration boundary condition at the top/bottom boundary and a leaky-aquifer boundary at the lateral boundaries to represent interlayer solute mass movement across these boundaries for multicycle simulations. The simulations yielded recovery efficiencies of 74 and 58 percent compared to 56 percent estimated after ten cycles. This indicates that constant pressure/constant concentration boundaries are important in the determination of the recovery efficiency in multicyle simulations, while leaky-aquifer boundaries have a very small effect on recovery efficiency in multicyle simulations.

Sensitivity Analysis

A series of simulation runs that started with the base model were done to determine changes in recovery efficiency due to variations in model parameters, including DS concentration of injection zone water, permeability, anisotropy, longitudinal and transverse dispersivities, and effective porosity. The sensitivity

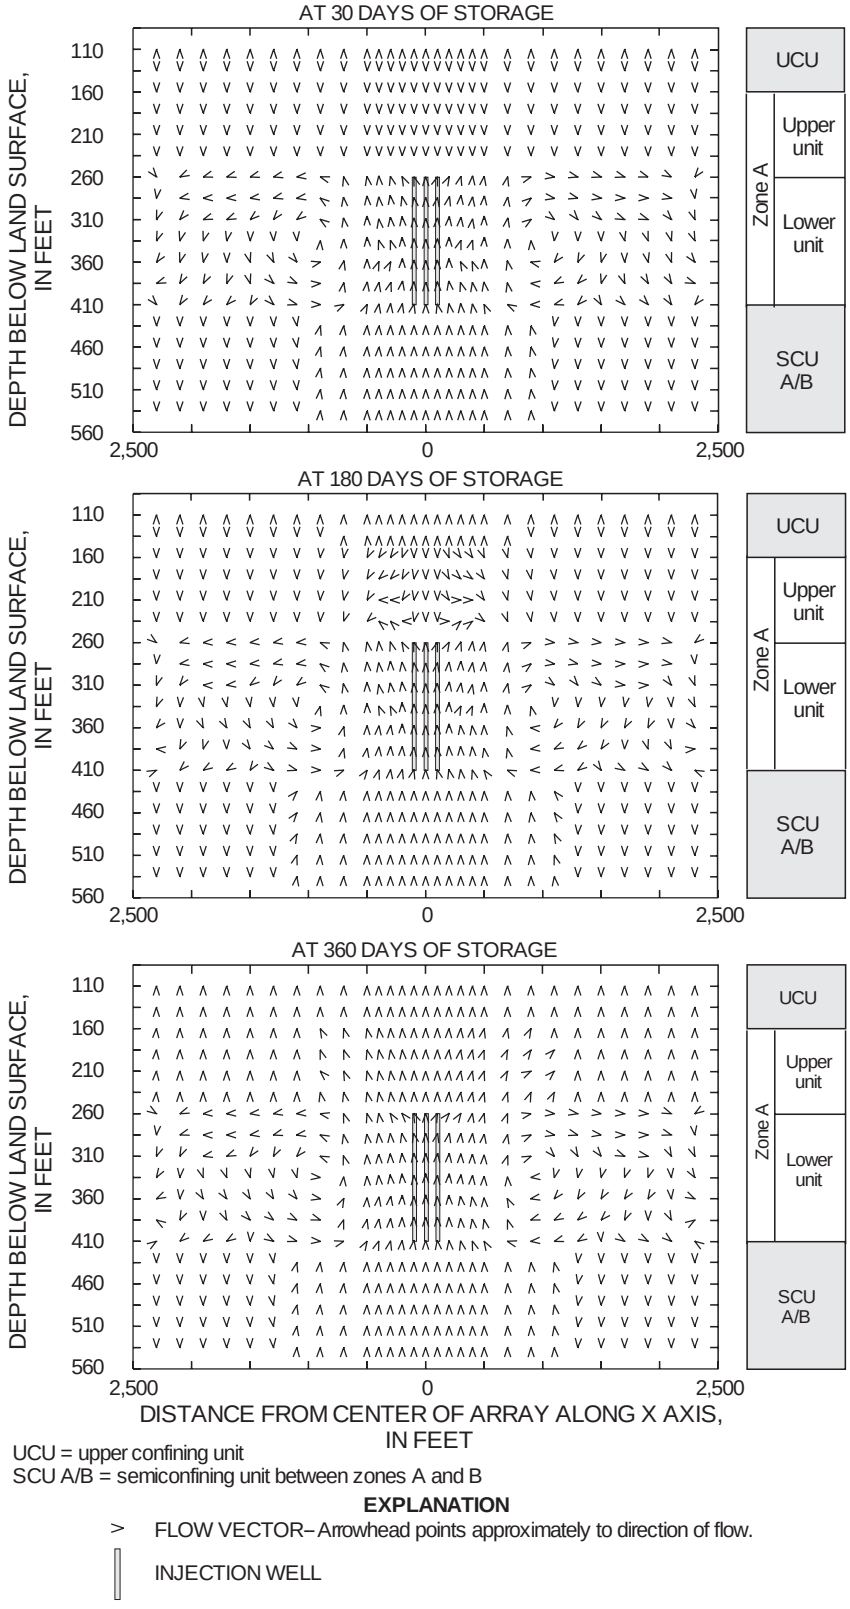

Figure 13. Simulated flow field along vertical plane 16 at the end of 30, 180, and 360 days of storage.

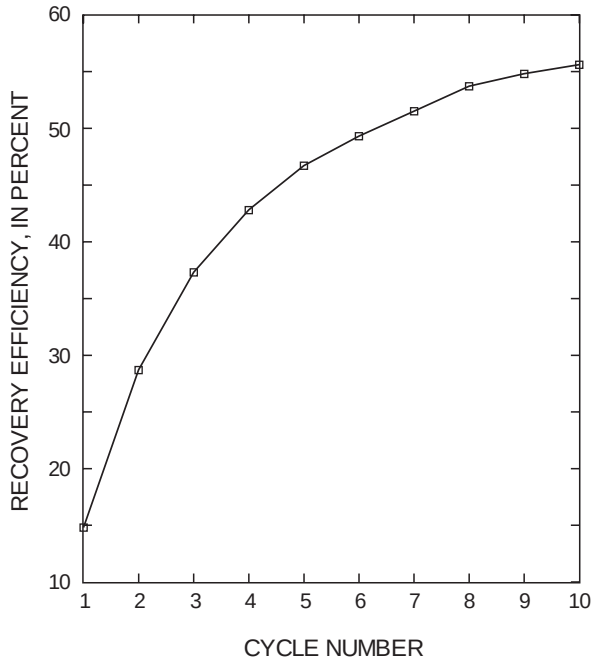

Figure 14. Recovery efficiency for ten successive injection/withdrawal cycles at 4.0 million gallons per day. (Withdrawal in each cycle ceases when the dissolved-solids concentration of water withdrawn reaches 1,500 milligrams per liter.)

analysis was conducted to assess the uncertainty of estimating selected matrix and fluid properties. For each simulation run, the value of an individual model parameter was changed by an amount that might reasonably be expected to vary from the value used in the base simulation, and noting the change in recovery efficiency as a result of the change. The simulation used as a base for comparison consisted of a single cycle of 90 days of simultaneous injection of effluent in three wells at a rate of 4.0 Mgal/d and then equal rate withdrawal of 4.0 Mgal/d until the pumped water in each well reached a DS concentration of 1,500 mg/L. A recovery efficiency of 14.8 percent was estimated for the base simulation.

The general results from the analysis, which are described in the following sections, indicate that the DS concentration of the injection zone is the most important factor, producing the greater change in recovery efficiency. The second most important factor producing significant changes in recovery efficiency is changes in longitudinal and transverse dispersivity values. Generally, recovery efficiency increased when parameter values decreased and recovery efficiency decreased when parameter values increased. The one exception is that recovery efficiency increased when there was an order of magnitude increase in the ratio of horizontal to vertical anisotropy.

Dissolved-Solids Concentration of the Injection Zone

Simulations were made to study the effects of different DS concentration of the injection zone (zone A lower unit) on recovery efficiency. The greater the salinity of the native water, the greater will be the range of salinity across the zone of dispersion; hence, density gradients will be greater causing bouyant movement and the proportion of recoverable water within the zone will be smaller. Six DS concentrations were selected for comparison: (1) 500 mg/L, representing the least saline layer of the model; (2) 1,000 mg/L, an arbitrary value representing water somewhat more saline than the base value of the injection zone; (3) 2,000 mg/L, an arbitrary value representing slightly saline water, (4) 3,400, mg/L, an arbitrary value representing a mix of the least saline layer of the model and that of the composite base value of the injection zone, (5) 7,800 mg/L, representing the composite base value of the injection zone, and (6) 16,900 mg/L, representing the most saline layer.

Results of the simulations indicate recovery efficiency is highly sensitive to changes in the DS concentration of the injection zone (fig. 15A). Recovery efficiency decreases at a great rate as low DS concentrations increase, decreasing from about 77.8 to 23.6 percent when DS concentrations increased from 500 to 3,400 mg/L; but the rate of decrease is small at higher DS concentrations, decreasing from about 23.6 to 6.1 percent when the DS concentration of the injection zone increased from 3,400 mg/L to 16,900 mg/L. This analysis indicates that: (1) increases in DS concentrations of the injection zone can decrease recovery efficiency significantly, and (2) SSR is most promising when the DS concentration of the injection zone is low and least promising when the DS concentration of the injection zone is high.

Permeability

Permeability and effective porosity control the velocity of injectant flow. Uncertainty in the permeability value will affect the advective and dispersive components of the transport computations and, hence, the rate of solute transport. Generally, low permeability optimizes recovery efficiency, assuming that injection wells remain practical at low permeabilities.

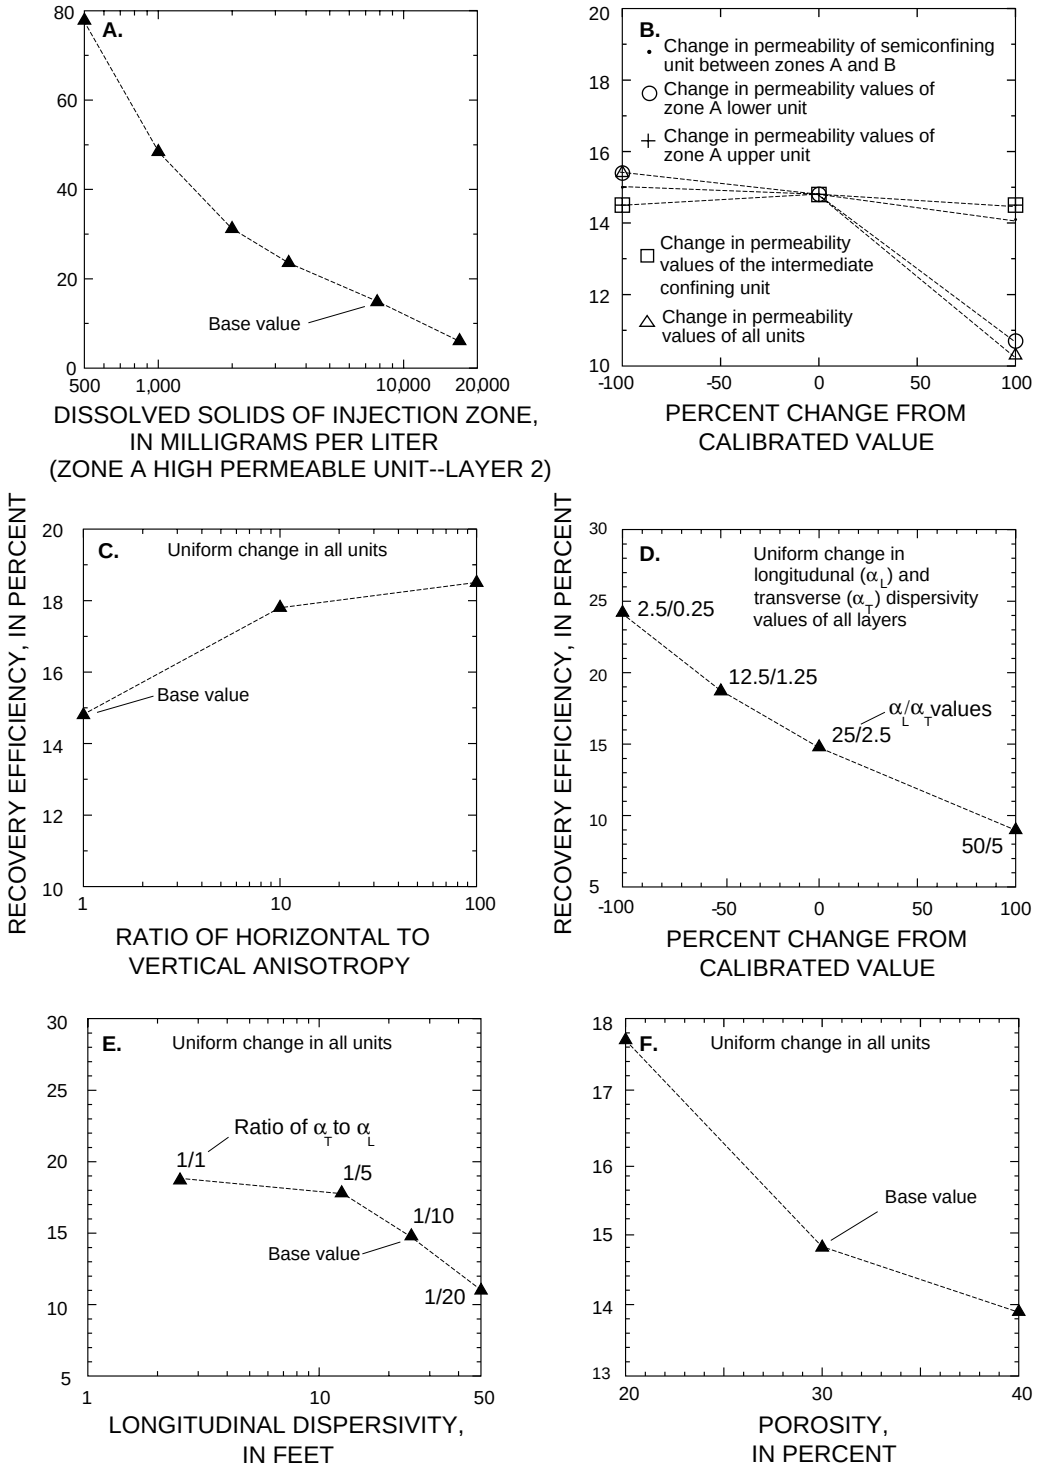

Figure 15. Relation between recovery efficiency and variations in selected model parameters.

The magnitude of permeability was changed in five different ways in the base simulation model: (1) uniform changes in all permeability values; (2) changes in permeability values of the intermediate confining unit; (3) changes in permeability values of zone A upper unit; (4) changes in permeability values of zone A lower unit; and (5) changes in permeability values of the semi-confining unit between zones A and B.

Figure 15B illustrates the variation of recovery efficiency due to permeability changes. Changes in the permeability values of all units produced the greatest change in recovery efficiency while changes in permeability values of zone A lower unit (injection zone) produced the second greatest change in recovery efficiency. Increasing permeability of the injection zone by a factor of 10 decreased recovery efficiency by about one-third (from 14.8 to 10.6 percent). The decrease in recovery efficiency is expected because of easier horizontal and vertical transport of the injected fluid, which results in greater stratification and buoyancy flow that prevents complete mixing of the injected and native waters. Also, figure 15B shows that when permeability of each layer was reduced by a factor of 0.1, recovery efficiency was not significantly affected. The major effect of the variation at lower permeability values is the increased wellhead pressure or drawdown required at the specified injection/withdrawal rate.

Anisotropy

If flow conditions vary with direction in a geologic formation, the formation is anisotropic and has differences in horizontal (k_h) and vertical (k_v) permeability. The greater the anisotropy ratio (k_h/k_v), the easier the injectant front moves along the axis of the larger permeability component. In the base simulation model, permeability is equal in all directions. To test for the effects of anisotropy, the ratio of k_h to k_v was varied from an isotropy base value ($k_h/k_v = 1$) to $k_h/k_v = 10$ and $k_h/k_v = 100$ (fig. 15C). Increasing k_h/k_v resulted in recovery efficiency increasing by about one-quarter (from 14.8 to 18.5 percent). Recovery efficiency increases because simulation of a larger k_h/k_v causes more lateral flow and inhibits upward movement of buoyant injectant.

Dispersivity

Dispersivity is a scale-dependent property of the porous medium that controls the mixing of injected and native formation fluids at their interface. When dispersivity is increased, more mixing occurs and a widening of the transition zone between the injectant and native formation waters occurs. Dispersion is a restrictive process that can severely limit recovery efficiency (Merritt, 1985).

Two different tests of the base model were made for the α_T and α_L values. In the first test, both dispersivity values were simultaneously changed by the same percentage, keeping the ratio of α_T to α_L equal to 1/10. In the second test, the ratio of α_T to α_L was changed by keeping the α_T value constant while changing the α_L value.

Figures 15D and 15E illustrate results of the simulations. The analysis indicates that uniform changes in both α_T and α_L values produced more significant changes in recovery efficiency than when the ratio of α_T to α_L was changed. Increasing α_T and α_L uniformly by 100 percent decreased recovery efficiency by about one-third (from 14.8 to 9.0 percent); while decreasing α_T and α_L uniformly by 100 percent increased recovery efficiency by about two-thirds, from 14.8 to 24.2 percent. When α_L was decreased from 25 to 2.5 ft (α_T to α_L =1/1) recovery efficiency increased by about one-quarter, from 14.8 to 18.7 percent. When α_L was increased from 25 to 50 ft (α_T to α_L = 1/20) recovery efficiency decreased by about one quarter, from 14.8 to 11.0 percent. In both cases, recovery efficiency decreases as dispersivity increases. A large rate of decrease in recovery efficiency is shown as the dispersivity value or ratio of α_T to α_L, increases from low values, but the rate of decrease is small at larger dispersivity values or ratios.

Effective Porosity

Effective porosity is part of the ground-water hydraulic equation and the advective-dispersive solute-transport equation. In addition to the effect on the storage term for the transport equation, the effective porosity value is combined with the specific discharge (obtained from the ground-water flow equation) to determine the average pore-water velocities, which are used to represent the advection term in the transport equation (Quinones and Wexler, 1995).

Effective porosity of the aquifer material was tested at 20 and 40 percent to bracket the base model value of 30 percent. Figure 15F illustrates the variation of recovery efficiency due to changes in porosity. Increasing porosity caused recovery efficiency to decrease slightly, from 14.8 to 13.9 percent, whereas decreasing porosity caused recovery efficiency to increase by about one-fifth, from 14.8 to 17.7 percent. The greater the porosity, the slower the solute front will move; thus, the longer the time it takes to replace the volume of native formation water in a given volume of the aquifer and the greater the dispersive mixing. Low porosity has the opposite effect.

SUMMARY AND CONCLUSIONS

A model-based study of subsurface storage and recovery (SSR) was made to assess the potential for SSR using multiple wells at the Southwest St. Petersburg WRF. SSR is a strategy of water conservation used to augment exiting water supplies. The study was specifically aimed toward applying a density-dependent, ground-water and solute-transport model to assess various operational variables and physical properties on recoverability of injected effluent.

The hydrogeologic framework used for this study was developed from interpretations of data from previous studies. The sediments underlying the study area form a sequence of two aquifers and one confining unit. The framework includes the unconfined surficial aquifer, and the confined Upper Floridan aquifer. The units are separated by the intermediate confining unit.

General aquifer characteristics were estimated from field and laboratory data including drillers logs, aquifer tests, and geophysical logs collected from previous studies. Hydraulic properties of the hydrostratigraphic units were estimated using numerical simulation of aquifer-test data. A cylindrical numerical model was calibrated by obtaining a satisfactory match between observed and model-generated head change data.

A three-dimensional numerical model of variable density ground-water flow and solute transport (HST3D) was used to evaluate the effects of changing various operational parameters on recovery efficiency of treated effluent stored in a saline aquifer underlying the study site using multiple wells. About 75 hypothetical tests of SSR were made to evaluate the efficiency of this operation in the study area. A base simulation of simultaneous injection of 4 Mgal/d in three wells for 90 days and then withdrawal of 4 Mgal/d from all wells until the pumped water exceeded a dissolved-solids concentration of 1,500 mg/L was used as a reference to compare the effects of changing selected operational factors on recovery efficiency. A recovery efficiency of 14.8 percent was estimated for the base simulation. The effects of the following operational factors were assessed using the model:

1. multiple-well configurations;
2. rates of injection and recovery;
3. volume of water injected;
4. storage time and regional flow, and
5. successive cycles of storage and recovery.

Simulation results for hypothetical conditions indicate that recovery efficiency increases when the volume of injectant increases; increases with successive injection and recovery cycles, and increases slightly when the ratio of recovery rate to injection rate increases. Recovery efficiency decreases significantly when the storage time increases significantly and decreases slightly when the ratio of recovery rate to injection rate decreases. Recovery does not change significantly when the rate of injection increases or decreases.

Model results show that recovery efficiencies of about 7 to 17 percent can be achieved for different SSR operational schemes. Ten successive injection and recovery cycles can increase the recovery efficiency to about 56 percent. Other results indicate that recovery efficiency does not improve significantly in particular geometric arrangement of wells or number of wells when the volume of water injected remains constant. Recovery efficiency for the various configurations tested was nearly the same as if injection and recovery had been from a single well.

Sensitivity analysis were performed to determine changes in recovery efficiency to variations in model parameters, including:

1. dissolved-solids concentration of the injection zone,
2. permeability,
3. anisotropy,
4. dispersivity, and
5. effective porosity.

The general results from the analysis indicate that changes in the dissolved-solids concentration of

the injection zone produced the greatest change in recovery efficiency. Uniform changes in dispersivity values produced the second most significant change in recovery efficiency. Generally, recovery efficiency increased when each parameter value decreased and recovery efficiency decreased when each parameter value increased.

Density differences between native and injected waters were the most important factor affecting recovery efficiency in this study. High salinity of native water at a given permeability level permits rapid buoyancy stratification and brings about a substantial loss of recovery efficiency. Simulation results indicated that recovery efficiency decreased rapidly when the dissolved-solids concentration increased, decreasing from about 77.8 to 23.6 percent when dissolved-solids concentration increased from 500 to 3,400 mg/L.

Dispersivity is an important factor to the model sensitivity and is a restrictive process that can severely limit recovery efficiency. However, the dispersivity values used for this model were not field tested and may not be representative of the actual dispersive characteristics of the aquifer system at the study site.

Simulation of Subsurface Storage and Recovery of Treated Effluent Injected in a Saline Aquifer, St. Petersburg, Florida

By Dann K. Yobbi

Abstract

The potential for subsurface storage and recovery of treated effluent into the uppermost producing zone (zone A) of the Upper Floridan aquifer in St. Petersburg, Florida, is being studied by the U.S. Geological Survey, in cooperation with the city of St. Petersburg and the Southwest Florida Water Management District. A measure of the success of this practice is the recovery efficiency, or the quantity of water relative to the quantity injected, that can be recovered before the water that is withdrawn fails to meet water-quality standards. The feasibility of this practice will depend upon the ability of the injected zone to receive, store, and discharge the injected fluid.

A cylindrical model of ground-water flow and solute transport, incorporating available data on aquifer properties and water quality, was developed to determine the relation of recovery efficiency to various aquifer and fluid properties that could prevail in the study area. The reference case for testing was a base model considered representative of the saline aquifer underlying St. Petersburg. Parameter variations in the tests represent possible variations in aquifer conditions in the area. The model also was used to study the effect of various cyclic injection and withdrawal schemes on the recovery efficiency of the well and aquifer system.

A base simulation assuming 15 days of injection of effluent at a rate of 1.0 million gallons per day and 15 days of withdrawal at a rate of 1.0 million gallons per day was used as reference to compare changes in various hydraulic and chemical parameters on recovery efficiency. A recovery efficiency of 20 percent was estimated for the base simulation. For practical ranges of hydraulic and fluid properties that could prevail in the study area, the model analysis indicates that (1) the greater the density contrast between injected and resident formation water, the lower the recovery efficiency, (2) recovery efficiency decreases significantly as dispersion increases, (3) high formation permeability favors low recovery efficiencies, and (4) porosity and anisotropy have little effect on recovery efficiencies. In several hypothetical tests, the recovery efficiency fluctuated between about 4 and 76 percent.

The sensitivity of recovery efficiency to variations in the rate and duration of injection (0.25, 0.50, 1.0, and 2.0 million gallons per day) and withdrawal cycles (60, 180, and 365 days) was determined. For a given operational scheme, recovery efficiency increased as the injection and withdrawal rate is increased. Model results indicate that recovery efficiencies of between about 23 and 37 percent can be obtained for different subsurface storage and recovery schemes. Five successive injection, storage, and recovery cycles can increase the recovery efficiency to about 46 to 62 pecent. There is a larger rate of increase at smaller rates than at larger rates. Over the range of variables studied, recovery efficiency improved with successive cycles, increasing rapidly during initial cycles then more slowly at later cycles.

The operation of a single well used for subsurface storage and recovery appears to be technically feasible under moderately favorable conditions; however, the recovery efficiency is highly dependent upon local physical and operational parameters. A combination of hydraulic, chemical, and operational parameters that minimize dispersion and buoyancy flow, maximizes recovery efficiency. Recovery efficiency was optimal where resident formation water density and permeabilities were relatively similar and low.

INTRODUCTION

The city of St. Petersburg owns and operates one of the largest urban reclaimed-wastewater reuse systems in the world. Currently (1995), approximately 21 Mgal/d of advanced secondary-treated effluent is piped from the city's four water reclamation facilities (WRF) through a 260-mile irrigation system to water residential and commercial properties. Demand for reclaimed water is seasonal. There is a deficiency of effluent for irrigation in the dry months and an excess in the wet months, during which the excess is disposed of through deep underground injection wells. The injected water from these deep permeable zones cannot be effectively recovered because the disposal zone is in a highly fractured dolomite saturated with saltwater (Hickey and Ehrlich, 1984). One solution, known as subsurface storage and recovery (SSR), to this dilemma involves the injection of effluent into shallow, less transmissive formations of low or moderate salinity, by one or more wells, for storage during wet periods when demand is low. The injected water would be withdrawn later for irrgation use during dry periods when demand is high. SSR is especially appropriate for areas like St. Petersburg where there is: (1) seasonal variations in water supply and demand, and (2) availability of moderately permeable aquifers near the surface that contain brackish water.

The feasibility of a SSR system will depend upon the ability of the injected zone to receive, store, and discharge the injected effluent. A measure of the success of a SSR system is the quantity of water that can be recovered relative to the quantity injected, or recovery efficiency. Recovery efficiency, usually expressed as a percentage per cycle of injection, storage, and recovery, is defined as the volume of water recovered before the withdrawn water fails to meet some prescribed chemical standard. In this report, the standard has been taken to be when the water that is withdrawn exceeds a dissolved solids (DS) concentration of 1,500 mg/L.

Two primary physical processes limit the recoverability of the injected water: (1) mixing by advection and hydrodynamic dispersion, and (2) density stratification. Mixing and dispersion creates a diffused zone between the injected and formation waters as a result of molecular diffusion and mechanical dispersion. Density stratification describes the tendency for the lighter fluid to rise above the denser fluid. Unfavorable physical and solute properties of the aquifer system can strengthen these deleterious processes and reduce the recoverability of injected water.

An assessment of the potential recovey efficiency for the aquifer system underlying St. Petersburg needs to be made before a commitment of resources is made for operational testing at a specific site. This requires a semi-quantitative understanding of the dependence of recovery efficiencies on hydrogeologic and chemical characteristics of the aquifer system and on system designs and management parameters. A cost-effective alternative to field testing is simulation modeling, in which many combinations of conditions can be investigated with relatively inexpensive computer simulations.

In 1994, the U.S. Geological Survey (USGS), in cooperation with the city of St. Petersburg and the Southwest Florida Water Management District (SWFWMD), began a model-based investigation of the hydrogeologic and operational aspects of subsurface injection and storage of effluent, and possible future retrieval for nonpotable use. The study area is the city of St. Petersburg, located on the southern tip of Pinellas County (fig. 1).

Throughout this report, statements are made concerning the salinity of water. The terminology used to describe the salinity is modified slightly from a USGS classification system of water based on dissolved solids (Heath, 1989, table 2, p. 65), as follows:

Classification	Dissolved-solids concentration (milligrams per liter)	Percent seawater
Freshwater	<500	<1.5
Slightly saline (brackish water)	500 to 3,000	1.5 to 8.6
Moderately saline (brackish water)	3,000 to 10,000	8.6 to 29
Very saline (saltwater)	10,000 to 35,000	29 to 100
Brine	>35,000	>100

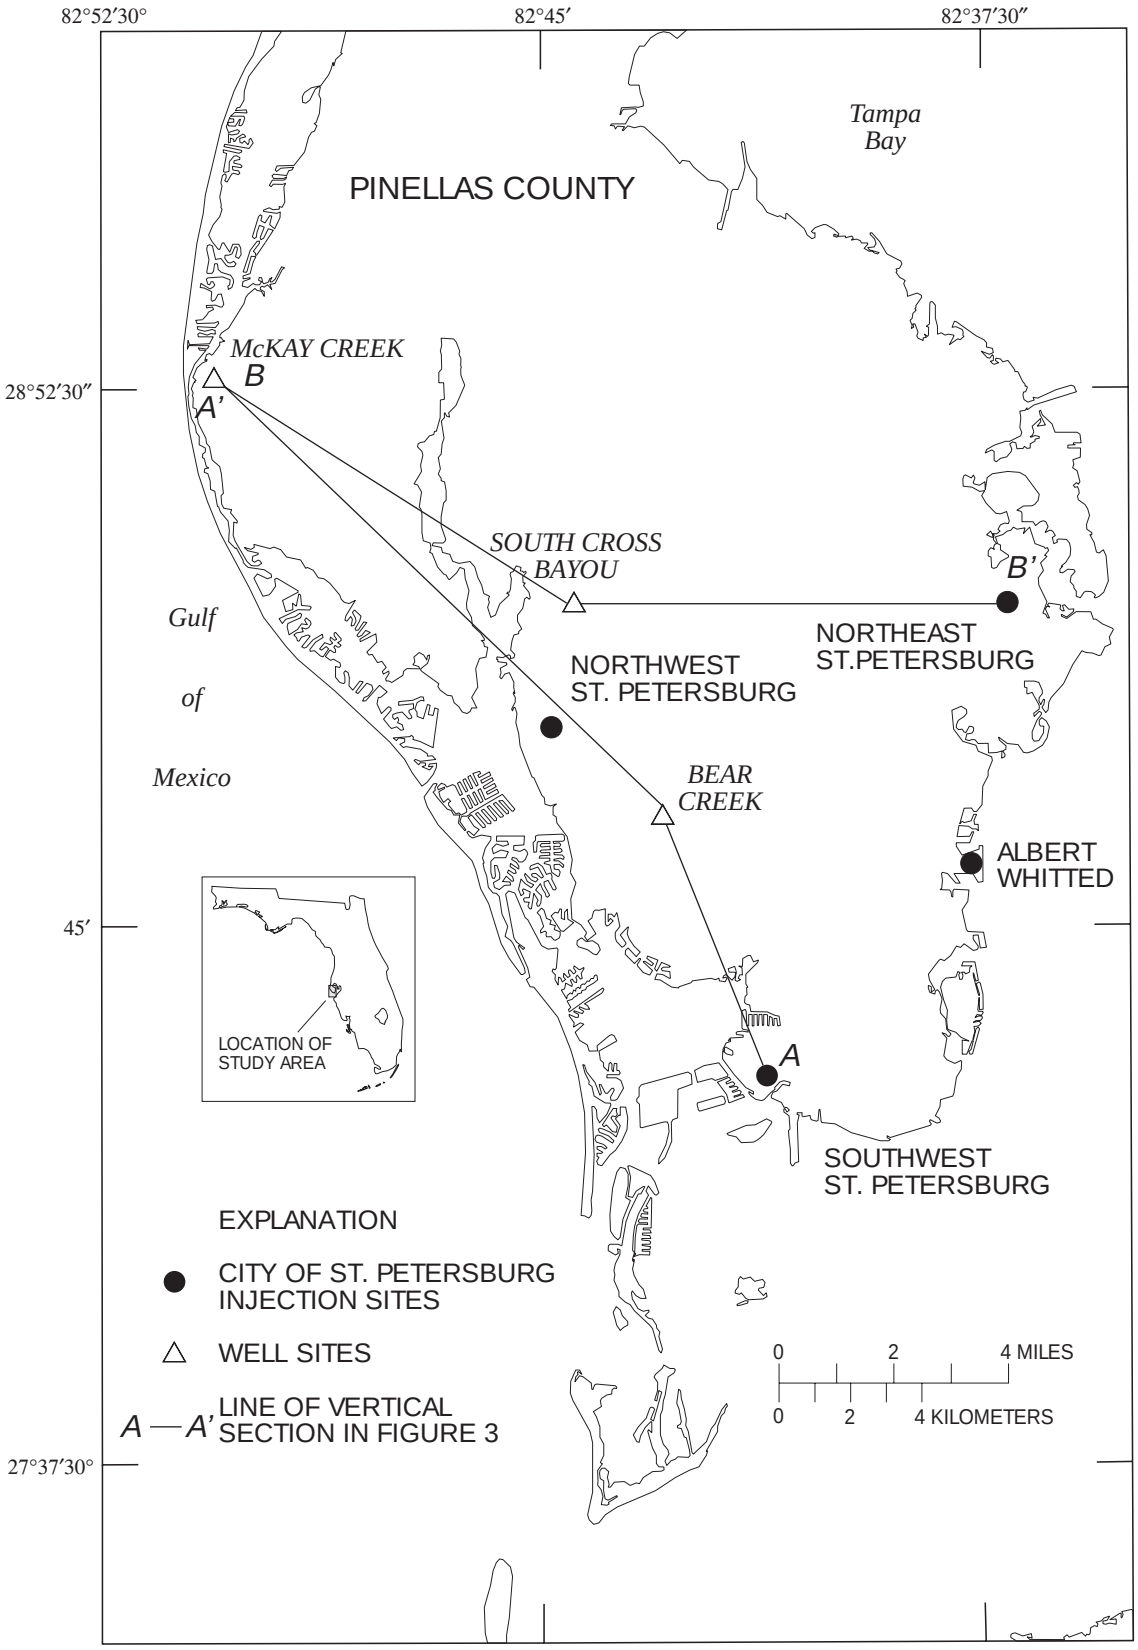

Figure 1. Location of study area, injection sites, and lines of vertical sections.

Freshwater meets the DS concentration limit for potable water. Slightly saline water is nonpotable, but it may be suitable for irrigation. Moderately saline water is suitable for desalinization, and very saline water and brine are considered unusable.

Purpose and Scope

This report presents the results of a study conducted to provide a better understanding of the potential for SSR in a moderately transmissive, slightly to moderately saline-water bearing, limestone aquifer underlying St. Petersburg. Specifically, the objectives are (1) define the hydrogeologic framework and quality of ground water, (2) determine the geochemical interactions associated with SSR, and (3) illustrate the application of a solute-transport model as a tool for understanding the relative importance of individual physical properties and operational variables on recovery efficiency. The scope of the study is limited to a preliminary analysis because no data exist for comparison with model results.

Information on the hydrogeologic framework, hydrologic properties, matrix properties, and water chemistry of the aquifer system was compiled from files of the USGS and from engineering reports of the city's four WRF injection well sites.

The possibilities for geochemical interactions between the injected and aquifer waters were evaluated using aqueous speciation (WATEQF) and chemical mass-balance (PHREEQE) models (Plummer and others, 1976; Parkhurst and others, 1980). The models were used to assess the potential for both precipitation and dissolution of certain carbonate minerals.

The three dimensional heat-and solute-transport model (HST3D), developed by Kipp (1987), was used to simulate a typical injection/recovery well system. Injection and withdrawal in a prototype aquifer were simulated and recovery efficiency was computed. The model was used to assess the relation of recovery efficiency to various aquifer and fluid properties and to simulate recovery efficiencies under selected hypothetical operational schemes.

HYDROGEOLOGIC FRAMEWORK

The hydrogeologic units beneath the study area consist of a thick sequence of carbonate rock overlain by clastic deposits. The sediments are subdivided into a sequence of discrete lithologic units that form a layered sequence of two aquifers and one confining unit. The framework includes the unconfined, surficial aquifer and the confined, Floridan aquifer system (fig. 2). The units are separated by the intermediate confining unit.

Surficial Aquifer

The surficial aquifer is the uppermost water bearing formation. It consists of undifferentiated sands and clays that vary in composition both laterally and vertically. The aquifer is a source of recharge to the Floridan aquifer system and is mainly used as a source of water for lawn irrigation. The surficial aquifer is generally less than 30 ft thick and is generally saturated to within 10 ft of land surface during dry weather. During wet weather, the water table in the surficial aquifer is generally close to land surface. The surficial aquifer has a horizontal hydraulic conductivity ranging from 13 to 33 ft/d and a vertical hydraulic conductivity ranging from 0.3 to 13 ft/d (Cherry and Brown; 1974; Sinclair, 1974; Hutchinson and Stewart, 1978).

Intermediate Confining Unit

The intermediate confining unit of low-permeability lies between the surficial aquifer and the Floridan aquifer system. The unit coincides with the undifferentiated Arcadia Formation of the Hawthorn Group and consists of a clastic and carbonate sequence. The carbonates in the sequence are generally underlain and overlained by clays and marls of relatively low permeability (Hickey, 1981). Thickness of the intermediate confining unit averages about 90 ft and ranges from about 50 to 140 ft. The confining unit is highly variable both spatially and vertically. A wide range of hydraulic characteristics occurs within the unit due to lithologic heterogeneity within the unit. Vertical hydraulic conductivity for the intermediate confining unit as reported by Sinclair (1974) and Black, Crow, and Eidsness, Inc. (1978) ranges from 1.3×10^{-4} to 6.9×10^{-3} ft/d.

Floridan Aquifer System

The Floridan aquifer system is a thick, regionally extensive sequence of Tertiary age carbonates. Miller (1986) defines the Floridan aquifer system to include the Upper Floridan aquifer, the middle confining unit, and the Lower Floridan aquifer. In the study area, the

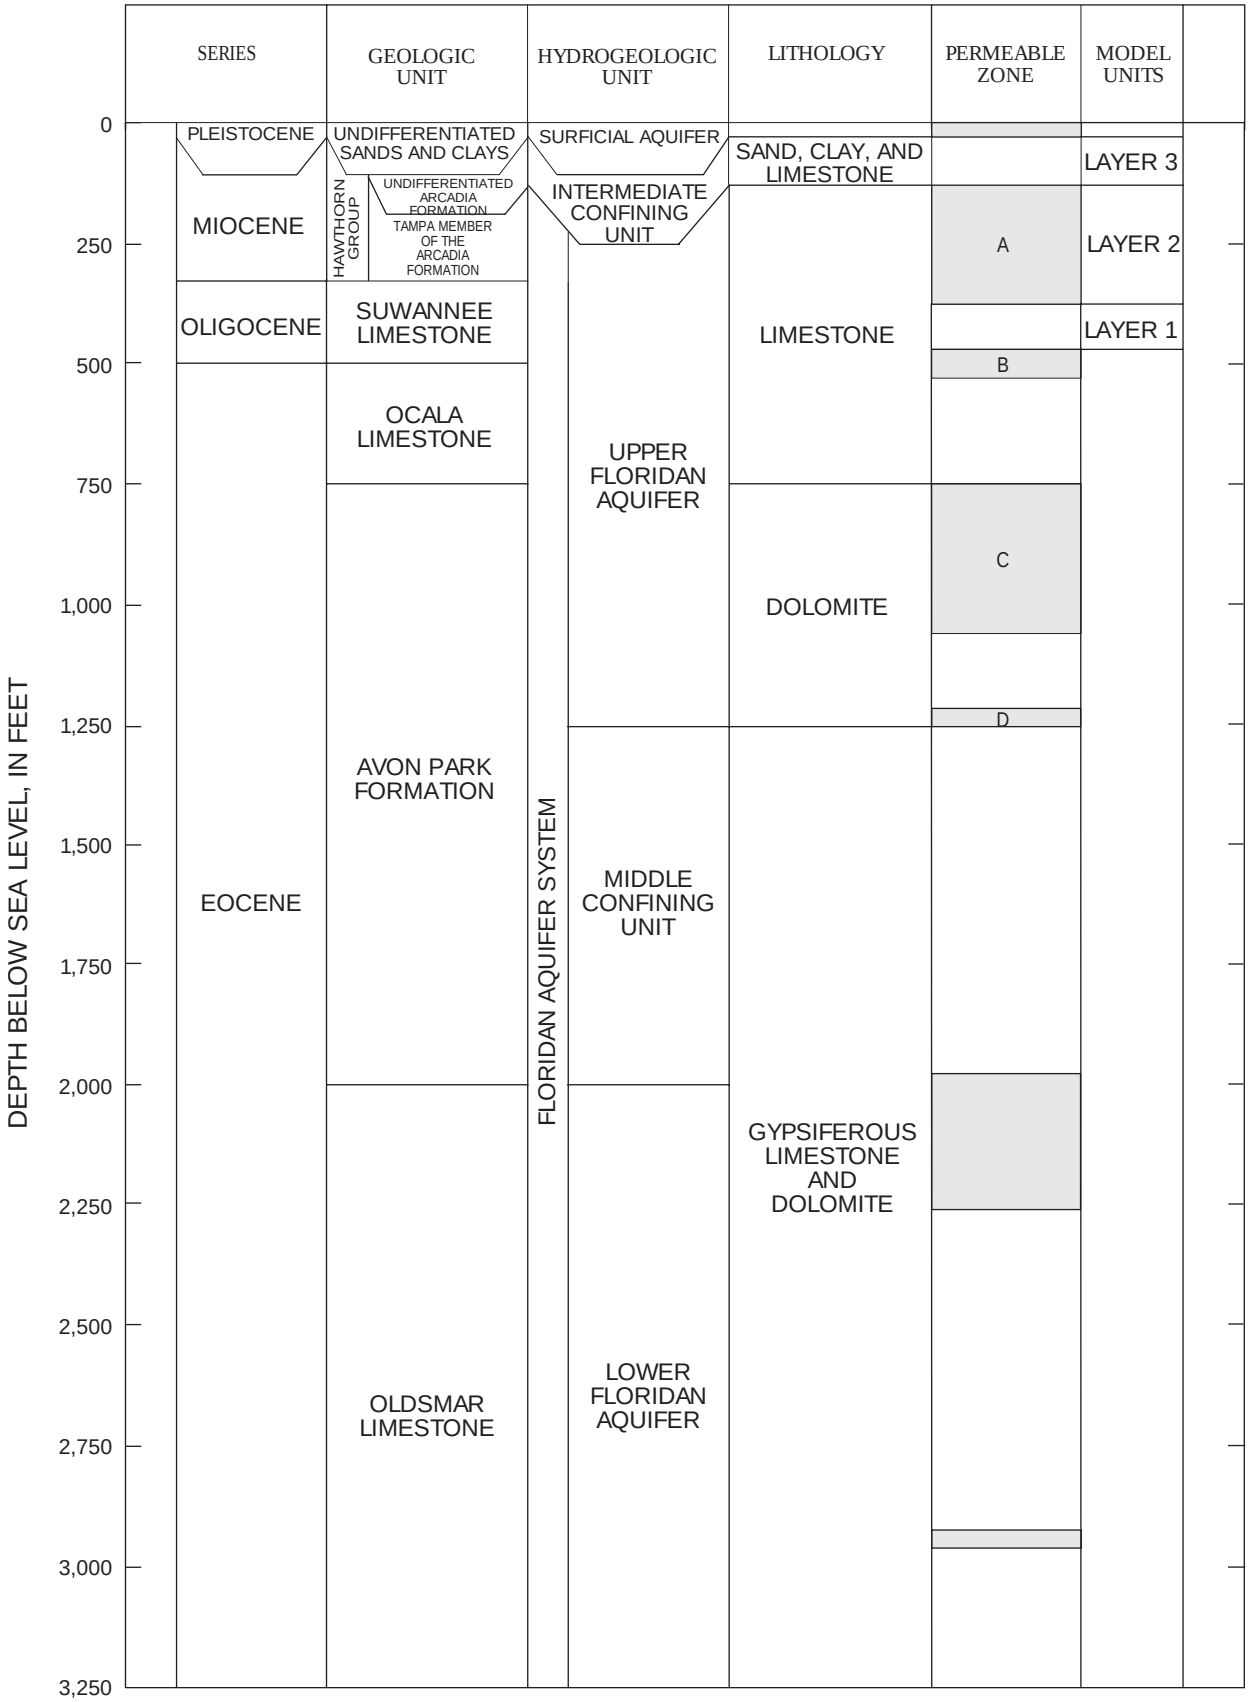

Figure 2. Generalized stratigraphic and hydrogeologic section, Pinellas County. (Modified from Hickey, 1982.)

middle confining unit and the Lower Floridan aquifer contain water comparable to seawater; the base of the freshwater flow system is limited to the Upper Floridan aquifer. The geologic formations that make up the Upper Floridan aquifer consists of limestone and dolomite rocks of, in ascending order, the Avon Park Formation, the Ocala and Suwannee Limestones, and the Tampa Member of the Arcadia Formation of the Hawthorn Group. The top of the Upper Floridan aquifer is defined as the first occurrence of a persistent carbonate sequence; the base of the Upper Floridan aquifer is defined as the first occurrence of interbedded gypsum in the carbonates below a dark-brown, microcrystalline dolomite in the Avon Park Formation (Hickey, 1982). In St. Petersburg, the Upper Floridan aquifer is subdivided into four permeable zones separated by semiconfining units (Hickey, 1982). The zones are alphabetically labeled with increasing depth from A to D (fig. 2). This study is concerned only with the uppermost producing zone of the Upper Floridan aquifer (zone A) , the overlying confining unit, and the underlying semiconfining unit between zone A and B, and further discussion will be restricted to these units.

Zone A

Zone A comprises the Tampa Member of the Arcadia Formation of the Hawthorn Group and the uppermost part of the Suwannee Limestone. Zone A is the shallowest and freshest of the producing zones and is the only potential receiving zone for SSR in St. Petersburg. Thickness of zone A averages about 180 ft and ranges from about 115 to 245 ft. Thickness varies from site to site, occurring with no regional pattern (Hickey, 1982). Geraghty and Miller, Inc. (1976), Robertson and Mallory (1977), Black, Crow, and Eidsness, Inc. (1978), Hickey (1982), and Brown and Associates (1986) reported values of transmissivity for zone A that ranged from 2.2×10^4 to 3.5×10^4 ft^2/d and values of storativity that range from 4×10^{-4} to 8×10^{-4}. Average values of porosity of zone A , estimated from geophysical logs, are 26, 32, and 41 percent (Hickey, 1982).

Semiconfining Unit Between Zones A and B

Underlying zone A (the uppermost permeable zone) is the first of a series of poorly transmissive carbonate rock that acts as semiconfining units that separate permeable zones. The existence of the semiconfining units was determined during previous studies by Hickey (1982). The semiconfining unit below zone A is in the limestone unit of the Suwannee Limestone. Thickness of the semiconfining unit averages about 150 ft and ranges from about 125 to about 170 ft. Average porosity of the semiconfining unit from geophysical logs is about 30 percent and ranges from 22 to 36 percent (Hickey, 1982). The semiconfining unit is considered a nonproducing zone in St. Petersburg.

Vertical hydraulic conductivity of the semiconfining unit between zones A and B, determined from laboratory and aquifer tests reported by Hickey (1982), ranges from 1.3×10^{-3} to 2.6 ft/d. The value of 1.3×10^{-3} ft/d was determined from a laboratory test of a limestone core from the northeast St. Petersburg WRF where a higher percentage of clay occurred in the limestone matrix than at other sites in St. Petersburg. Test results at southwest St. Petersburg WRF and South Cross Bayou indicate that a value of less than 0.1 ft/d probably is not representative of general conditions (Hickey, 1982). Comparison of aquifer and laboratory tests indicate that the plausible range of vertical hydraulic conductivity applicable to semiconfining units that do not contain clay would be in the range of 0.1 to 1.0 ft/d (Hickey, 1982). For the semiconfining beds that contain clay between zones A and B, the vertical hydraulic conductivity could be on the order of 10^{-2} to 10^{-3} ft/d.

Data from Black, Crow, and Eidsness (1978) collected at the southwest St. Petersburg WRF injection site, show little difference between vertical and horizontal hydraulic conductivity in the semiconfining units. This data agrees with Stewart's (1966) data from equivalent strata in Polk County, which also show little or no difference between vertical and horizontal conductivity.

WATER QUALITY

Freshwater, saltwater, and a mixture of the two occur in the rocks underlying St. Petersburg. Saline ground water predominates; freshwater typically occurs as a thin layer above the saltwater. Freshwater is maintained by recharge from rainfall that infiltrates the rocks underlying St. Petersburg. Sources of saline ground water are probably the Gulf of Mexico, Tampa Bay, and residual seawater from the geologic past (Hickey, 1982). Hydrodynamic dispersion or mechanical mixing is the dominant process associated with the spreading of the solute.

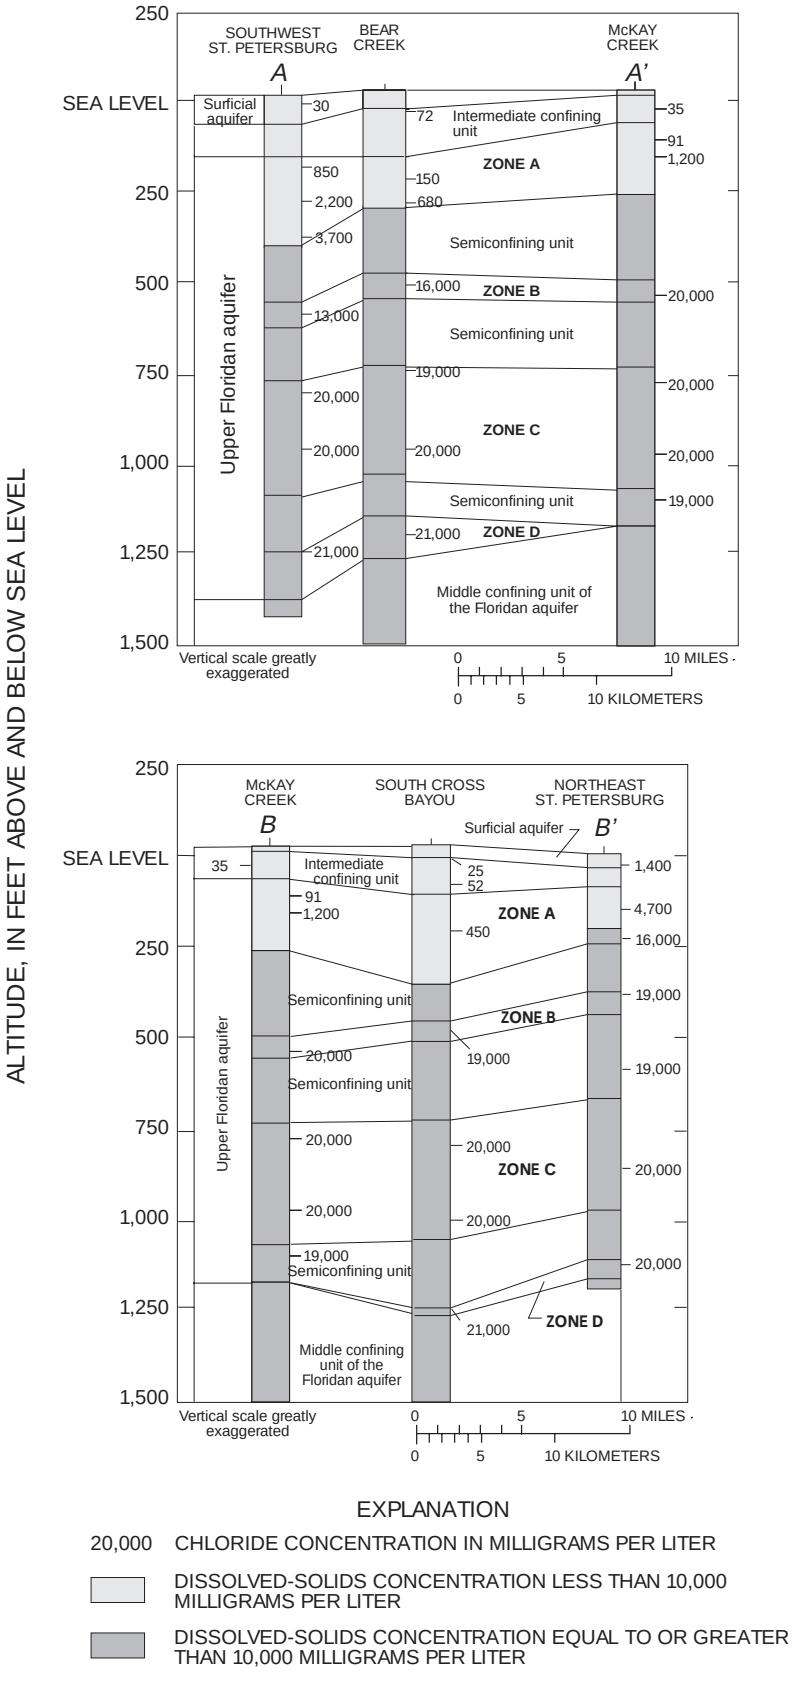

Figure 3. Vertical sections A-A' and B-B' showing chloride and dissolved-solids concentration in ground water. (Modified from Hickey, 1982.)

Native Ground Water

Water within the Upper Floridan aquifer is more mineralized than water from the surficial aquifer. Figure 3 shows vertical and lateral profiles of chloride and dissolved solid concentrations in ground water along lines A-A' and B-B'. Chloride concentrations in water from the surficial aquifer range from 30 to 1,400 mg/L. Chloride concentrations in water from zone A range from 91 to 16,000 mg/L and in water from zones B through D from 13,000 to 21,000 mg/L. Water in zones C and D is comparable to seawater.

The salinity of water within rocks comprising zone A varies both vertically and areally. Freshwater, where present, is typically in a thin lens at the top of the zone. Dissolved-solids concentrations increase with depth. Ground water near the coastal margins of St. Petersburg have higher concentrations in both the upper and lower parts of zone A. The vertical variation in water quality suggests that water in zone A is density stratified (Hickey, 1982).

Water-quality characteristics of zone A at each of the city's four WRF's are shown in table 1 (CH2M Hill, 1993). Most water in zone A is slightly to moderately saline with DS concentrations ranging from 2,520 to 32,900 mg/L. Waters of zone A generally are a sodium choride type (fig. 4).

Effluent

Effluent at each of the city's four WRF's is aerated, filtered, and chlorinated reclaimed wastewater. The water quality of the effluent is variable due to differences in the influent (incoming waste) and the treatment processes at each WRF (table 1). The average pH is about 7 and the effluent contains low concentrations of suspended solids (less than 3.0 mg/L). The DS and chloride concentrations range between about 400 to 900 mg/L and about 125 to 350 mg/L, respectively. All waters are a sodium chloride type (fig. 4).

Geochemical Interactions

The injection of water into an aquifer having water of different quality than the injected water may change local conditions, resulting in geochemical interactions that lead to changes in water-quality and aquifer properties. Mixing of two waters of different chemical character may produce chemical reactions that could precipitate minerals, thus, reducing transmissivity and porosity; dissolve minerals, thus, increasing transmissivity and porosity, or the injected water may be in equilibrium with the aquifer minerals and native water, resulting in no chemical reactions.

The potential for a chemical reaction can be determined by calculating the chemical equilibrium of the injected and aquifer waters. The equilibrium state of the water with respect to a mineral phase can be determined by calculating a saturation index (SI) using analytical data. The SI is defined as the logarithm of the ratio of the ion activity product to the mineral equilibrium constant at a given temperature. If SI is equal to zero (0), the water is in equilibrium with the mineral; if it is less than 0, the water is undersaturated and if present, that mineral will dissolve; if the ratio is greater than 0, the water is supersaturated and mineral precipitation would be possible. Because of uncertainties in analytical and thermodynamic constants, a water with a SI value between 0.1 and -0.1 is assumed to represent saturation conditions or is in equilibrium with respect to the mineral phase (Swancar and Hutchinson, 1992).

The SI for the resident native waters and for the effluent, with respect to minerals commonly found in carbonate aquifers, was calculated using the computer program WATEQF (Plummer and others, 1976) and values are given in table 1. The values in table 1 show that most of the native ground water is saturated to supersaturated with respect to calcite and dolomite, and undersaturated with respect to the remaining minerals. The ground-water sample for the northeast WRF was undersaturated with respect to calcite and dolomite. This water has a very high concentration of DS and probably is residual seawater. The effluent is undersaturated with respect to all minerals; therefore, these waters apparently could dissolve minerals including calcite and dolomite, the principal minerals that compose carbonate aquifers.

The mass-balance model PHREEQE (Parkhurst and others, 1980) was used to simulate the geochemical reactions that may occur when effluent is mixed with native ground waters. PHREEQE is a generalized aqueous speciation, solubility, mass-transfer computer code that can simulate several types of reactions including the mixing of two waters of different chemical compositions. Modeled reactions were evaluated based on the equilibrium state of a 50 percent mix of the two water types with respect to selected mineral phases. Two simulations were made: The first model run simulated effluent from the Albert Whitted WRF entering the aquifer monitored by well MW-3. The second model run simulated effluent from the southwest WRF entering the aquifer monitored by well B-5. Results of the simulations indicate that the mixed effluent and ground water would be undersaturated with respect to all minerals (table 2). These data infer that the injected effluent, upon entering the aquifer and mixing with the aquifer waters, may dissolve calcite and dolomite. This process could produce a more porous limestone with increased transmissivity.

Table 2. Selected saturation indices from PHREEQE model results

SIMULATION OF SUBSURFACE STORAGE AND RECOVERY OF TREATED EFFLUENT

A finite-difference cylindrical-flow model of ground-water movement and solute transport was used as a simulation tool to determine the recovery efficiency of a prototype SSR system for a moderately transmissive, slightly to moderately saline aquifer, underlying St. Petersburg. Specific questions to be answered are: (1) In what quantitative fashion will the physical and operational variables influence recovery efficiency?, and (2) Will recovery efficiency improve when SSR is conducted as a multiple-cycle operation?

To answer these questions, HST3D was used to simulate a well in a hypothetical hydrogeologic section representing St. Petersburg. The analysis implemented a conceptual modeling approach (Merritt, 1985), in comparison to a calibration and predictive approach (Merritt,1994), as no data exist for comparison with model results. This type of analysis permitted many combinations of conditions that could be investigated using parameters generally similar to those of the aquifer system underlying St. Petersburg. Sensitivity tests were used to examine the response of the model to a range of hydrogeologic and fluid properties and the effect of various injection/withdrawal schemes on the recovery efficiency of the SSR system.

Numerical Model

The HST3D model (Kipp, 1987) is a computer program written in FORTRAN-77 that simulates variable density fluid movement and transport of either dissolved substances or energy in the subsurface. The model, as used in this report, solves for two interdependent variables: pressure and mass-fractional concentration in cylindrically symetrical coordinates under isothermal conditions. Backward-in-space and backward-in-time finite-difference equations were used for solution of ground-water flow and the solute-transport equations in the numerical model. The reader is referred to Kipp's (1987) report for a complete discussion of the model code and numerical methods.

Design of Base Model

A base model used as a standard for comparisons for subsequent sensitivity analyses was designed to be representative of the slightly to moderately saline artesian limestone aquifer underlying St. Petersburg. Hydraulic and solute properties used in the model are representative of the city's four WRF injection sites and, as such, do not represent any specific location in St. Petersburg. Data were obtained from previous studies and laboratory values reported in text books.

To apply the HST3D model, the hydrologic and hydrogeologic characteristics of the aquifer system in St. Petersburg was simplified into the rectangular section in figure 5. The cylindrical-flow base model simulates the intermediate confining unit, permeable zone A, and the lower semiconfining unit. It consists of 26 variable-width node spacings in the vertical direction and 88 variable-width node spacings in the radial direction. The model dimensions are 2,500 horizontal ft and 420 vertical ft. The vertical spacing ranges from 10 to 50 ft. Radial spacing expands logarithmically from 0.14 ft at the well up to a maximum of 50 ft. The base model was used as the reference for sensitivity testing.

Several simplifying assumptions were made in the conceptualization and simulation of the flow system:

1. The aquifer system is homogeneous and isotropic in all directions,
2. Hydrostatic conditions initially prevail,
3. Regional horizontal and vertical flow is negligible,
4. A uniform native fluid density exists within each model layer,
5. The water-quality profile is laterally homogeneous throughout the model area,
6. The viscosities of the injected and native fluids are the same, and
7. Dispersivity is constant throughout each model layer.

Model Parameters

The strategy for the model analysis was to choose parameter values that, even though nonunique, would approximate conditions representative of the system so that the major processes affecting the mass fraction distribution during injection and withdrawal would be simulated. The parameters simulated in the model include boundary conditions, matrix properties, fluid properties, and well characteristics. A description of each model parameter follows:

1. Boundary conditions.--Boundary conditions are used to constrain the lateral and vertical extent of the simulated flow system providing a simplified representation of the flow and transport processes at the model limits. The top and bottom boundaries of the model are specified pressure boundaries because the producing zones are very permeable relative to the entire Floridan aquifer system (Knochenmus and Thompson, 1991). Pressure on the upper boundary is set at 12.967 lb/in^2, equivalent to the pressure exerted from an overlying 30 ft column of freshwater presumed to exist in the overlying hypothetical surficial aquifer. Pressure on the lower boundary is 195.719 lb/in^2, equivalent to the pressure exerted from a 450-ft column of freshwater and saline water presumed to exist in the overlying formations. The inner radial edge is defined by

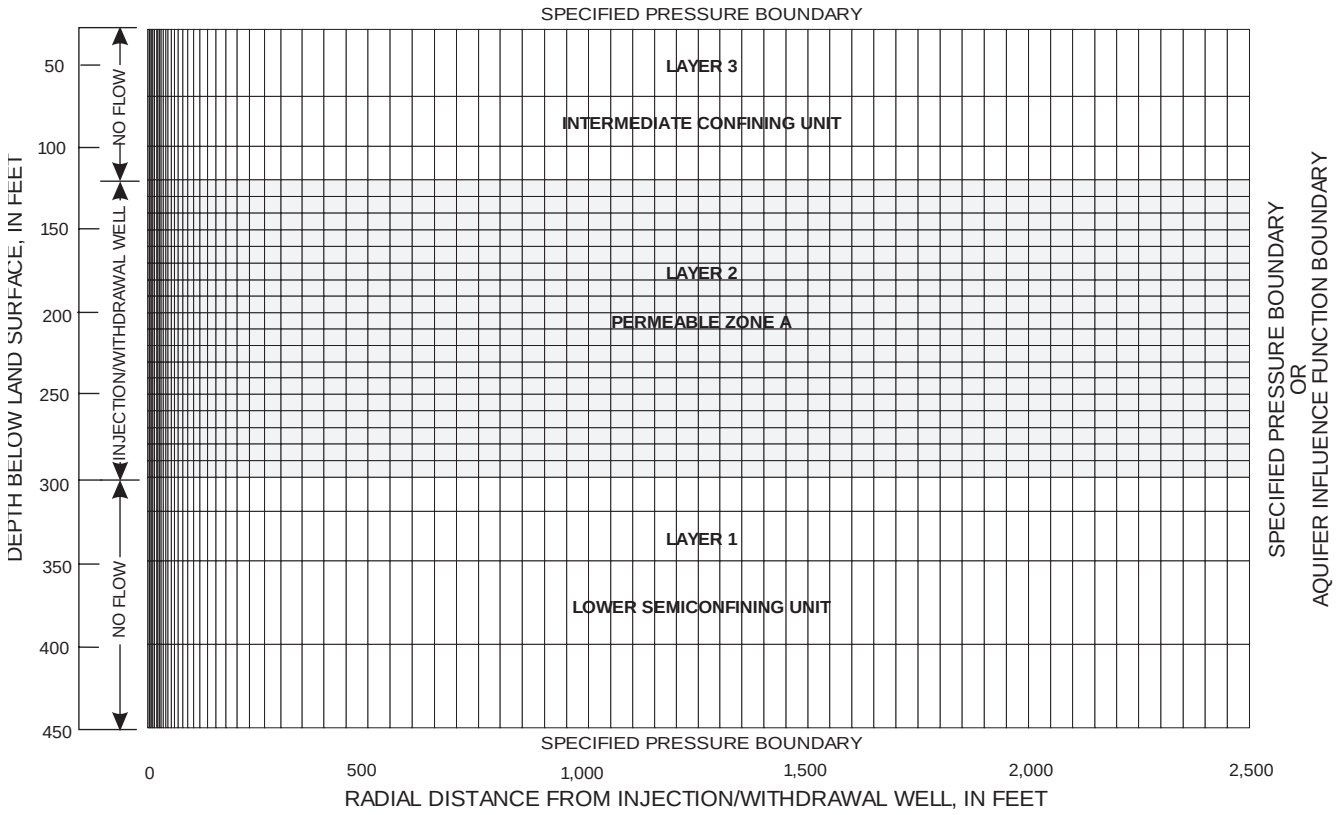

Figure 5. Radial-model grid, boundary conditions, and model layering.

the injection/production well in zone A and a no-flow boundary condition for the confining units above and below the well. The outer radial edge is specified pressure for the single 30-day test cycle and hydrostatic pressures at each node are based on a column of water having DS concentration specified as a function with depth. Water that enters the section at a given node as a result of a pressure gradient at the boundary is of specified concentration; water that exits at such a node is of ambient aquifer concentration. For the multiple-test cycles, the outer radial edge is defined by a transient flow, aquifer influence function (AIF). AIF utilizes the Carter-Tracy approximation (Kipp, 1987) to compute flow rates between the inner gridded aquifer region and an infinite homogeneous outer region where aquifer properties are known only in a general sense. The radius of the inner region was set at 2,500 ft and the outer region is modeled as an infinite cylinder with a height of 420 ft. Initial hydrostatic pressures throughout the model were set based on the boundary conditions.

2. Matrix properties.--Matrix properties are defined for each of the three hydrogeologic layers for the model in table 3. The porous media properties are intrinsic permeability, matrix compressibility, effective porosity, longitudinal dispersivity, and transverse dispersivity. Intrinsic permeability was calculated from hydraulic conductivity values reported by Hickey (1982), with conversion factors from Freeze and Cherry (1979, p. 29). Values of hydraulic conductivity and matrix compressibility were based on aquifer tests and laboratory tests of limestone samples collected during previous studies. The value of porosity used in this model, 0.3, is an estimate based on geophysical logs at the WRF injection sites in St. Petersburg. Longitudinal (α_L) and transverse (α_T) dispersivities of the system were set at 12.5 ft and 2.5 ft, respectively. Even though the spatial gridding stability rule-of-thumb criteria recommended in Voss (1984, p. 232), suggest that α_L and α_T be greater than one-fourth and one-tenth of the radial and vertical spacings, an acceptable solution was computed using an α_T value equal to 2.5 ft.

Table 3. Fluid and matrix properties assumed for simulation

[^{o}F, degrees Fahrenheit; lb/ft^3, pounds per cubic foot; in^2/lb, inch squared per pound; ft^2/d, foot squared per day; ft/d, foot per day; ft^2; foot squared]

Parameter	Lower semi-confining unit	Zone A	Intermediate confining unit

Scaled mass fraction	1.0	0.25	0.025
Matrix properties			
Hydraulic conductivity (ft/d)	1.0	167.0	8.0E^{-4}
Intrinsic permeability (ft^2)	3.877E^{-12}	6.475E^{-10}	3.102E^{-15}
Porosity (unitless)	0.3	0.3	0.3
Longitudinal dispersivity (feet)	12.5	12.5	12.5
Transverse dispersivity (feet)	2.5	2.5	2.5
Matrix compressibility (in^2/lb)	6.2E^{-6}	6.2E^{-6}	6.2 E^{-6}

3. Fluid Properties.-- The fluid properties of the native formation water assumed for the simulations are listed in table 3 and include temperature, specific weight, viscosity, compressibility, molecular diffusivity, and DS expressed as scaled-solute mass fraction (SSMF). The model was simplified with the assumption of a vertically uniform initial DS concentration distribution assigned to each layer although a vertical salinity gradient has been documented. Isothermal conditions at 75^{o}F were assumed to prevail. Fluid densities assigned to injected and native waters were based on the measured or estimated concentration of DS in each fluid. Viscosity of the injected and native formation waters vary with temperature and solute fraction. Because isothermal conditions were assumed to prevail and because the viscosity of freshwater and saltwater differ by only 0.06 centipose, viscosity was assumed invariant in the simulations. The assigned value of viscosity was held constant at 0.8904 centipose (viscosity of pure water at 75^{o}F). Compressibility of water was held constant at 3.03x10^{-6} in^2/lb (Freeze and Cherry, 1979, p. 52), and molecular diffusivity of the solute in the porous media was set at 9.30x10^{-5} ft^2/d (Kimbler and others, 1975). The model SSMF is a dimensionless relative solute-concentration term ranging in value from 0 to 1. Any fluids present within the aquifer system, or entering it in simulation exercises, are considered to be a mixture of the two fluids by the appropriate specification of SSMF values. SSMF = 0 was used to represent pure freshwater, and SSMF = 1 represents the most saline water residing within the aquifer system, that in the lower confining unit. The assigned densities of 62.241 lb/ft^3 (SSMF = 0) and 63.177 lb/ft^3 (SSMF = 1) at 75^{o}F and atmospheric pressure were obtained from a standard handbook (Chemical Rubber Company, 1982). The SSMF values of the injected effluent, the water of the aquifer system, and water in mixtures of effluent and native formation waters are assigned based on their salinity relative to the two extremes. SSMF values of 0.025 (500 mg/L DS) and 0.25 (5,000 mg/L DS), representing the composite background water quality collected at the WRF injection sites, were assigned to the intermediate confining unit and zone A, respectively, based on the ratio of DS concentration to the estimate DS concentration of the lower confining unit. Measured injected-water DS concentration was about 700 mg/L and was assigned a SSMF value of 0.035.

4. Well information.--The well occurs at the first column of nodes and the open-hole interval of the well is defined by row numbers. Injection and withdrawal of effluent is through 18 nodes distributed vertically which, when combined, represent permeable zone A (180-ft interval). Injection and withdrawal flow at the well bore is allocated over rows 5 to 23 by mobility factors that are based on cell position, relative hydraulic conductivity, and an element completion factor. An element completion factor of 0 means the well is cased off from the aquifer in that element, whereas an element completion

factor of 1 means equivalent flow across the cell length.

Effects of Hydrologic Parameter Variations on Recovery Efficiency

When the results of a simulation study are largely based upon assumed estimates of data rather than measured data, as in this case, determining the effect of parameter variations on simulation results is of particular interest. To learn which properties and conditions substantially affect recovery efficiency, a series of simulation runs were made that started with the base model. For each simulation run, the value of an individual model parameter was changed by an amount that it might reasonably be expected to vary from the value used in the base simulation, then noting the change in recovery efficiency as a result of the change. The base simulation used as a standard for comparison consisted of a single cycle of 15 days of injection of effluent at a rate of 1.0 Mgal/d at a temperature of 75°F and a maximum of 15 days of withdrawal at a rate of 1.0 Mgal/d. Thus, one injection/withdrawal cycle is completed in 30 days. Withdrawal was assumed to end when the increasingly saline water exceeded the maximum DS concentration (1,500 mg/L) deemed acceptable for irrigation use. For the base model, a DS concentration of 1,500 mg/L was reached in 3 days. The recovery efficiency calculated for the base model single 30-day cycle simulation is 20.0 percent.

The effect of parameter changes on recovery efficiency is presented in the following sections. Discussion of individual parameters is ordered from most to least sensitive.

Resident Fluid Dissolved-Solids Concentration of Zone A

A series of sensitivity tests were used to show the relation between recovery efficiency and resident fluid DS concentration of the injection zone (zone A). Two resident fluid DS concentrations of zone A were selected for comparison with the 5,000 mg/L base value: (1) 2,300 mg/L, an arbitrary value representing water somewhat less saline than the composite base value, and (2) 20,000 mg/L, representing the most saline layer in the model. Relations were established for a range of α_L and α_T combinations. DS concentrations simulated for the base model were 500 mg/L for the intermediate confining unit, 5,000 mg/L for zone A, and 20,000 mg/L for the lower semiconfining unit.

Because of the lack of local field data to indicate the degree of dispersion in the carbonate system, three additional dispersion values (sets of longitudinal α_L and transverse α_T dispersivities representing some hypothetical degree of dispersion) were chosen to compare to the dispersion used in the base model. The additional dispersion values used for analysis are summarized below:

Dispersion value set	α_L (ft)	α_T (ft)
1	4.0	1.0
2	25.0	1.0
3	25.0	5.0

Dispersion value set 1 is a low degree of dispersion in the radial flow direction and a low degree of interlayer dispersion. Value set 2 introduces an appreciable degree of dispersion in the radial flow direction. Value set 3 represents appreciable degrees of dispersion in the radial flow direction and between layers.

Figure 6a shows the decline of recovery efficiencies with increasing resident fluid DS concentration for the various dispersivity combinations. The larger the DS difference between the injected water and resident formation water, the less efficient the SSR process. Recovery efficiency was shown by the model to be significantly less in aquifers of high salinity than in slightly saline aquifers. With higher resident fluid DS concentration, less water within the zone of mixing is acceptable for withdrawal. Higher DS concentrations also make density stratification of the fluids more likely to occur at a given permeability level, decreasing recovery efficiency. Recovery efficiency was shown to be greater when the level of dispersive mixing decreased, or such as when a smaller volume of injected fluid combines with more saline native formation water. Thus, recovery efficiency is most promising when resident fluid DS concentrations are low, and least promising when DS concentrations are high.

Dispersivity

Dispersivity is a scale-dependent property of the porous medium that controls the mixing of injected and resident formation fluids at their interface. When dispersivities are increased, there is more mixing that results in a widening of the transition zone between the injectant and native formation waters.

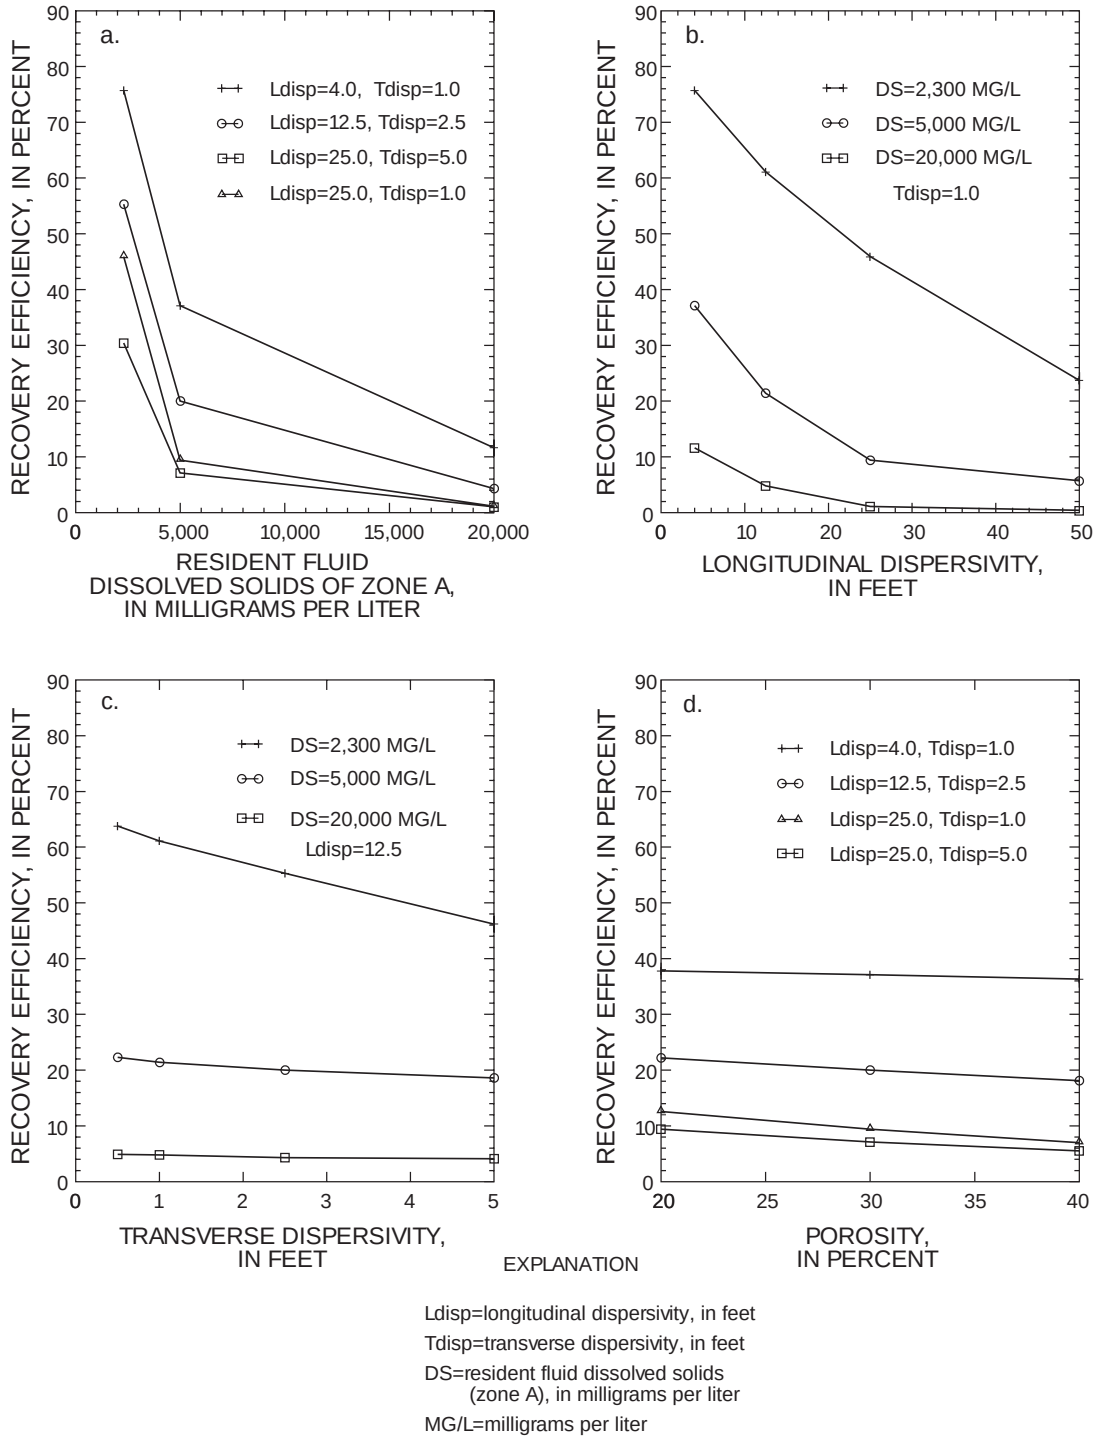

Figure 6. Relation between recovery efficiency and variations in selected model parameters.

Dispersion is a deleterious process that can severely limit recovery efficiency. Merritt (1985) reported that recovery efficiency is limited when the upper limit of the concentration of some constituent considered acceptable in recovered water is less than half of the average concentration of the injected and native formation waters. In the hypothetical test case posed in this analysis, the acceptable limit for DS concentration (1,500 mg/L) was equal to or less than the average of the injected water (700 mg/L) and the native water (2,300 to 20,000 mg/L).

Various values of dispersion in the direction of flow (longitudinal) and interlayer (transverse) were tested. Values of α_L were varied between 4 and 50 ft with respect to 12.5 ft in the base model, and values of α_T were varied between 0.5 and 5.0 ft with respect to 2.5 ft in the base model, when the rate and duration of injection and withdrawal was kept constant.

Figure 6b and c illustrates the results from the analysis for the three previously cited resident fluid DS concentrations (2,300, 5,000, and 20,000 mg/L). Results show the decline of recovery efficiency as the dispersivity value increases. A large decrease of recovery efficiency is shown as α_L increases from low values of α_L, but the rate of decrease is small at larger values of α_L. Recovery efficiency was slightly affected by changes in α_T at low ranges of the parameter but at higher ranges, recovery efficiency was relatively unaffected by its variation. Evidently, for every resident fluid TDS concentration, there are values of α_L and α_T above which recovery efficiency is significantly reduced

Porosity

Porosity of the injection zone (zone A) was tested at 0.2 and 0.4 to bracket the base model value of 0.3. Permeability and porosity control the velocity of injectant flow and, hence, the rate of solute transport. The greater the porosity, the slower the solute front will move; thus, the longer the time it takes to replace the volume of native formation water in a given volume of aquifer and the greater the dispersive mixing. Low porosity has the opposite effect.

Figure 6d illustrates the variation of recovery efficiency due to porosity changes in relation to the four previously cited dispersivity combinations. Increasing porosity caused recovery efficiency to decrease slightly for each dispersion model. Recovery efficiency decreased significantly, however, as the level of dispersive mixing increased.

Horizontal and Vertical Permeability of Zone A

The permeability of the aquifer material and the density contrast of the injected and native water determines whether an appreciable level of density stratification or buoyancy flow can occur. Density stratification refers to the physical process in which less dense injected fluid rises and flows over the more dense fluid. Generally, low permeability reduces stratification and optimizes recovery efficiency.

Values of horizontal (k_h) and vertical (k_v) permeability were changed simultaneously by the same factor that ranged from 0.1 to 10, with all other parameters remaining the same. The ratio of k_h to k_v was held to 1. Results of the simulations are as follows:

k_h and k_v (multiplier)	Recovery efficiency (percent)
0.5	19.8
1.0	20.0
2.0	19.5
5.0	15.7
10.0	7.7

When permeability was doubled or halved, recovery efficiency was not affected. The major effect of the variation at these permeability values was the wellhead pressure required at the specified injection/withdrawal rate. However, when permeability was made 10 times greater, recovery efficiency was reduced by 61.5 percent. This is because simulation of a larger permeability allowed for easier horizontal and vertical transport of the injected fluid, which resulted in greater stratification and buoyancy flow that prevented complete mixing of the injected water with the native water. Upon withdrawal, a greater percentage of native water was immediately available to the well.

Ratio of Horizontal to Vertical Permeability

If flow conditions vary with direction in a geologic formation, the formation is anisotropic and differences in horizontal (k_h) and vertical permeability (k_v) can influence fluid movement. The greater the anisotropy ratio (k_h/k_v), the easier the salt front moves along the axis with the larger permeability component which contains the injected water within the open interval of the injection well. In the base model, permeability is equal in all directions. Anisotropy in the model only can be simulated by varying the ratio of k_h to k_v. To test for the effects of anisotropy on model results the ratio of k_h to k_v was varied from an isotropic base condition ($k_h/k_v = 1$) to kh/kv equal to 100. Results of the simulations are as follows:

k_h/k_v	Recovery effciency
1	20.0 percent
10	21.9 percent
100	23.6 percent

Simulation of different values of k_h/k_v had a small affect on computed recovery efficiencies. Increasing k_h/k_v caused recovery efficiency to increase slightly. This is because simulation of a larger k_h/k_v causes more lateral flow and inhibits upward movement of buoyant injectant.

Effects of Operational Factors on Recovery Efficiency

The success of a SSR system is determined by the quantity of injected water that can be recovered from an aquifer. The sensitivity analyses indicated the physical and chemical parameters that substantially affect recovery efficiency. In addition to these parameters, operational factors also will affect the recovery efficiency of the SSR system. These factors include the duration and rate of injection and withdrawal, plus well construction. A series of model simulations was performed to evaluate the response of the model to changes in these factors. The base values of hydraulic and fluid properties were used in all simulations. Modifications were made to the HST3D model to simulate the shutdown of the production well when the solute fraction of the withdrawn water reached 0.0745, corresponding to a DS concentration of 1,500 mg/L. The production well was shutoff until the scheduled beginning of the next simulation.

Duration of Injection and Withdrawal Cycle

Two series of multicycle model simulation tests were used to illustrate the effects of variations in the duration of injection/withdrawal cycles on recovery efficiency. The first series of tests consisted of 3 simulations of five uniform successive cycles (60, 180, and 365 days) of injection and withdrawal of 1.0 Mgal/d. The following schedules were simulated:

1. 30 days of injection followed by a maximum of 30 days withdrawal
2. 90 days of injection followed by a maximum of 90 days of withdrawal
3. 183 days of injection followed by a maximum of 182 days of withdrawal

Figure 7 shows the results of the first series of testing cycles for five successive 60-, 180-, and 365-day cycles. The plot indicates that recovery efficiency improves with each successive cycle for the various operational schemes even if the volume of injectant

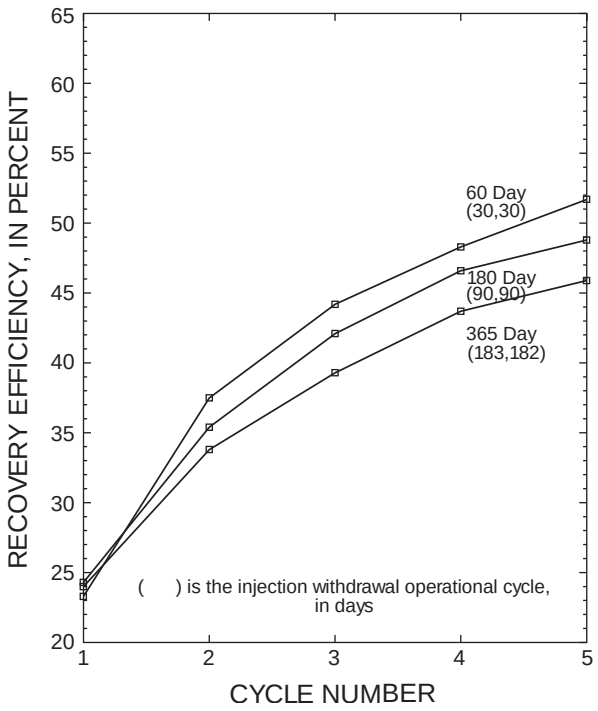

Figure 7. Recovery efficiencies for five successive 60-, 180-, and 365-day injection/withdrawal cycles at 1.0 million gallons per day. (Withdrawal in each cycle ceases when the dissolved-solids concentration of withdrawn water exceeds 1,500 milligrams per liter.)

does not increase. This is because of the continuous growth of the zone of dispersion (mixing zone) and the retarding effect of the zone of dispersion on the rate of gravitational segradation (Kumar and Klimbler, 1970). With each cycle, the zone of dispersion is greater due to mixing of the injectant with the residual water that was not completely recovered from the previous cycle. The graph also shows recovery efficiency increasing very rapidly in intitial cycles and then more slowly at later cycles for each operational schedule. After five cycles, recovery efficiencies ranged between 46 and 52 percent. Recovery efficiencies at the end of the first cycle had ranged between 23 and 24 percent.

Higher recovery efficienies were obtained for simulation tests when the duration of injection and recovery phases was shorter. This is expected because of the nature of the conceptual system in which migration of the solute particles across the low permeable units will reduce the recoverability for tests of longer duration (Quinones-Aponte and Wexler, 1995).

An operational SSR system would not function on uniform cycles but rather on irregular cycles based on seasonal surplus and demand. In the second series of tests, a hypothetical yearly schedule of injection and withdrawal was simulated. The schedule consisted of

five successive 1-year cycles of 4-months of injection, followed by a maximum of 3-months of withdrawal, followed by 3-months of injection, and finally followed by a maximum of 2 months of withdrawal. In St. Petersburg, the injection periods correspond to December through March and July through September (months when irrigation reuse is low), and the withdrawal periods might correspond to April through June and October through November (months when irrigation reuse is high).

Figure 8 shows the results of the second series of tests. The model conditions are similar to those previously described for the five successive 60-, 180-, and 365-day cycles. Recovery efficiencies range between 27 and 47 percent for the 0.5 Mgal/d simulations, 31 and 55 percent for the 1.0 Mgal/d simulations, and 37 and 62 percent for the 2.0 Mgal/d simulations. Results indicate that recovery efficiency approach an asymptote after several cycles, where for practical purposes, no improvement of recovey efficiency occurrs. For the 2.0 Mgal/d simulation the maximum recovery efficiency probably will be between 65 and 70 percent.

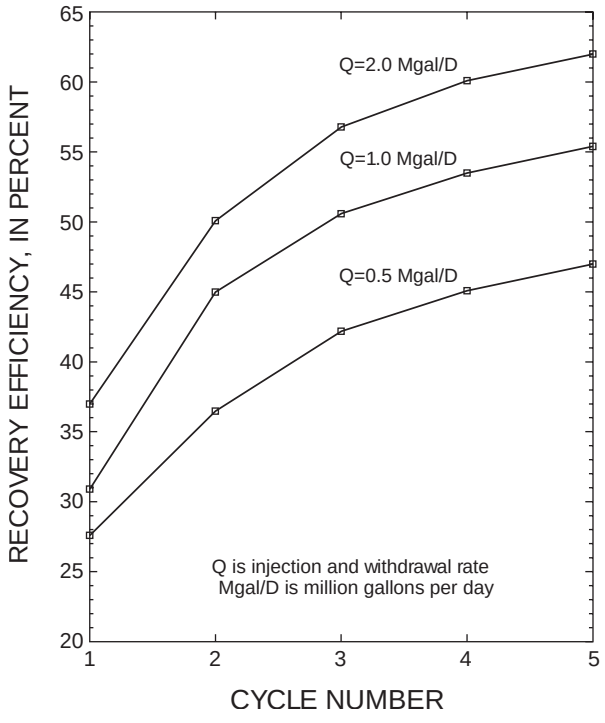

Figure 8. Recovery efficiencies for five successive 1-year cycles of 121 days of injection, 91 days of withdrawal, 92 days of injection, and 61 days of withdrawal at rates of 0.5, 1.0, and 2.0 million gallons per day. (Withdrawal in each cycle ceases when the dissolved-solids concentration of withdrawn water exceeds 1,500 milligrams per liter.)

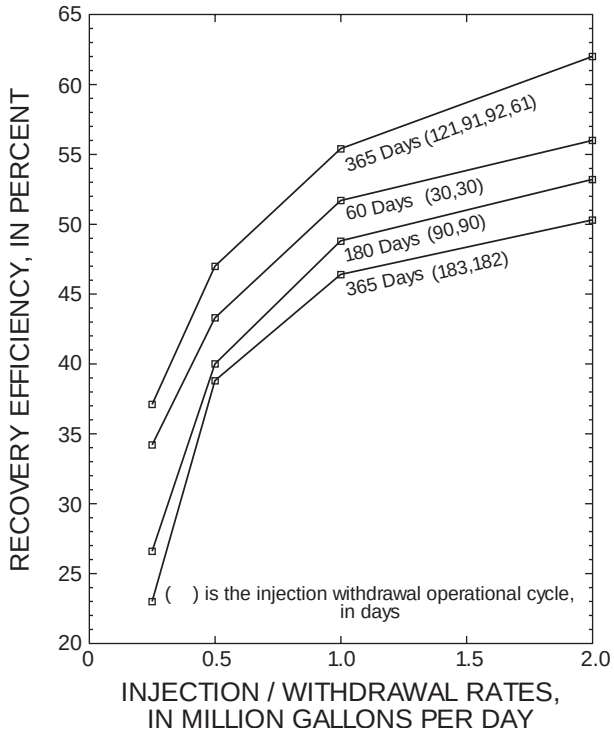

Figure 9. Recovery efficiencies after five cycles for various injection/withdrawal rates and operational schemes.

Rate of Injection and Withdrawal

The rate of injection and withdrawal for a fixed time period and for various operational schemes was varied from 0.25 and 2.0 Mgal/d to determine whether certain injection/withdrawal rates favor higher recovery efficiencies. Zero recovery efficiency would occur for a sufficiently small injection volume because of mixing. Results of the tests suggest that recovery efficiency is directly proportional to the injected flow volume. For a given operational scheme, recovery efficiency increases with higher volumes (fig. 9). There is a larger rate of increase of recovery efficiency at smaller volumes than at larger volumes. Recovery efficiencies after five cycles ranged between 50 and 62 percent for an injection/withdrawal rate of 2.0 Mgal/d and between 23 and 37 percent for an injection/withdrawal rate of 0.25 Mgal/d.

Partially Penetrating Well

Several well-completion designs were simulated to evaluate the effects of partial penetration. Operational wells may be open only to part of an aquifer; thus, it is of interest to compare the recovery

efficiency of a partially penetrating well with recovery efficiency of a well open to the full thickness. The recovery efficiency was expected to be higher in partially penetrating wells than for fully penetrating wells because a buffer zone of fresher water would exist between the pumped zone and the underlying water of poor quality. The simulated well penetrations ranged from 100 to 25 percent. The 25-percent penetration well is open to the upper 45 ft of layer 2. Results of the simulations are shown below:

Well penetration (percent)	Recovery efficiency (percent)
100	20.0
75	22.3
50	23.4
25	24.1

Simulations show a slight increase in recovery efficiency with a decrease in penetration depth. Merritt (1985) reported similiar results and suggests that recovery efficiencies in stratified aquifers may not be significantly affected if the well is open only to part of the aquifer. However, to generalize these results, a more-detailed study focusing on this aspect (injection into different flow zones) is needed.

SUMMARY AND CONCLUSIONS

A model-based study of the confined saline aquifer system underlying St. Petersburg is being conducted to analyze the hydrogeologic and operational aspects of underground injection, storage, and withdrawal of advanced secondary treated effluent in a single representative well. The study is specifically aimed toward (1) defining the hydrogeologic framework and ground-water quality in the study area, (2) assessing the geochemical interactions associated with the injection of effluent, and (3) applying a density-dependent, ground-water flow and solute-transport model to understand the relative importance of physical and chemical properties and operational variables on recoverability of injected effluent.

The sediments underlying the study area form a layered sequence of two aquifers and one confining unit. The framework includes the unconfined, surficial aquifer, and the confined Upper Floridan aquifer. The units are separated by the intermediate confining unit.

The surficial aquifer is composed of a layer of clastic deposits that is generally less than 30 ft thick. The aquifer is a source of recharge to the Floridan aquifer system and is primarily used as a source for lawn irrigation.

The intermediate confining unit is composed of clastic and carbonate sediments of Miocene and younger age. The carbonates are generally underlain and overlained by clays of relatively low permeability. Thickness of the unit averages about 90 ft and ranges from about 50 to 140 ft. The vertical hydraulic conductivity of the unit ranges from about 1.3×10^{-4} to 6.9×10^{-3} ft/d.

The Upper Floridan aquifer consists of a thick, regionally extensive sequence of Tertiary-aged carbonate rocks that comprise the following formations (in ascending order): Avon Park Formation, Ocala and Suwannee Limestones, and the Tampa Member of the Arcadia Formation which is part of the Hawthorn Group. The Upper Floridan aquifer underlying St. Petersburg contains four permeable zones separated by semconfining units. The zones are alphabetically labeled with increasing depth from A to D. The proposed receiving zone is within the uppermost part of the Upper Floridan aquifer (zone A) in the permeable limestone section of the Tampa Member of the Arcadia Formation of the Hawthorn Group and the Suwannee Limestone. Thickness of zone A averages about 180 ft and ranges from about 115 to 245 ft. Transmissivity of zone A ranges from 2.2×10^4 to 3.5×10^4 ft^2/d.

A semiconfining unit within the Suwannee Limestone is below the proposed injection zone and has a vertical hydraulic conductivity estimated to range from about 0.1 to 1.0 ft/d where the beds do not contain clay. Average thickness of this unit below the proposed injection zone is about 150 ft.

Limited fresh ground-water supplies exist in the Upper Floridan aquifer underlying St. Petersburg. Fresh ground water, where it is found, typically occurs as a thin layer within the uppermost permeable zone. Most water in the aquifer is saline with chloride concentration in the proposed injection zone ranging from 91 to 16,000 mg/L.

The chemical contrast between the injection and resident formation waters may lead to chemical reactions. The mix of the two water types would be understaturated with respect with calcite and dolomite. This might lead to dissolution of calcite and dolomite producing a more porous limestone with increased transmissivity.

A numerical model of variable density groundwater flow and solute transport (HST3D) was used to evaluate the importance of parameter variations affecting the recovery of effluent stored in a saline aquifer underlying the study area. The analyses consisted of a sensitivity testing approach, as opposed to the more familiar site-specfic calibration and prediction objective of modeling. Cyclic injection in a prototype aquifer was simulated and recovery efficiencies were calculated.

Sensitivity analyses were performed to determine changes in recovery efficiency when physical and chemical parameters of a base model are varied. The simulation cycle used as a standard for comparisons consisted of 15 days of injection of effluent at a rate of 1.0 Mgal/d and 15 days of withdrawal at a rate of 1.0 Mgal/d.

On the basis of computer simulations for hypothetical aquifer conditions, sensitivity tests for individual physical and chemical properties indicate:

1. The greater the density difference between the injected effluent and resident formation water, the lower the recovery efficiency during the first cycle. Higher salinity makes density stratification of the fluids more likely to occur at a given permeability level, thereby causing recovery efficiency to decrease.
2. Recovery efficiency decreases significantly as dispersivity increases. Dispersion is a deleterious process that can severely limit recovery efficiency.
3. Generally, high formation permeability causes poor recovery efficiencies. When the simulated permeability was increased by a factor of 10, recovery efficiency was reduced by 61.5 percent. This is because simulation of a larger permeability allowed for easier transport of the injected fluid, which resulted in greater stratification and buoyancy flow.
4. When the injection well was represented as open to only part of the aquifer, simulations show little difference as when the well was open to the entire aquifer.
5. For hypothetical conditions studied, porosity and anisotropy variations do not significantly alter recovery efficiencies.

The preliminary radial-flow and solute transport model also was used to examine the effects on recovery efficiency of hypothetical multicycle operations. Simulations consisted of five injection/withdrawal cycles of various duration and varying injection and withdrawal rates. Results of the simulations are:

1. Over the range of variables studied, the recovery efficiency per cycle increases with total number of cycles, provided that each recovery cycle phase ends when the DS concentration of withdrawn water reaches some prescribed value less than that of the more saline formation water. Thus, even though conditions may be such that recovery would be poor on the first cycle, the process should improve on subsequent cycles.
2. Recovery efficiencies increase rapidly during initial cycles and more slowly at later cycles. Recovery efficiencies may approach a maximum value after a number of cycles.
3. For a given operational scheme, recovery efficiencies increase with higher volumes of injected effluent. There is a larger rate of increase of recovery efficiency at small injection/withdrawal volumes than at larger injection/withdrawal volumes.

The operation of a single SSR well appears to be technically feasible under moderately favorable conditions. Model results indicate that recovery efficiencies from about 23 to 37 percent can be achieve for different SSR operational schemes. Five successive injection, storage, and recovery cycles and varying injection and recovery rates can increase the recovery efficiency to about 47 to 62 pecent. The recovery efficiency that will be attained, however, is highly dependent upon local physical and operational conditions. A combination of hydraulic, chemical, and operational parameters that minimize dispersion and buoyancy flow, maximizes recovery efficiency. The parameters that favor optimum recovery efficiencies are low aquifer water density and low to moderate permeabilities. SSR is most promising where native fluid density is low. The smaller the density contrast between resident formation water and injected water the better the recovery efficiency. A high injection rate and a small difference in density between the injected and resident formation waters should yield better results than a low injection rate and a large difference in density. Recoverability improves with successive cycles of injection, storage, and recovery even if initial recovery efficiency is low.

The results presented are preliminary and make up a part of the study in progress. Development of a fully three-dimensional variable density-ground-water flow and solute transport model is presently underway

to extend the analysis to multiwell systems for testing of large-scale injection. In a field application of the SSR process, a well field likely will be needed to handle the required inflow rates and wellhead pressures.

APPENDIX

APPENDIX: LISTING OF MODEL INPUT FILE

A sample input-data listing is provide for the single cycle base simulation of 15 days of injection at 1.0 million gallons per day followed by 15 days of withdrawal at 1.0 million gallons per day. The listing contains 276 lines, of which 147 lines are comments that aid construction of the data file. Critical comments are keyed to input record descriptions of Kipp (1987). The following order generally is observed for data input: (1) fundamental and dimensioning information, (2) spatial geometry and mesh information, (3) fluid properties, (4) porous medium properties, (5) source information, (6) boundary condition information, (7) initial condition information, (8) calculation parameters, and (9) out specifications.

Tests of Subsurface Storage of Freshwater at Hialeah, Dade County, Florida, and Numerical Simulation of the Salinity of Recovered Water

United States Geological Survey Water-Supply Paper 2431

Prepared in cooperation with the South Florida Water Management District and the Miami-Dade Water and Sewer Authority Department

AVAILABILITY OF BOOKS AND MAPS OF THE U.S. GEOLOGICAL SURVEY

Instructions on ordering publications of the U.S. Geological Survey, along with prices of the last offerings, are given in the current-year issues of the monthly catalog "New Publications of the U.S. Geological Survey." Prices of available U.S. Geological Survey publications released prior to the current year are listed in the most recent annual "Price and Availability List." Publications that may be listed in various U.S. Geological Survey catalogs (**see back inside cover**) but not listed in the most recent annual "Price and Availability List" may be no longer available.

Reports released through the NTIS may be obtained by writing to the National Technical Information Service, U.S. Department of Commerce, Springfield, VA 22161; please include NTIS report number with inquiry.

Order U.S. Geological Survey publications **by mail** or **over the counter** from the offices given below.

BY MAIL

Books

Professional Papers, Bulletins, Water-Supply Papers, Techniques of Water-Resources Investigations, Circulars, publications of general interest (such as leaflets, pamphlets, booklets), single copies of Earthquakes & Volcanoes, Preliminary Determination of Epicenters, and some miscellaneous reports, including some of the foregoing series that have gone out of print at the Superintendent of Documents, are obtainable by mail from

U.S. Geological Survey, Map Distribution
Box 25286, MS 306, Federal Center
Denver, CO 80225

Subscriptions to periodicals (Earthquakes & Volcanoes and Preliminary Determination of Epicenters) can be obtained ONLY from the

Superintendent of Documents
Government Printing Office
Washington, DC 20402

(Check or money order must be payable to Superintendent of Documents.)

Maps

For maps, address mail orders to

U.S. Geological Survey, Map Distribution
Box 25286, Bldg. 810, Federal Center
Denver, CO 80225

Residents of Alaska may order maps from

U.S. Geological Survey, Earth Science Information Center
101 Twelfth Ave. - Box 12
Fairbanks, AK 99701

OVER THE COUNTER

Books and Maps

Books and maps of the U.S. Geological Survey are available over the counter at the following U.S. Geological Survey offices, all of which are authorized agents of the Superintendent of Documents:

- **ANCHORAGE, Alaska**—Rm. 101, 4230 University Dr.
- **LAKEOOD, Colorado**—Federal Center, Bldg. 810
- **MENLO PARK, California**—Bldg. 3, Rm. 3128, 345 Middlefield Rd.
- **RESTON, Virginia**—USGS National Center, Rm. 1C402, 12201 Sunrise Valley Dr.

Temperature, given in degrees Fahrenheit (°F), can be converted to degrees Celsius (°C) by the following equation:

$$°C = 5/9\ (°F - 32)$$

Temperature, given in degrees Celsius (°C), can be converted to degrees Fahrenheit (°F) by the following equation:

$$°F = 9/5\ (°C) + 32$$

Milligrams per liter (mg/L) is a unit expressing the concentration of chemical constituents in solution as weight (milligrams) of solute per unit volume (liter) of water. For concentrations less than 7,000 mg/L, the numerical value is the same as for concentrations in parts per million.

Sea level: In this report, "sea level" refers to the National Geodetic Vertical Datum of 1929 —a geodetic datum derived from a general adjustment of the first-order level nets of both the United States and Canada, formerly called Sea Level Datum of 1929.

Tests of Subsurface Storage of Freshwater at Hialeah, Dade County, Florida, and Numerical Simulation of the Salinity of Recovered Water

By Michael L. Merritt

Abstract

Injection and observation wells were drilled in late 1974 for the purpose of conducting tests of storage and recovery of potable water in the brackish Upper Floridan aquifer. Three tests, involving storage and recovery cycles of varying volumes and storage period lengths, were performed between July 1975 and January 1980. Recovery was by natural artesian flow, and recovery efficiencies were 32.9, 47.8, and 38.5 percent. Wellbore plugging occurred during the injection stages, but injectivity was restored by periodic 2- to 3-hour backflushes at the natural artesian flow rate.

An interval of shelly limestone between 1,015 and 1,050 feet below land surface contained the flow zone. Data from an analysis of 18 spinner flowmeter logs indicated that the principal part of the flow zone extended from 1,024 to 1,036 feet below land surface and that minor amounts of flow occurred to a depth of about 1,047 feet. A neutron porosity log indicated the bulk porosity of both the flow zone and confining layers to be 35 percent. Chloride and dissolved-solids concentrations of water in the flow zone were 1,200 and 2,700 milligrams per liter, respectively.

A three-dimensional, finite-difference flow and solute-transport code was used to simulate pressure data measured during an aquifer test and observed salinity increases in recovered water during storage and recovery cycles. The aquifer test conducted in February 1975 was simulated by using a hydraulic conductivity estimate of 800 feet per day and a rock compressibility estimate of 0.0000400 (pound per square inch)$^{-1}$. The equivalent transmissivity and storage coefficients were 9,600 cubic feet per day per square foot times foot of aquifer thickness and 7.8×10^{-5}, respectively. Simulation of observed salinity increases during the three recoveries required dispersivities of 65 feet, a molecular diffusivity of 0.0002 foot squared per day, and a regional pore velocity of 260 feet per year. Central differencing in space and time was used for the solute-transport computations as well as an experimental method of computing vertical dispersion that used a scaling factor of 0.013.

Additional simulations of the aquifer-test data and recovery salinities were obtained based on assumptions that (1) the flow zone was 21 feet thick, (2) flow-zone effective porosity was 20 percent, and (3) flow-zone hydraulic conductivity was bipolar anisotropic by a ratio of 10:1. The four sets of simulation values were used in model runs in which 10 years of annual injection, storage, and recovery cycles were simulated. Computed recovery efficiencies increased from 40 percent in the first year to 68 percent in later cycles. The high regional pore velocity required for model calibration substantially limited the recovery efficiency achieved in later cycles.

INTRODUCTION

The subtropical climate of southern Florida has attracted a large and rapidly expanding population in recent decades, a trend likely to continue. As a result

of the population increase, the need for potable water has increased dramatically. Large quantities of potable water are available from the surficial Biscayne aquifer of Dade, Broward, and Palm Beach Counties, and smaller quantities are available from surficial or shallow artesian aquifers on the west coast, on the upper east coast (Martin and St. Lucie Counties), and in the interior of the southern peninsula (fig. 1).

The population growth of southern Florida has raised concerns about the adequacy of current sources of water supply to meet future demands. Since the early 1970's, water-management agencies have sponsored investigations into ways of augmenting these sources, particularly during the seasonal dry period (November–May) that is characteristic of the subtropical climate of southern Florida. Potable water normally is available in considerable surplus during the annual wet season (June–October), when the regional canal system is used to lower the water table throughout much of the area.

In 1974 the U.S. Geological Survey (USGS), in cooperation with the Central and Southern Florida Flood Control District, now the South Florida Water Management District (SFWMD), and the Miami-Dade Water and Sewer Authority (MDWSA) Department, began a pilot study to test the feasibility of injecting surplus potable water into the Floridan aquifer system for later retrieval when the supply of potable water became deficient. This water conservation strategy is particularly suited for the region because of its seasonal cycle of surplus and deficit of water supply. Because permeable zones in the Ocala Limestone and the upper part of the Avon Park Limestone of the Floridan aquifer system were known to contain brackish water, they were the injection zones selected for study.

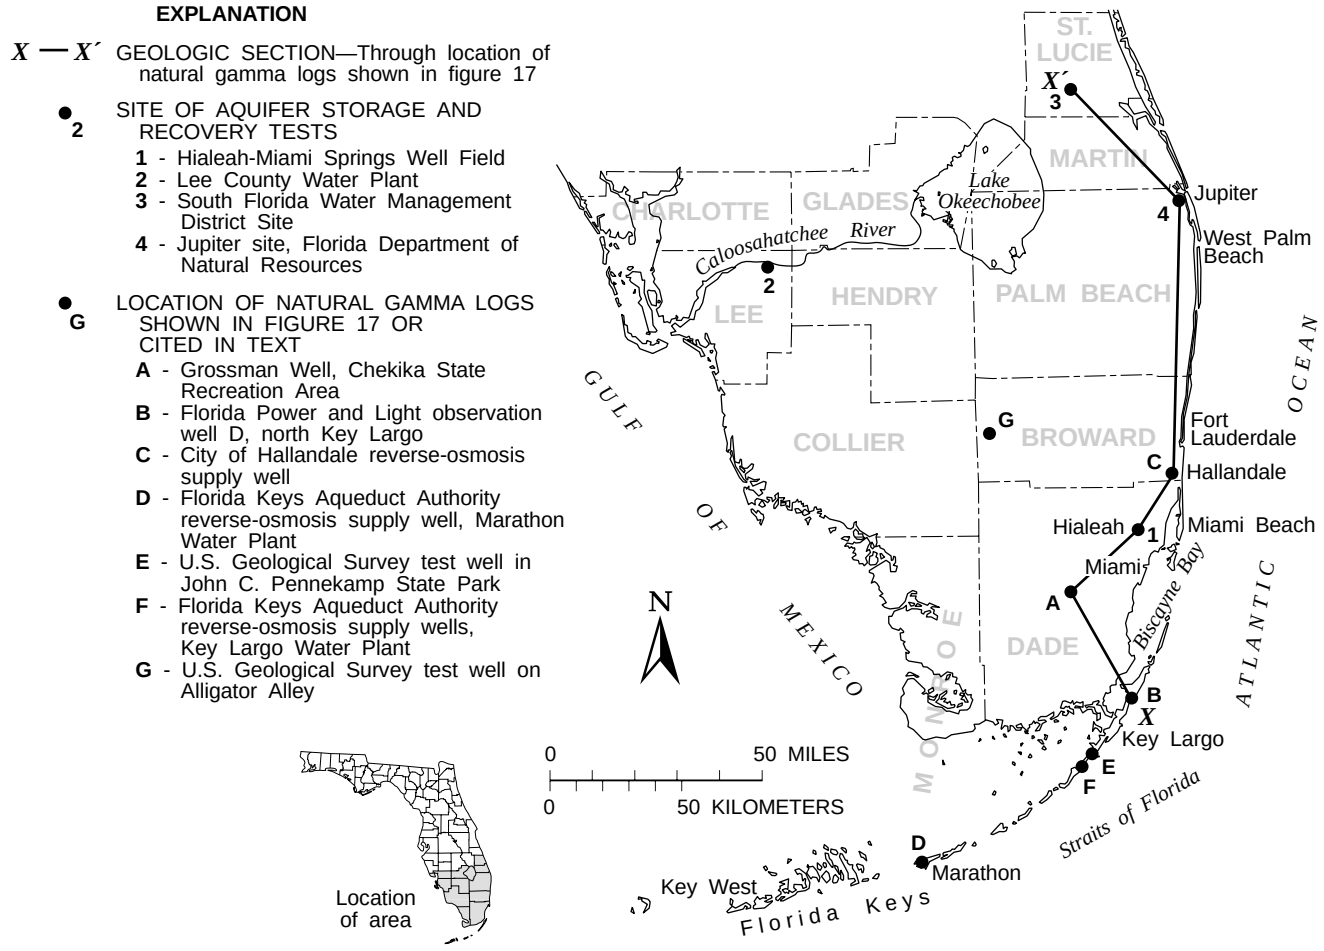

Figure 1. Location of Upper Floridan aquifer wells in southern Florida cited in this report.

The proposed study originally envisaged successive deepenings of an aquifer storage and recovery (ASR) well and two observation wells after performing ASR cycles in higher zones of interest. However, the funding provided limited activity to the testing of the uppermost permeable zone and the drilling of one observation well. The Hialeah-Miami Springs Well Field in Dade County, which at that time was the primary source of potable water for domestic consumption in the Miami area, was the site selected for the tests (fig. 1, site 1).

The injection and observation wells were constructed in October, November, and December 1974. Three ASR tests were performed, beginning in July 1975. The recovery phase of the third and last test continued until January 1980. During well construction and the subsequent ASR tests, a variety of data were collected, including pressure data, water-quality data, and volumetric measurements of quantities of inflow and outflow as a function of time. The present study interprets this data set to gain insight into the hydrogeologic processes occurring at the test site during the ASR cycles and to better define the potential feasibility of this technology in southern Florida.

In 1980–81, data from the tests at Hialeah were used by the USGS in an areal assessment of the feasibility of ASR as a water-conservation alternative for southern Florida which was conducted in cooperation with the U.S. Army Corps of Engineers. The ASR process and operational experience acquired by that time were summarized in the report presenting the results of the assessment (Merritt and others, 1983), and their relation to water-management needs in specific areas was considered. Data describing conditions at the Hialeah site were used to design a generalized aquifer prototype to be used for digital modeling to determine relations between hydrogeologic and operational conditions and the recoverability of injected water (Merritt, 1985). The modeling consisted of sensitivity analyses in which a simulation of injection, storage, and recovery in the aquifer prototype was repeated as various parameters were altered to represent changes in hydrogeologic conditions or operational management.

As useful as the results of the sensitivity analyses were, the more challenging problem remained of actually simulating the injection, storage, and recovery of water at Hialeah. The additional difficulty of simulation modeling compared to using a model of a hypothetical prototype to test relations and concepts arises from the need for realistic identification of parameters describing the processes of flow and transport in the aquifer, usually given inadequate data that require experience and intuition to interpret. In the present study, such a simulation model was constructed and used for predictive analyses to indicate the quantity of potable water that could be made available by an operational ASR program.

Opportunities for the application of computer simulation have increased as a result of recent advances in computer technology that make possible the more efficient use of three-dimensional solute-transport models and that facilitate their application to data sets such as that from Hialeah. The techniques for computer simulation of the transport of fresh water and brackish water during injection and recovery operations presented in this report can be used by water managers to estimate the amount of injected water that can be recovered at sites where data to support simulation are available and, also, to test various design and management alternatives.

Purpose and Scope

The complete data set acquired at the Hialeah ASR site is presented in this report to describe hydrogeologic conditions in the Upper Floridan aquifer, to describe hydrogeologic processes occurring during the injection and recovery tests, and to support the approach used for the simulation analysis. Selected data from other locations on the East Coast are included to augment the description of Upper Floridan aquifer conditions and for a tentative delineation of an areally extensive flow zone used for ASR at some locations and for reverse-osmosis plant supply at other locations. The remainder of the report describes the use of solute-transport modeling techniques to further interpret data from the field study by simulating the transport of fresh water and brackish water during the injection and recovery cycles, and describes the use of the calibrated simulation for predictions of recovery efficiency under hypothetical operational conditions.

Acknowledgments

The USGS expresses its appreciation to the SFWMD for providing funding for this study and to the late William B. Storch, former Executive Director, for his interest and encouragement. The USGS also expresses its gratitude to Garrett M. Sloan, former Director of the MDWSA, for the provision of various equipment and a water supply for conducting the tests. The author

benefited greatly from the help of Frederick W. Meyer (USGS, retired), who directed the subsurface storage and recovery tests at Hialeah over a period of many years and provided substantial guidance that helped the author to interpret data from the tests. Many of Fred Meyer's suggestions were incorporated into the analyses that follow in the remainder of this report.

SUMMARY DESCRIPTION OF INJECTION AND RECOVERY TESTS

The following pages present a brief description of the activities at the field site of the injection and recovery tests. This is followed by a summary of test results and a description of data collected at the site. Evidence indicating plugging of the wellbore during injection is also discussed.

Well Construction and Preliminary Data Collection

The sequence of stages in the construction and testing of the injection and observation wells is shown in figure 2. Drilling was principally by mud rotary. Casing extended to a depth of 955 feet (ft) in the completed injection well and to 953 ft in the observation well. The injection-well borehole was drilled to a depth of 1,105 ft, and the observation-well borehole was drilled to a depth of 1,064 ft. The deepest part of the injection well (below 960 ft) was drilled by reverse air, using a closed circulation system with discharge to a storm sewer. A supply well that tapped the Biscayne aquifer (Preston No. 7) provided a water supply for the injection tests. Drilled in June 1972, this well was 106 ft deep and was cased with 42-inch (in.) pipe to 65 ft. A suction line extended from the supply well to the injection wellhead.

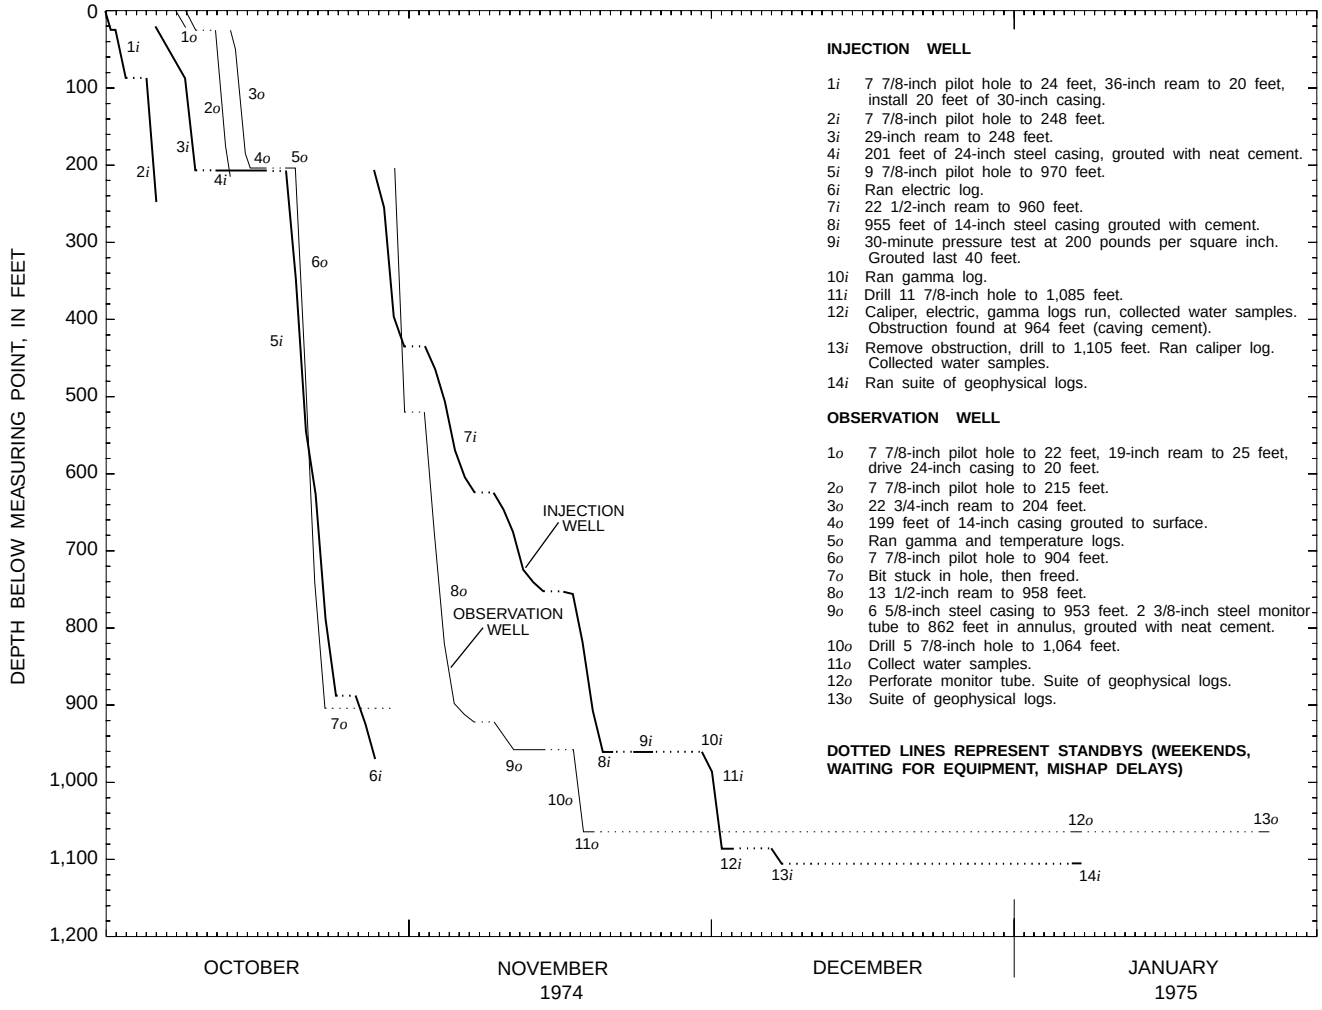

Figure 2. Details of the construction and testing of injection and observation wells at the Hialeah site.

During drilling, a 2-in. inside diameter (ID) steel tube was embedded in the cement annulus surrounding the 6 5/8-in. (OD) casing of the observation well to a depth of 862 ft. All casings in the injection and observation wells had a wall thickness of 3/8 in. except the 5 7/8-in. (ID) inner casing of the observation well, which had a wall thickness of 1/2 in. The 14-in. inner casing of the injection well was pressure tested at 200 pounds per square inch (lb/in^2) for 30 minutes (F.W. Meyer, USGS, written commun., 1974). USGS and Florida Geological Survey (FGS) identifiers for the wells, land-surface datums, and USGS datum measuring points at the injection and observation wells (selected as the tops of the concrete floors) are

Type of well	USGS local well number	FGS number	USGS site identifier	Datum, in feet above sea level	
				Land surface	Measuring point
Injection	G-3061	W-12997	254941080171701	8.39	9.44
Observation	G-3062	W-12998	254944080171801	5.43	5.93
Supply	S-3000	—	254943080172001	—	—

The injection and observation wells were located in Township 53 South, Range 41 East, Section 18, NW$^{1/4}$, SW$^{1/4}$ (near the junction of Okeechobee Road and West Third Avenue in Hialeah). The site was in the Hialeah-Preston Well Field near the north bank of the Miami Canal, on property adjacent to the Hialeah Water Treatment Plant. The observation well is about 289 ft north-northwest of the injection well. The wells and surrounding features present when construction was completed in 1974 are shown in figure 3. On June 4, 1980, the observation well was plugged with neat cement. The observation-well site now is covered by an MDWSA warehouse.

A comprehensive suite of data was obtained during and immediately after well construction. Geophysical logs made during this period are included in table 1, which is a complete and annotated summary of geophysical logging performed during the project. A driller's log of lithology recorded by the USGS at both the injection and observation wells is included as Appendix A. An analysis of cuttings from the two wells was made by the FGS, and descriptions of the lithology are included as Appendix B. The first two water samples collected for chemical and biological

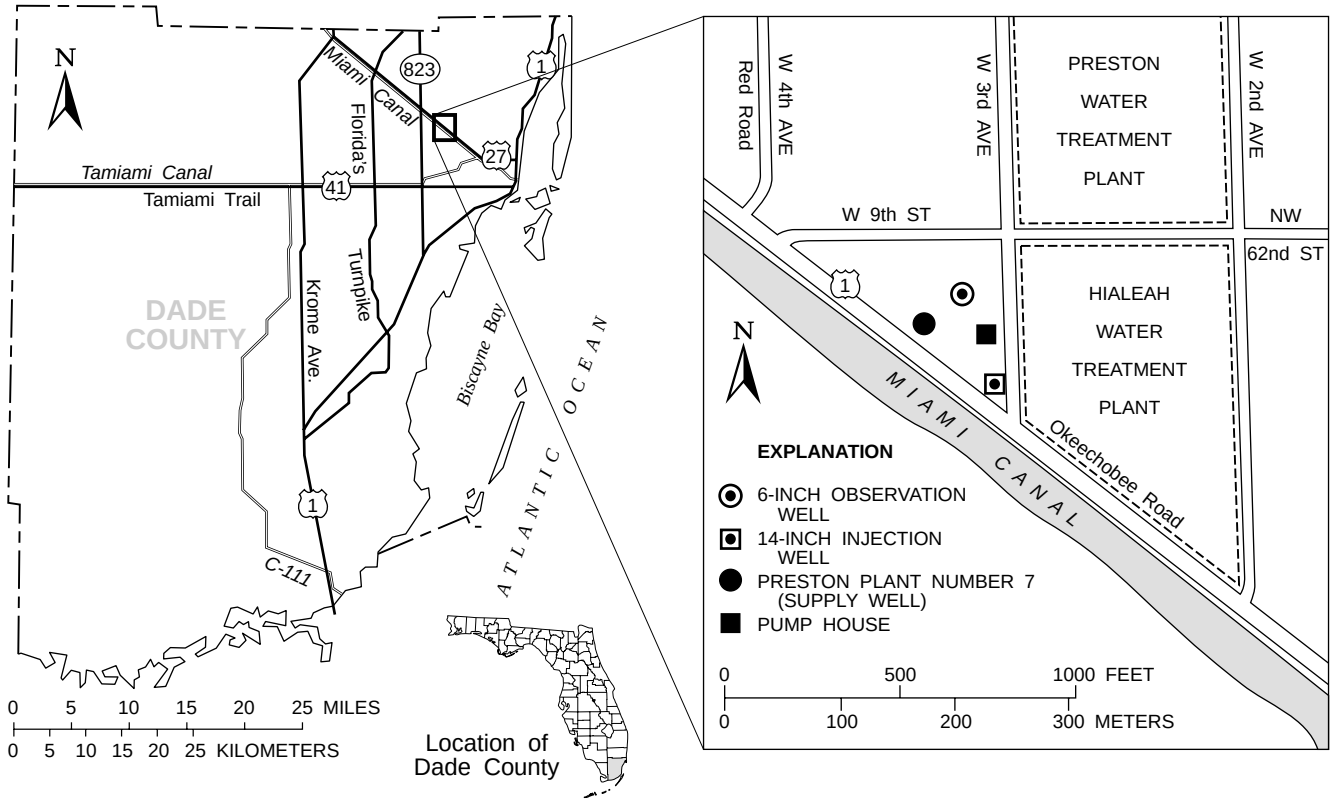

Figure 3. Location of wells and surrounding features at the Hialeah site at the time of well construction in 1974.

Table 1. Geophysical logging data obtained during construction and testing of the injection and observation wells and during subsequent storage and recovery tests at Hialeah, 1974–79

[All logs run by the U.S. Geological Survey, except where noted. OW, observation well; IW, injection well]

Date acquired	Type of log or data	Depth (feet)	Well	Remarks
		Construction		
10/21/74	Natural gamma	0–150	OW	Three days after cementing 14-inch casing.
	Temperature	0–125	OW	Same as above.
10/30/74	Electric	0–970	IW	Single-point resistivity and spontaneous potential. In a 9 7/8-in. pilot hole filled with aquagel. Shows correlation with layering of limestone and clay. Done in 14-in. casing with plug.
12/02/74	Natural gamma	0–970	IW	Poor log.
12/04/74	Electric	900–1, 085	IW	Single-point resistivity and spontaneous potential. Three runs.
	Natural gamma	0–1,085	IW	Three runs. Poor reproducibility.
	Caliper	865–1,080	IW	Showed obstruction at 964 ft.
12/09/74	Caliper	869–1,105	IW	Open hole to total depth.
		Postconstruction Testing		
01/07/75	Cement bond and natural gamma	0–960	OW	Schlumberger log.
01/08/75	Oriented perforation	840–844	OW	A 2-inch monitor tube perforated at 840 feet. Schlumberger log.
	Caliper	0–1,061	OW	Open hole to total depth.
	Borehole compensated sonic	955–1,088	IW	Schlumberger log.
	Cement bond	0–964	IW	Poor bond, except in isolated intervals and bottom of well. Schlumberger log.
	Compensated neutron-formation density and natural gamma	0–1,096	IW	Used for porosity estimates. Schlumberger log.
	Induction-electrical log	950–1,088	IW	Correlated with hard layers, 975–985 ft. and 1,030–1,040 ft. Schlumberger log.
01/27/75	Caliper	918–1,053	OW	
	Temperature	7–1,057	OW	Well flowing about 288 gal/min (1.36 gal/min in 6-inch casing). Temperature decreases with depth.
	Natural gamma	3–1,056	OW	
	Temperature	940–1,085	OW	Inverse of previous temperature log. Well flowing. Three flowmeter stations—tool would not go below 984 ft.
	Neutron porosity	3–1,056	OW	
	Gamma-gamma density	4–1,056	OW	
	Standard electric	943–1,053	OW	Spontaneous potential, long and short normal formation resistivity.
	Fluid resistivity	800–1,056	OW	

Table 1. Geophysical logging data obtained during construction and testing of the injection and observation wells and during subsequent storage and recovery tests at Hialeah, 1974-79--Continued

Date acquired	Type of log or data	Depth (feet)	Well	Remarks
During First Recovery				
10/10/75	Caliper	930 - 1,093	IW	
	Temperature	0 - 1,104	IW	Shows warmer water below 1,047 feet. Temperature increases with depth.
	Natural gamma	0 - 1,100	IW	High counts 950 to 1,040 feet.
	Fluid resistivity	0 - 1,102	IW	Shows fresher water below 1,047 feet.
	Neutron porosity	0 - 1,099	IW	
	Gamma-gamma density	0 - 1,100	IW	
	Standard electric	953 - 1,103	IW	Spontaneous potential, long and short normal formation resistivity. Two runs.
	Spinner flowmeter	612 - 1,097	IW	Three runs.
Last Day of First Recovery				
10/20/75	Standard electric	0 - 1,105	IW	Spontaneous potential, long and short normal formation resistivity. Warmer water below 1,047 feet.
	Fluid resistivity	0 - 1,103	IW	No good.
	Spinner flowmeter	0 - 1,105	IW	Up and down runs. Flowing at 835 gallons per minute.
During Second Recovery				
05/25/76	Standard electric	946 - 1,098	IW	Spontaneous potential, long and short normal formation resistivity.
	Caliper, spinner flowmeter	930 - 1,100	IW	Up and down runs of flowmeter.
	Fluid resistivity	920 - 1,102	IW	Shows water freshening below 1,020 feet.
During Third Injection				
08/27/76	Spinner flowmeter	920 - 1,100	IW	Up and down runs before, during, and after backflush.
During Third Recovery				
04/20/78	Acoustic televiewer	950 - 1,096	IW	Only parts in U.S. Geological Survey files.
	Temperature	60 - 1,100	IW	Shows warmer water below 1,040 feet.
	Fluid resistivity	900 - 1,100	IW	Shows fresher water below 1,040 feet.
	Spinner flowmeter	800 - 1,087	IW	Up and down runs.
07/17/79	Acoustic televiewer	950 - 1,096	IW	Only some duplicates in U.S. Geological Survey files.
	Spinner flowmeter	930 - 1,092	IW	Two runs up, one run down.
	Fluid resistivity	40 - 1,098	IW	Water below 1,040 feet is slightly saltier.
	Temperature	20 - 1,100	IW	Decreases with depth to 1,040 feet. Warmer water below 1,040 feet. Cooler water below 1,060 feet.
	Caliper	800 - 1,098	IW	

analysis (from injection and observation wells) are measurements of the preinjection quality of native water in the injection zone immediately after well construction. A complete list of the results of chemical and biological analyses of water samples collected from the injection and observation wells during the testing program is presented in Appendix D. The chemical and biological analyses normally consisted of major inorganic ions, bacteria, chemical oxygen demand, biochemical oxygen demand, nutrients, total organic carbon, metals, field pH, alkalinity, and specific conductance.

Additional data were collected during the period between well completion and the beginning of freshwater injection in July 1975. The 2-in. monitor tube in the observation well was perforated at 840 ft on January 8, 1975, by Schlumberger, Inc., as they ran a suite of logs on the injection and observation wells, and water samples began to be collected from this depth. On January 27, 1975, the USGS obtained static and flowing geophysical logs at the observation well (table 1). On February 6, 1975, prior to the aquifer test of February 10, 1975, flow and shut-in artesian heads were measured in the observation well and the 2-in. monitor tube, and shut-in pressure was also measured in the injection well. The heads measured in the injection and observation wells should be regarded as the same within measurement error. Flow from the observation well was measured at a 5-in. discharge orifice at an elevation of about 8 ft above sea level. Flow from the monitor tube was measured at an elevation of 6.23 ft above sea level. A flow estimate from the injection well had previously been obtained on December 10, 1974, as the well was being completed to total depth. The elevation of the point of discharge is unknown. During drilling of the injection well, the first flow 10–20 gallons per minute (gal/min) was reported when the well reached 985 ft in depth. The measured head and flow values are given below:

Type of well or tube	Shut-in head (feet above sea level)	Flow (gallons per minute)
Injection well	42.24	600
Observation well	42.13	280
Two-inch monitor tube	20.33	.5

Test Parameters and Observed Recovery Efficiencies

Three test cycles of injection, storage, and recovery were conducted between July 1975 and January 1980. Specific details of the test schedules are indicated in the annotation column of Appendix C, which also lists periodic measurements of the volume of injection and recovery. Injection was by forced pumping, and recovery was by natural artesian flow. The cycles differed considerably in the total volume injected and length of storage period. The recovery phase of the third cycle continued for 2.5 years, until recovered water approached the quality of background aquifer water. Results of the three cycles have been previously cited by Merritt and others (1983) and Meyer (1989b) and are summarized below:

Test parameters	Cycle 1 (July 17–Oct. 20, 1975)	Cycle 2 (Jan. 5 –July 20, 1976)	Cycle 3 (July 23, 1976–Jan. 30, 1980)
Quantity injected (gallons $\times 10^6$)	41.9	85.0	208.0
Storage period (days)	2	54	181
Quantity of potable water recovered (gallons $\times 10^6$)	13.8	40.7	80.1
Recovery efficiency	32.9	47.8	38.5

Recovery efficiency, in the above table, refers to the customary measure of the productivity of an ASR cycle. Recovery efficiency is defined as the volume of potable water recovered, expressed as a percent of the volume of water injected. The first attempt to do the second injection was terminated prematurely by a pump failure after 8.8×10^6 gal had been injected. This volume is included in the quantity injected for cycle 2 in the above table. Injection resumed 19 days after the pump failure.

Types and Methods of Data Acquisition During the Tests

An intensive and comprehensive data-collection program was designed for the program of injection and recovery testing. Types of data acquired were pressure, volumetric, water-quality, and geophysical data. The methods of data collection are described in the following sections. Most of the data are shown in illustrations or are listed in appendixes at the end of this report.

Pressure Data

Pressure gages with readouts in feet of head were placed on the injection wellhead and at the sampling ports of two monitoring tubes used for water-sample collection in the observation well. The tubes, part of a system described later in more detail, were the red monitor extending to a depth of 957 ft, which is near the top of the open borehole and about 65 ft above the flow zone, and the white monitor, the 2-in. pipe cemented in the annulus and perforated at a depth of 840 ft. The perforations were separated from the flow zone by about 180 ft of clayey marl and dense limestone. The head data, converted to pressures and referenced to sea level, are plotted on plate 1.

Pressure data from the injection well and red monitor (pl. 1) clearly show the effects of injection, storage, and recovery and the effect of backflushing operations. The pressure increase during the aborted second injection in December 1975 is readily apparent. The decrease of pressure during backflushes was usually not measured or only partly measured, and dashed lines are used on plate 1 to suggest the extent of the decrease when not recorded. During the third injection cycle, pressures generally were not recorded between backflushes, and upward trends due to wellbore clogging are not shown as they are for the first and second injection cycles. Pressure data from the 840-ft white monitor show no clear trends during the three ASR cycles, illustrating the degree of confinement provided by the marl and limestone beds separating the monitored zone from the receiving zone.

Volumetric Data

Injection-well inflow and outflow were directed through a single flowmeter by a pipe-and-valve arrangement. Meter readings were recorded frequently during injection and recovery. The cumulative volume of injected and recovered water during the three ASR cycles is shown on plate 1. Incremental volumes of recovered water were given a negative arithmetic value in compiling the volumetric curve, so that total volume in the figure decreases during recovery. Because the volume recovered during the third ASR cycle was quite large, the illustrated cumulative volume decreases below zero after November 1978.

A computed first difference of volumes recorded during injection and recovery was used to approximate the current rate (pl. 1). Like the pressure data, volumetric data were not collected often enough during the third injection phase to show the rate decrease between backflushes caused by wellbore clogging as they did in the first two injection phases. A tabulation of the volumetric data, calculated rates, and corresponding chloride concentration in recovered water is included in Appendix C.

Water-Quality Data

A considerable number of water samples were collected for field and laboratory analysis during the three ASR cycles. Most of the analytic results are stored in the computer files in the USGS office in Miami, Fla.

Before the first injection, a multiport sampling apparatus was installed in the injection horizon of the observation well. The apparatus consisted of a system of monitor tubes extending to various depths within the 6-in. open-hole part of the well. The tubes were attached to a 1/2-in. polyvinyl chloride (PVC) center pipe with a rosette attachment at each coupling of the center pipe (every 21 ft). Around the perimeter of the rosettes were five holes through which lengths of the 5/8-in. flexible plastic monitor tubing (polypipe) were inserted. The five polypipe tubes were color coded at the wellhead and extended to 957 ft (red monitor), 978 ft (green monitor), 999 ft (gold monitor), 1,020 ft (silver monitor), and 1,041 ft (black monitor). Depths are referenced to a flange about 4 ft above land surface, and about 3.5 ft above the measuring point used for referencing the geophysical logs; hence, the tube depths are shown slightly higher in subsequent illustrations. The center pipe extending to 1,062 ft was included in the automatic sampling system (blue monitor).

In the first few days of the first injection, daily samples were obtained manually from the monitor tubes and analyzed for specific conductance and chloride. After 5 days, an automatic sampler/recorder system was made operational. The sampler was pumped continuously at a rate of 5 gal/min. Every 30 minutes, the temperature, specific conductance, dissolved oxygen, and pH of the water were measured and recorded, and the sampler rotated to a different source tube. In this manner, each depth was sampled once every 3 hours. Of the automatically recorded data, only the silver monitor data (1,020 ft) were entered into the computer files. The 2-in. pipe extending to 840 ft (white monitor) was sampled separately.

Periodically, the automatic system was turned off, and samples were pumped from each of the six monitored depths and from the 2-in. pipe for field and laboratory measurements of temperature, specific conductance, and chloride. These data are shown on plate

1 for the three cycles. Automatic sampler-recorder data for the period of the first injection breakthrough (arrival of injected water at the observation well) are shown later in the report. The sampler/recorder was not used after the first cycle.

During the first injection, water from the supply well was sampled frequently for measurements of temperature, specific conductance, and chloride. Supply-well chloride data for all three cycles are shown on plate 1, and temperature data are shown later in the report. Five days into the first injection, a supply-well sample was obtained for chemical and biological analyses (App. D). Eighteen days into the first injection, a water sample was collected from the silver monitor for chemical and biological analyses.

The first injection was terminated at 1200 hours on September 8, 1975, in order to prepare for a short recovery test. About 1 hour later, the automatic sampler/recorder detected a significant freshening in the sample from the observation-well silver monitor (at 1,020 ft). After a few hours, as the other monitor tubes were sampled by the automatic sampling system, freshening was detected at all other monitoring depths except for the white monitor (at 840 ft) located in the overlying confining unit. Specific conductance data from the six injection-zone monitors during the period when freshening occurred are shown later in the report.

The first recovery began 2 days after the end of injection. Automatic sampler data continued to be recorded for the first 8 days of recovery. White-monitor data continued to be collected manually. After 8 days, weekly manual sampling of the six injection-zone monitor tubes was initiated for temperature, specific conductance, and chloride.

Water recovered from the injection well was also sampled and analyzed. During the initial 8 days of the first recovery, hourly measurements were made in the recovered water for temperature, specific conductance, dissolved oxygen, and pH. After 8 days, the measurement frequency was reduced to once per day. Temperature, specific conductance, and chloride were measured, and a flowmeter reading was recorded. Water samples collected 6, 13, 20, and 35 days into recovery received chemical and biological analysis (App. D).

During the second and third injections, sampling of the supply-well water for measurement of temperature, specific conductance, and chloride continued as before, but on a weekly schedule. One sample was collected for chemical and biological analyses during each injection (App. D).

During the second and third ASR cycles, samples were obtained from the seven monitor tubes in the observation well and analyzed for specific conductance, chloride, and sometimes temperature. The sampling was conducted weekly until the end of the third injection, bimonthly during the third storage, weekly for the first 6 months of the third recovery, monthly for another 10 months, and quarterly until January 1980. Water samples were collected from the seven monitoring tubes for chemical and biological analysis near the end of the second recovery (after 77 days of recovery); near the end of the third injection (after 181 days of injection), when water recovered from the monitor tubes consisted primarily of injected water; and near the end of the third recovery (after 729 days of recovery), when water in the monitoring zones virtually had returned to background quality (pl. 1).

During the second and third recovery cycles, measurements of the specific conductance and chloride concentration of the water recovered at the injection well were made frequently and tabulated with corresponding flowmeter readings. At the beginning of the second recovery, the measurement frequency was from one to five times each week, but was reduced to weekly near the end of the recovery. The measurement frequency was weekly during the first 6 months of the third recovery phase, but then was reduced to monthly and then quarterly, as at the observation well. Samples for chemical and biological analysis were obtained just prior to the second recovery, after 22 days of recovery, and near the end of the second recovery (after 77 days). Additional samples for chemical and biological analysis were collected just prior to the third recovery and near the end of the third recovery (after 729 days). Results of all chemical and biological analyses are listed in Appendix D.

Other water samples collected during the study were analyzed by university and private laboratories and by research laboratories of the USGS. Water samples were periodically sent to a private laboratory, Applied Research Laboratories of Florida, Inc., in Hialeah, for analysis of nitrate-reducing, sulfate-reducing, and iron-reducing bacteria. Results currently

available in USGS files are listed in Appendix D. Water samples were sent to the USGS research laboratory in Reston, Va., for dissolved-gas analyses. Results (D.H. Fisher, USGS, written commun., 1975, 1977) are also summarized in Appendix D. Three water samples (August 4, 1975, injection-supply water; September 23 and 30, 1975, backflowing water) were sent to Florida State University for uranium-isotope analysis (Meyer, 1989a).

Geophysical Data

Geophysical logging was performed by the USGS in the injection well on six occasions during the three ASR cycles. Five of these occasions were during recovery. The remaining logging was done before, during, and after a backflushing operation during the third injection. These six logging operations are depicted graphically on plate 1, and the logs obtained are listed in table 1.

The geophysical logging emphasis during the ASR cycles was on spinner flowmeter, temperature, and fluid-resistivity logs, which reveal the relative hydraulic characteristics of various strata within the injection interval (955–1,105 ft). However, caliper logs were obtained on three occasions and electric logs on two occasions. On October 10, 1975, natural gamma, gamma-gamma density, and neutron porosity logs were run in the injection well. Acoustic televiewer images were obtained in the open hole of the injection well on April 20, 1978, and July 17, 1979.

Wellbore Clogging

During injection, the wellhead pressure rose as the rate of injection dropped as a result of clogging of the wellbore. This is illustrated by pressure and rate data shown on plate 1 for the first and second ASR cycles. In the third cycle, measurements were made weekly at the time of backflushes, and pressure and rate changes in the intervening days were not measured. The 1-hour backflushes that began in the second cycle were effective in restoring injectivity, as shown by the general uniformity in peak pressures and injection rates. In the third ASR cycle, backflushes were by artesian flow for 2 to 3 hours at a rate of 500 to 600 gal/min. The well was not acidized.

According to F.W. Meyer (oral commun., 1986), air entrainment was not a problem after some initial difficulties with the pump were resolved. Furthermore, an X-ray diffraction analysis of the backflushed sediment revealed that it consisted mainly of very fine particles of calcite and an iron compound (not scale) that had precipitated (F.W. Meyer, oral commun., 1990).

Spinner flowmeter logs run before, during, and following a backflushing operation on August 27, 1976, during the third injection, were analyzed to detect any changes in the vertical distribution of permeability that occurred as a result of plugging. The data do not indicate that any such change occurred.

HYDROGEOLOGIC CONDITIONS IN AQUIFER USED FOR STORAGE OF FRESHWATER

A characterization of subsurface formations and the spatial variation of their properties is essential for an understanding of the design of the freshwater injection, storage, and recovery tests and their results. This characterization begins with a regional description of stratigraphy and hydrostratigraphy, which is followed by a detailed description of stratigraphy and properties of important formation sequences at the Hialeah site.

Regional Stratigraphy and Hydrostratigraphy

A generalized stratigraphic column showing the major formations and hydrologic units in southeastern Florida is presented in figure 4. Some authors (Miller, 1986; Scott, 1988) include the Tampa Limestone as part of the overlying Hawthorn Formation, but Meyer (1989a) treats it separately. The ASR wells in Hialeah and St. Lucie County tap permeable strata near the base of the Suwannee Limestone, as do wells used to supply brackish water for reverse-osmosis plants in the Florida Keys. The ASR well in St. Lucie County also taps permeable strata at the base of the Ocala Limestone that underlies the Suwannee Limestone. The Ocala Limestone is thin or absent in most of Monroe, Dade, and Broward Counties, and in south-central Palm Beach County, either never having been deposited or having been mostly eroded away (F.W. Meyer, USGS, oral commun., 1983). Chen (1965), however, infers the existence of a thin (less than 100 ft) layer of Ocala Limestone throughout the area on the basis of a few incomplete samples. Vertically adjacent limestone units of the lower part of the Suwannee Limestone and of the Ocala Limestone and upper part of the Avon Park Formation are considered the upper part of the Floridan aquifer system, referred to as the Upper Floridan aquifer, and contain thin, discrete zones of high permeability.

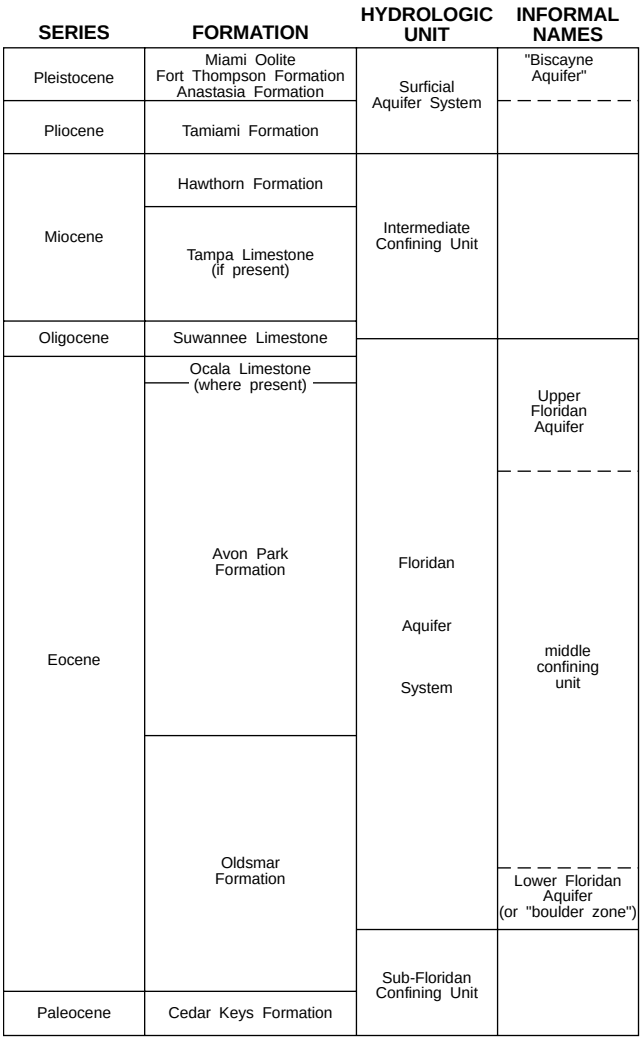

Figure 4. Generalized stratigraphic column for southeastern Florida showing major formations and hydrogeologic units.

Water quality in the Upper Floridan aquifer grades from brackish to saline with depth; hence, the permeable strata of the Upper Floridan aquifer is considered the most likely source of water in southeastern Florida for reverse-osmosis plant supply, or the most likely receptacle for temporary storage of freshwater. Where the aquifer contains water with less than 10,000 mg/L of dissolved solids, it is protected from contamination by Florida State law to ensure its continued availability for these and other uses. Water in the Upper Floridan aquifer originates as surface recharge in central Florida. Figure 5 shows estimated Upper Floridan hydraulic-head gradients and general direction of flows in the southern part of the Florida peninsula. Also shown is the region where water in the aquifer moving away from points of recharge retains a sufficient degree of freshwater recharge quality to be suitable for public consumption.

Stratigraphic and hydrostratigraphic units underlying the Upper Floridan aquifer generally are not suitable for freshwater storage because of their lack of permeability or the high salinity of the water contained within them. The lower part of the Avon Park Formation was formerly referred to as the Lake City Limestone, distinguished from overlying rocks primarily by its faunal composition, but Miller (1986) included it as part of the Avon Park Formation. The Lake City Limestone is no longer recognized as a formation by the USGS. The middle confining unit of the Floridan aquifer system contains discrete zones with solution porosity that generally are highly dolomitized and made up of very hard rock. No known aquifers match the high transmissivity of the cavernous, dolomitic Lower Floridan aquifer, better known by the drillers' term, boulder zone. This aquifer contains anomalously cold water of seawater-like composition. Meyer (1989a) presents data to support the thesis of Kohout (1965) that boulder-zone water originates as westerly flow through karst features or faults underneath the Straits of Florida near Fort Lauderdale. The boulder zone presently is used for the disposal of liquid wastes.

Stratigraphy and General Lithology at the Hialeah Site

A generalized sequence of predominant rock types at the Hialeah ASR site, based on a consideration of drillers' logs and sample descriptions from the injection and observation wells (Apps. A and B), is presented in figure 6. The upper 120 ft of limestone and sandstone at the site corresponds to the Pleistocene deposits that make up the upper part of the surficial aquifer system (the Biscayne aquifer and its overlying layer of compacted sands). Sandy, shelly, clayey marls interbedded with dense limestone or clay were found between a depth of 120 and about 975 ft. These beds correspond to the Tamiami Formation of Pliocene age, the Hawthorn Formation and Tampa Limestone of Miocene age, and the upper part of the Suwannee Limestone of Oligocene age. F.W. Meyer (USGS, written commun., 1975–80) picked 950 ft as the top of the Suwannee Limestone.

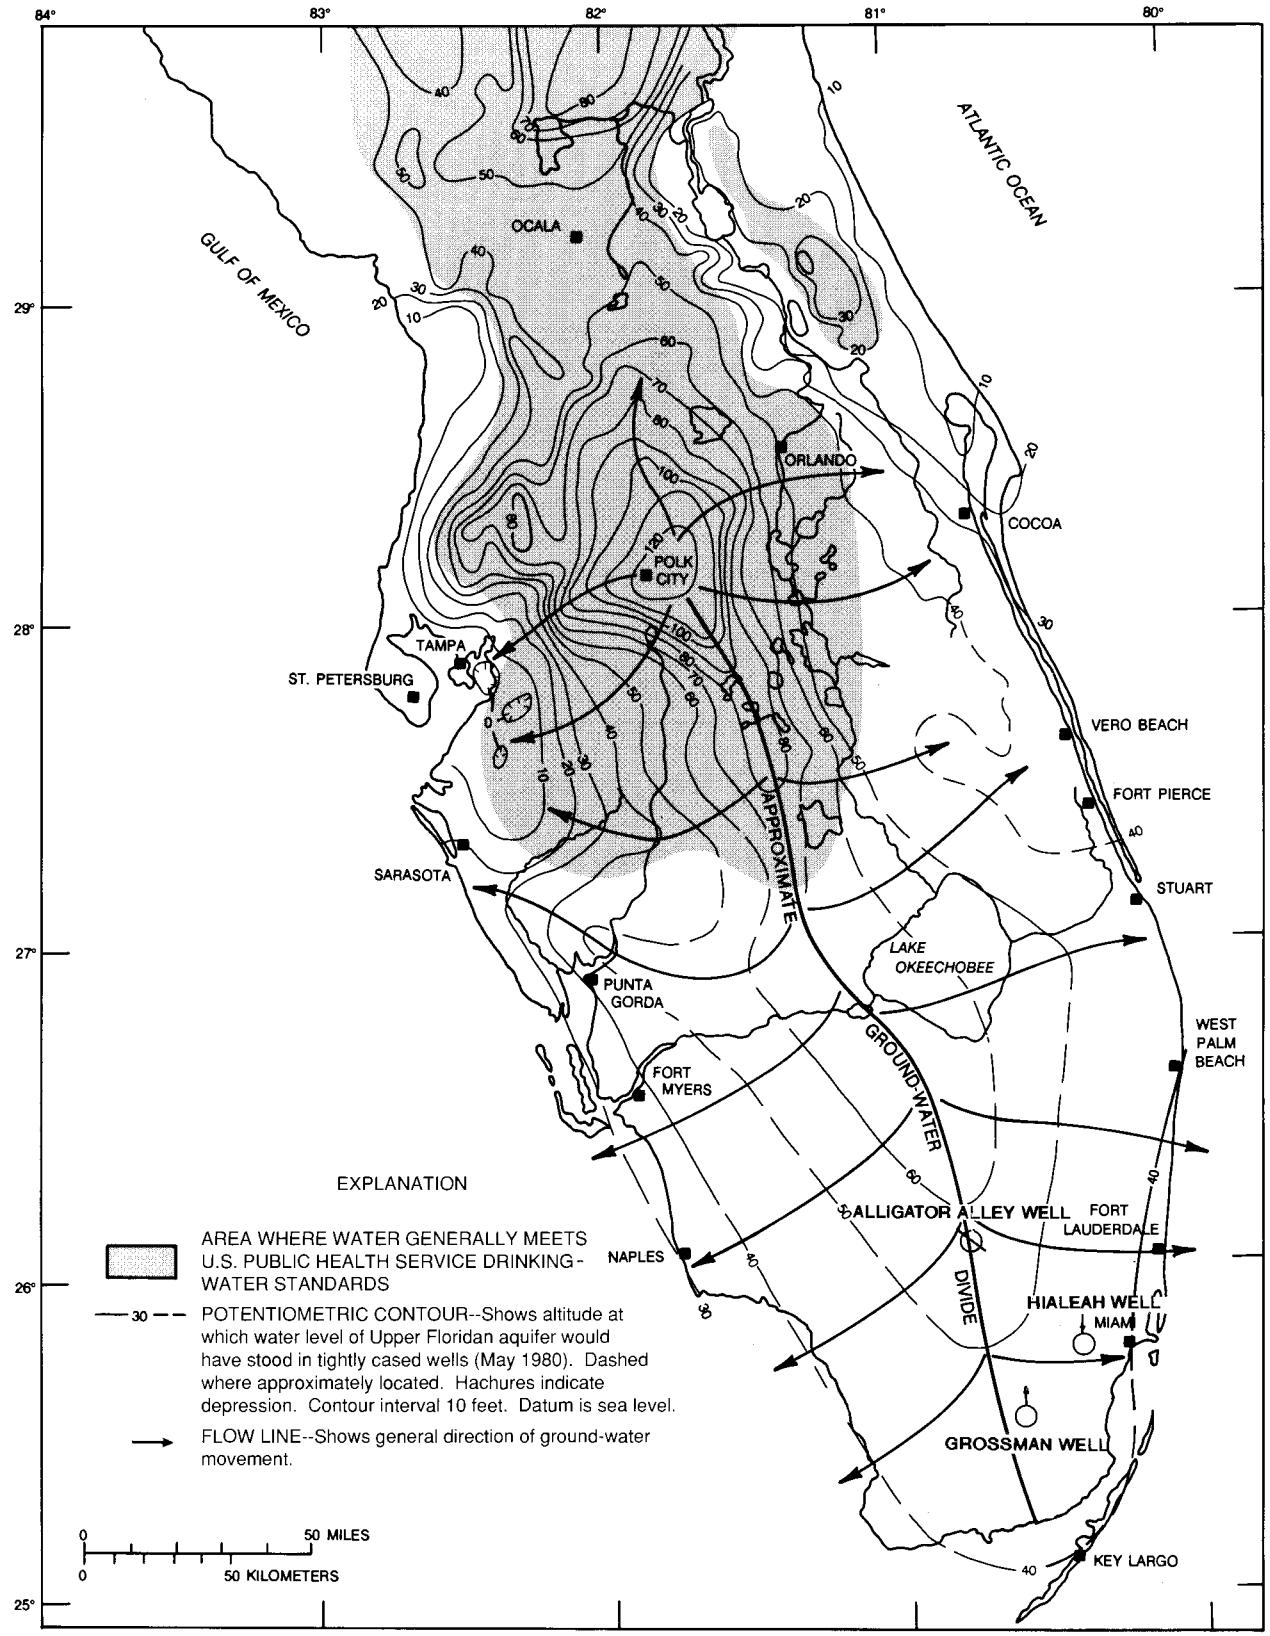

Figure 5. The potentiometric surface of the Upper Floridan aquifer in peninsular Florida in May 1980 and the area in which water in the aquifer is potable (from Meyer, 1989a).

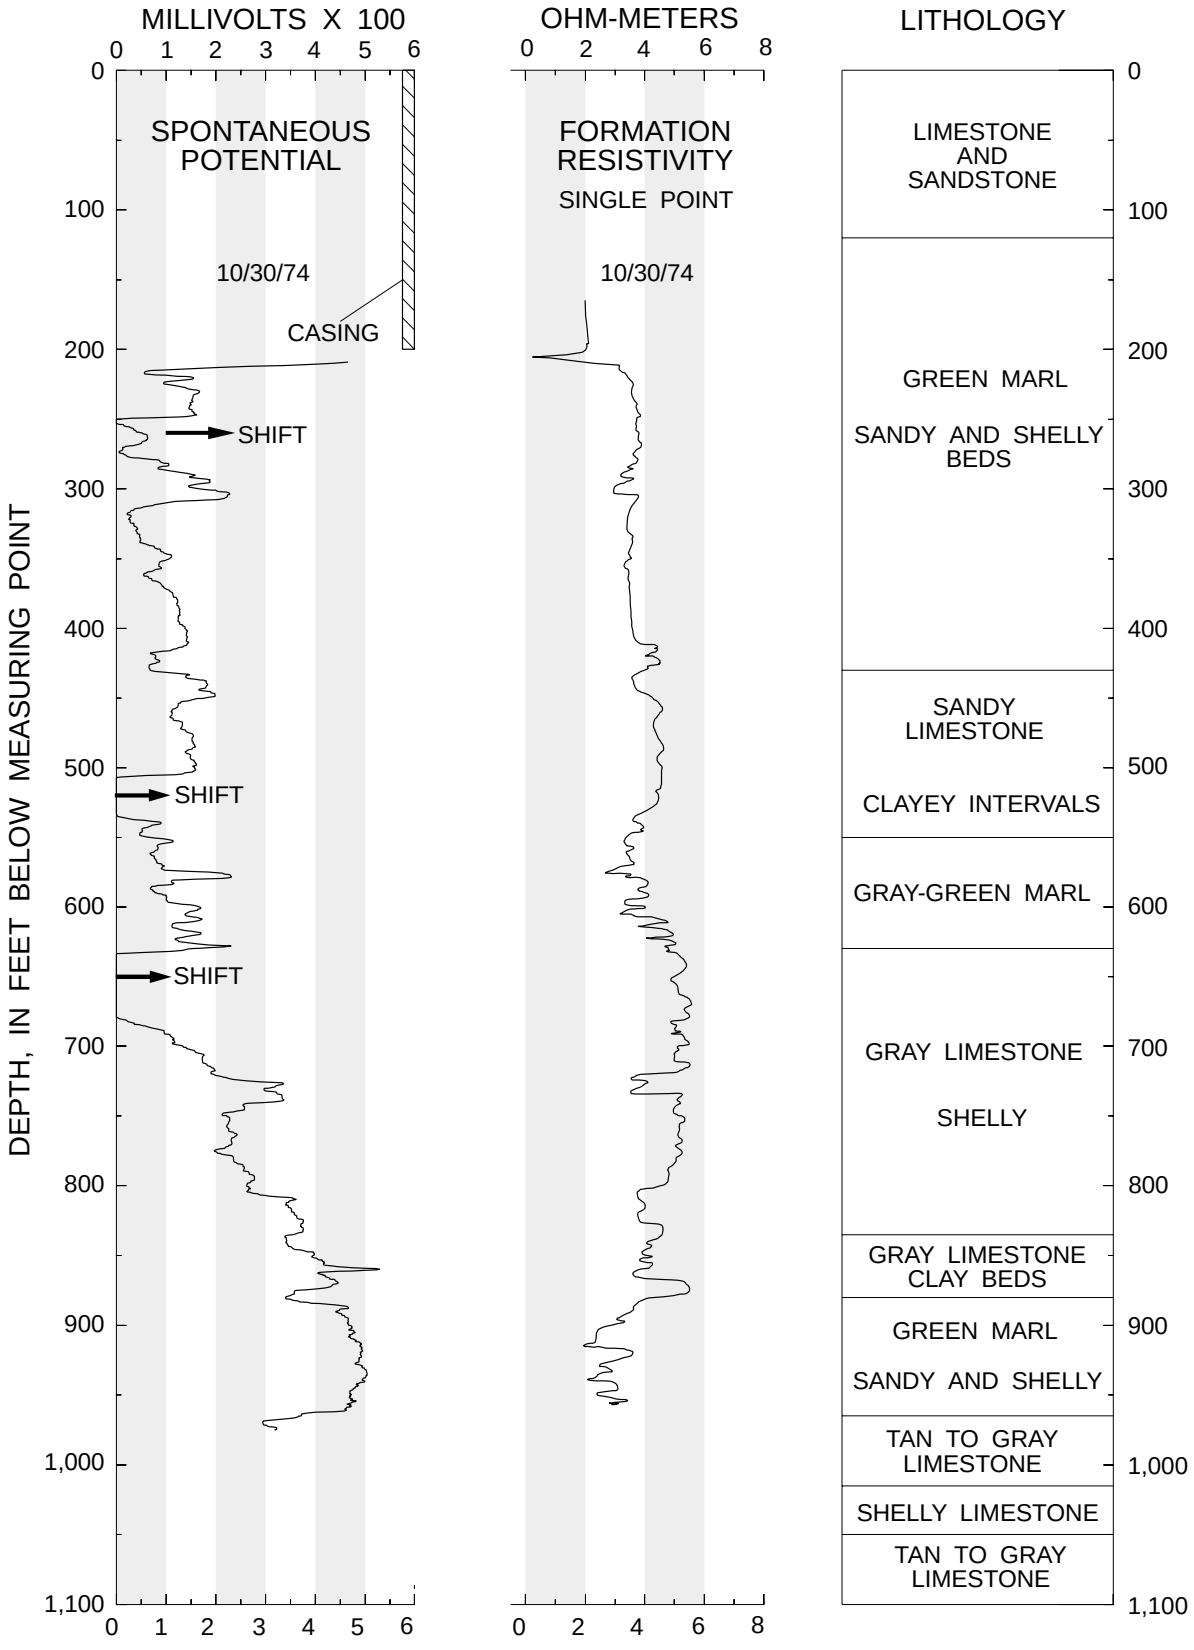

Figure 6. Electric logs of the Hialeah injection well (G-3061) and generalized lithology at the site.

Spontaneous-potential and single-point resistivity logs (fig. 6) were run to 975 ft in the nominal 10-in. injection-well pilot hole filled with aquagel on October 30, 1974. A correlation between the two log traces is evident. Increases in the spontaneous-potential readings that correlate with resistivity decreases indicate beds that predominantly are clay. The spontaneous-potential trace drifted, probably as a result of not grounding the borehole fluid, and was shifted three times to keep the pen on the left side of the chart. Inasmuch as the degree of the shifts is not indicated on the log, no attempt was made to compensate for them when the logs were digitized for report illustrations. The resistivity signal trace was highly oscillatory; thus, a trace of a line drawn through the center of the oscillating signal was digitized and provides the pertinent information. The single-point resistivity probe also commonly shows drift effects. The lower resistivity readings near the bottom of the hole probably indicate a more saline fluid.

The vertically contiguous, consolidated limestone beds of the Floridan aquifer system begin at a depth of about 975 ft and correspond to the lower part of the Suwannee Limestone of Oligocene age and the Avon Park Formation of Eocene age. The interval between depths of 1,015 and 1,050 ft is very shelly. Increases in flow were noted by the drillers as drilling progressed through this interval (App. A). The completed injection well was open to the depth interval between 955 and 1,105 ft, herein termed the injection zone. The receiving zone, or flow zone, is defined as the permeable interval between approximate depths of 1,024 and 1,036 ft that receives most of the inflowing freshwater.

Properties of the Injection Zone

Injection-zone properties needed to facilitate interpretation of the results of the injection and recovery tests are lithology, thickness of beds, hydraulic properties (hydraulic conductivity, porosity, and dispersivity), and the chemical quality of the water contained in the formation. These properties are described in the following sections.

Lithology

The generalized lithology of the depth interval 900–1,100 ft in the injection well (G-3061) is shown schematically in figure 7, which also depicts caliper, formation resistivity, natural gamma, and neutron porosity logs for correlation. The caliper log shows a decrease in diameter within the 14-in. casing below 940 ft from remains of the cement plug that was drilled through with a 12-in. bit. The log also shows part of the 22 1/2-in. reamed hole, just below the bottom of the casing, where cement washed out when drilling was resumed with a smaller bit. The caliper log does not show evidence of cavernous porosity or large solution features. In fact, the log gives no indication that any part of the injection zone has solution porosity. Thin hole enlargements at depths of 1,010, 1,050, 1,070, and 1,090 ft are probably the result of washouts occurring during successive stages of the drilling. Acoustic televiewer logs also failed to show evidence of solution porosity.

Other geophysical logs correlate with lithologic data. The large natural gamma counts from the bottom of the casing to 975 ft correlate with other wells regionally, as will be shown later in the report. The lithologic description for the injection well (App. B) notes phosphorite grains in the clay found in the depth interval from 900 to 975 ft. This mineral contains trace amounts of naturally radioactive material. The formation-resistivity logs (fig. 7) show high-resistivity zones centered at 986 and 1,032 ft, both apparently correlating with increases in natural gamma activity and a decrease of porosity on the neutron log. At the first depth, the drillers noted very hard streaks in the limestone. A hard dolomitic layer is found at the second depth, and the drillers log cites an increase in flow in this interval (App. A). Dolomite beds typically show higher resistivity because of their lower porosity and are sometimes found at the erosional surfaces of formations. The acoustic televiewer logs (not reproduced herein because of their generally poor quality) show what seem to be distinct bedding interfaces at 986 and 1,032 ft (F.W. Meyer, oral commun., 1975). A hypothesis consistent with these observations is that the hard beds mark upper and lower erosional surfaces of a thin section of the Ocala Formation. Verification of the existence of a thin bed of Ocala Formation rocks at this location, however, would require additional data acquisition and analysis.

A similar suite of geophysical logs (fig. 8) from the observation well (G-3062) helps to establish background conditions in the injection zone prior to the ASR cycles. The 16- and 64-in. normal-resistivity logs, the caliper log, and the natural gamma log have interpretations that are similar to those of logs from the injection well. The temperature and fluid-resistivity logs are discussed in the following sections. The schematic diagram (fig. 8) shows depths of the monitor tubes installed in the observation well.

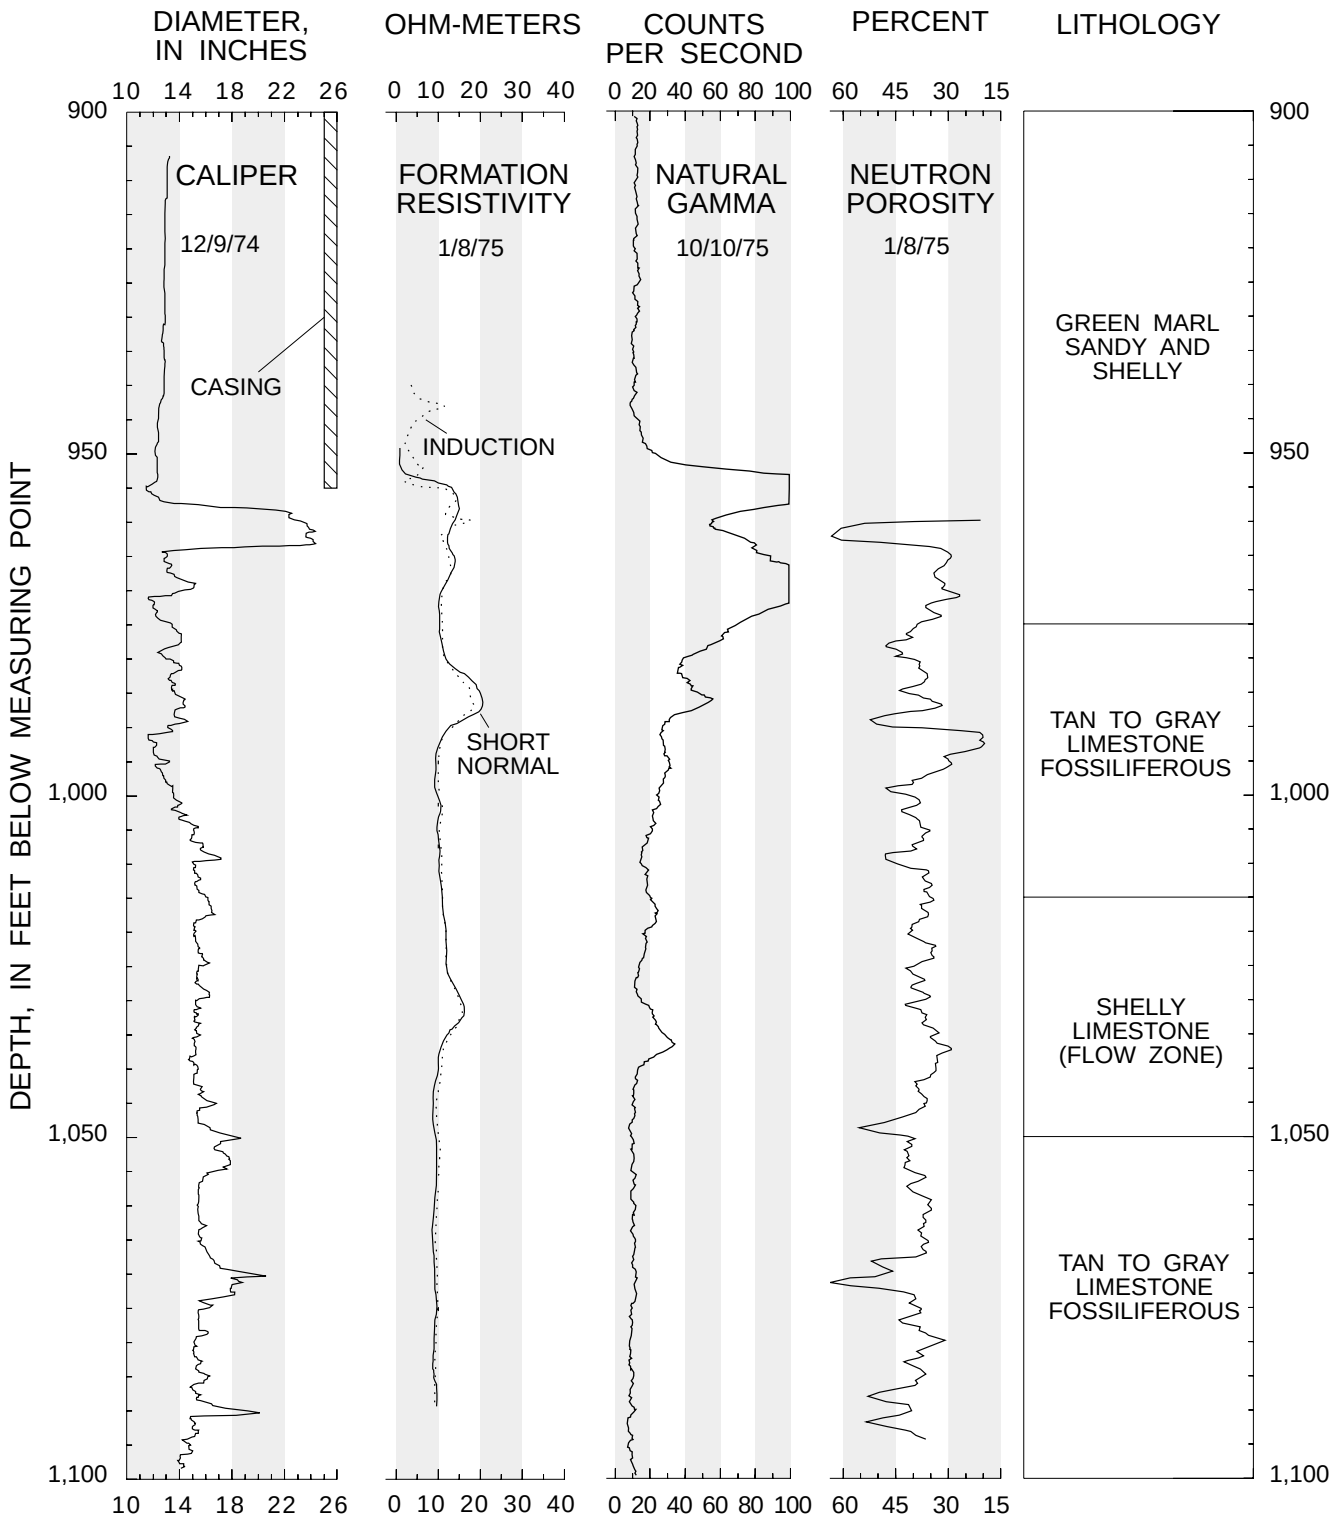

Figure 7. Geophysical logs of the Hialeah injection well (G-3061) and generalized lithology of the injection zone.

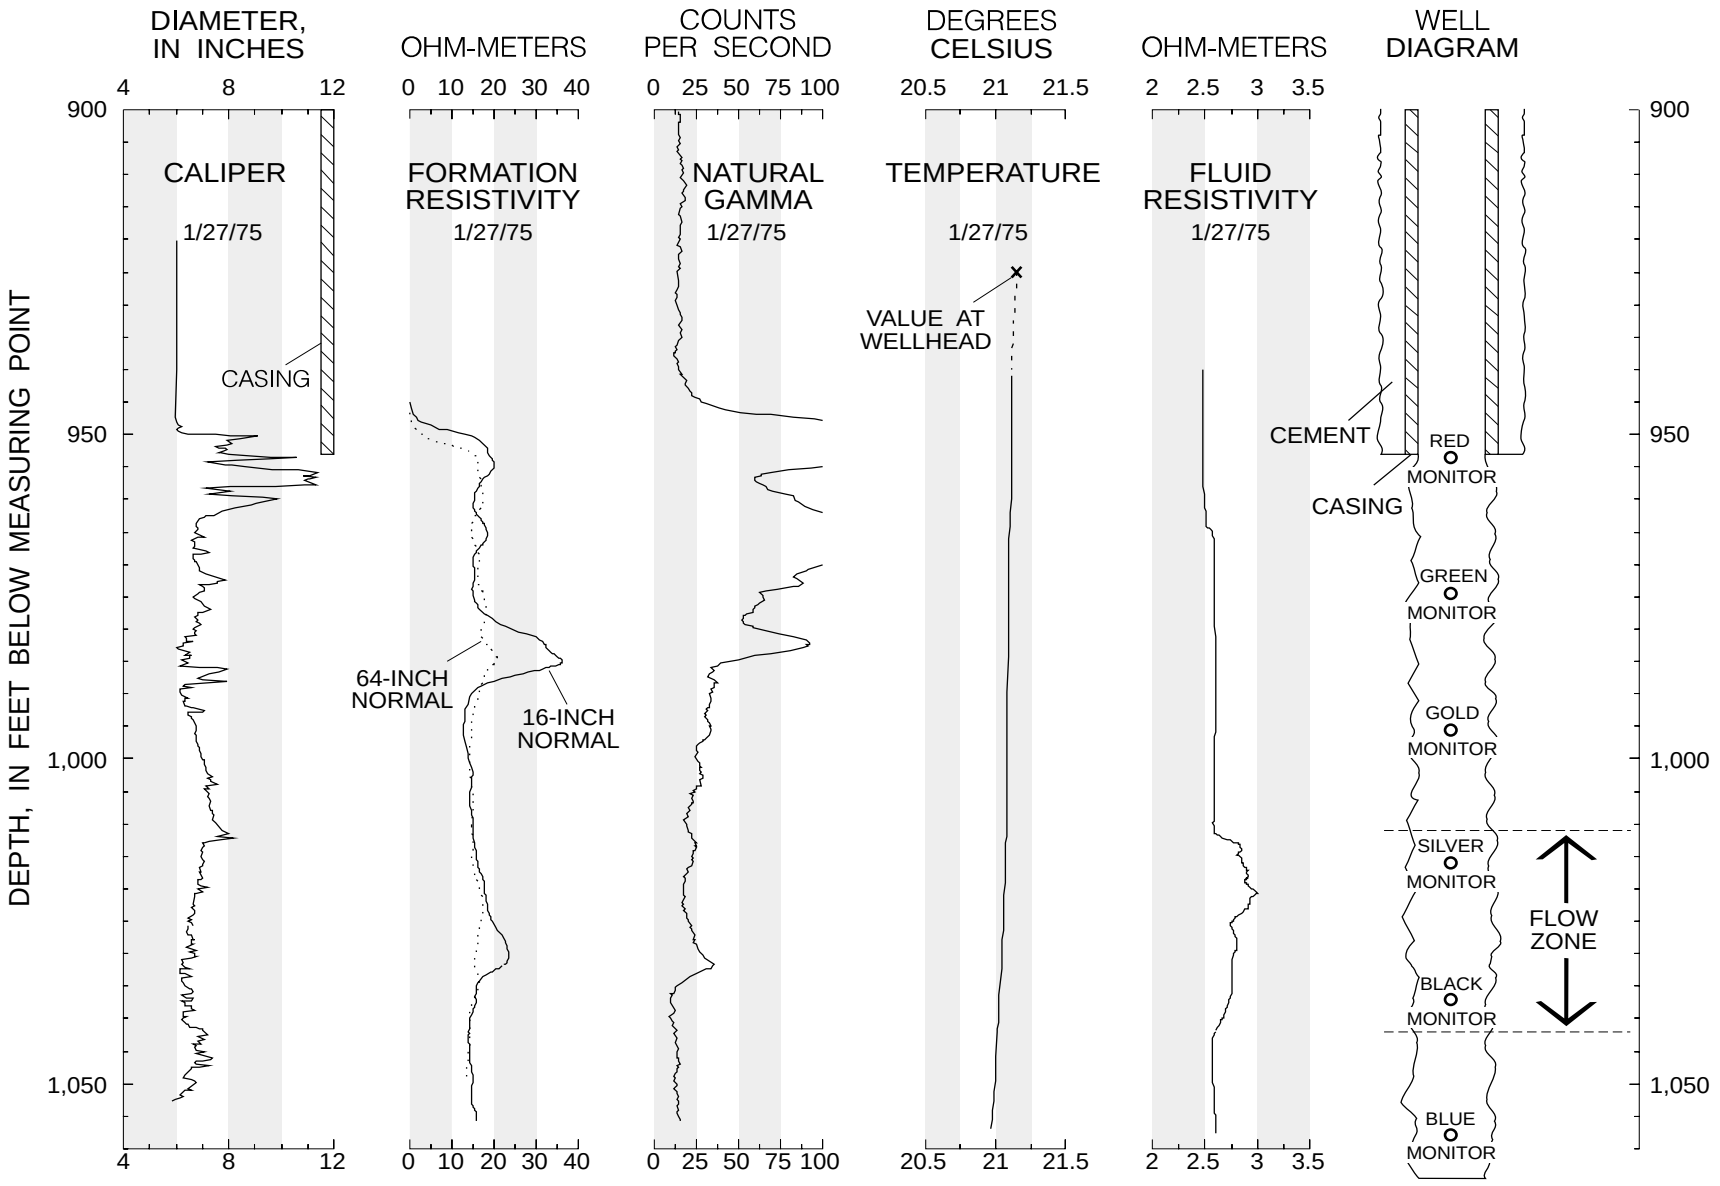

Figure 8. Geophysical logs of the Hialeah observation well (G-3062) and depths of monitor tubes.

Transmissivity

Aquifer tests were conducted to measure the composite transmissive capability of the 150-ft injection zone, known to be made up of strata of strongly contrasting permeability. When this information is combined with a knowledge of the thickness, distribution, and relative contribution of permeable flow zones obtained by geophysical logging under flowing conditions, a better understanding of the disposition of the water injected during the ASR process can be gained, and the transmissivity of each flow zone can be estimated. Estimates of hydraulic conductivity in individual zones can then be derived by dividing flow-zone transmissivities by their approximate thicknesses. The generic computer code used in this study requires input of estimates of hydraulic conductivity and the thickness and distribution of flow zones and confining layers for simulation of freshwater injection, storage, and recovery.

The first aquifer test was conducted on February 10, 1975, by allowing the 6-in. observation well at Hialeah to discharge for 100 minutes at 250 gallons per minute (gal/min) as pressures were measured in the injection well and in the 2-in. monitor tube open at 840 ft in the observation well. Discharge was measured using an orifice plate on the observation well. Two pressure gages, their readouts in feet of head, were used in the injection well. These gages had a display range of 0–60 ft of head at 0.2-ft scale divisions. The maximum drawdown at the injection well was 1.8 ft. Pressure changes during recovery were observed for 15 minutes immediately following the closing of the orifice. The following day, a second aquifer test, a constant-head discharge test, was performed.

During the first aquifer test, values of head from the two injection-well gages differed by about 2 ft and showed slightly different trends. Both drawdown data sets were analyzed for estimates of transmissivity (T) and storage coefficient (S) using the method of Jacob and Lohman (1952). Data from one gage, considered to be the more representative, were also analyzed using the Theis type-curve method. On the basis of the various analyses, transmissivity was estimated to be about 11,000 $[(ft^3/d)/ft^2]ft$ (Meyer, 1989b). The maximum drawdown in the 2-in. monitor tube was 0.2 ft (F.W. Meyer, written commun., February 1975), indicating that minor leakage occurred across the marly confining beds separating the injection zone from the perforations at 840 ft.

Flow-Zone Depth and Thickness

A delineation of the relative permeability of the various strata within the injection zone was partly based on a study of data collected during spinner flowmeter logging during injection and recovery. The quantitative analytic procedure developed for this study is described below. Also presented is a parallel description of the flow-zone depth and thickness based on an evaluation of fluid-resistivity and temperature logs.

Analysis of Data From Spinner Flowmeter Logs

Two sets of spinner flowmeter data were collected from the injection well on October 20, 1975, while the well backflowed under artesian pressure. These data are shown in figure 9, together with caliper log data, to illustrate a typical analysis for obtaining a vertical profile of the relative amount of flow in the wellbore. One set of data was recorded as the probe was lowered into the well, and the other as the tool was raised.

Spinner flowmeter probes contain a device that rotates in response to the relative speed of fluid movement past the probe. Measurements of the rotation speed are transmitted to the logger in counts per second. However, the probe does not indicate the direction of relative flow, only the rate of the spinner rotation. When the probe was lowered to the bottom of the well on October 20, 1975 (fig. 9), the direction of relative flow past the probe remained in the upward direction throughout the entire logged interval, including the stagnant zone between the flow zone and the bottom of the well. However, a different situation prevailed as the probe was raised from the bottom. The upward moving probe responded to apparent downward flow (relative to the changing position of the probe) in the stagnant zone. As the probe moved upward past the flow zone, relative flow through the probe reversed direction and was upward in the direction of discharge from the well. Therefore, as the relative flow direction changed, the spinner slowed, and a null reading was recorded, as shown at 1,028 ft in figure 9. Analysis of the recorded data to produce a vertical-flow profile requires reversing the arithmetic sign of the data at the depth where the null occurs.

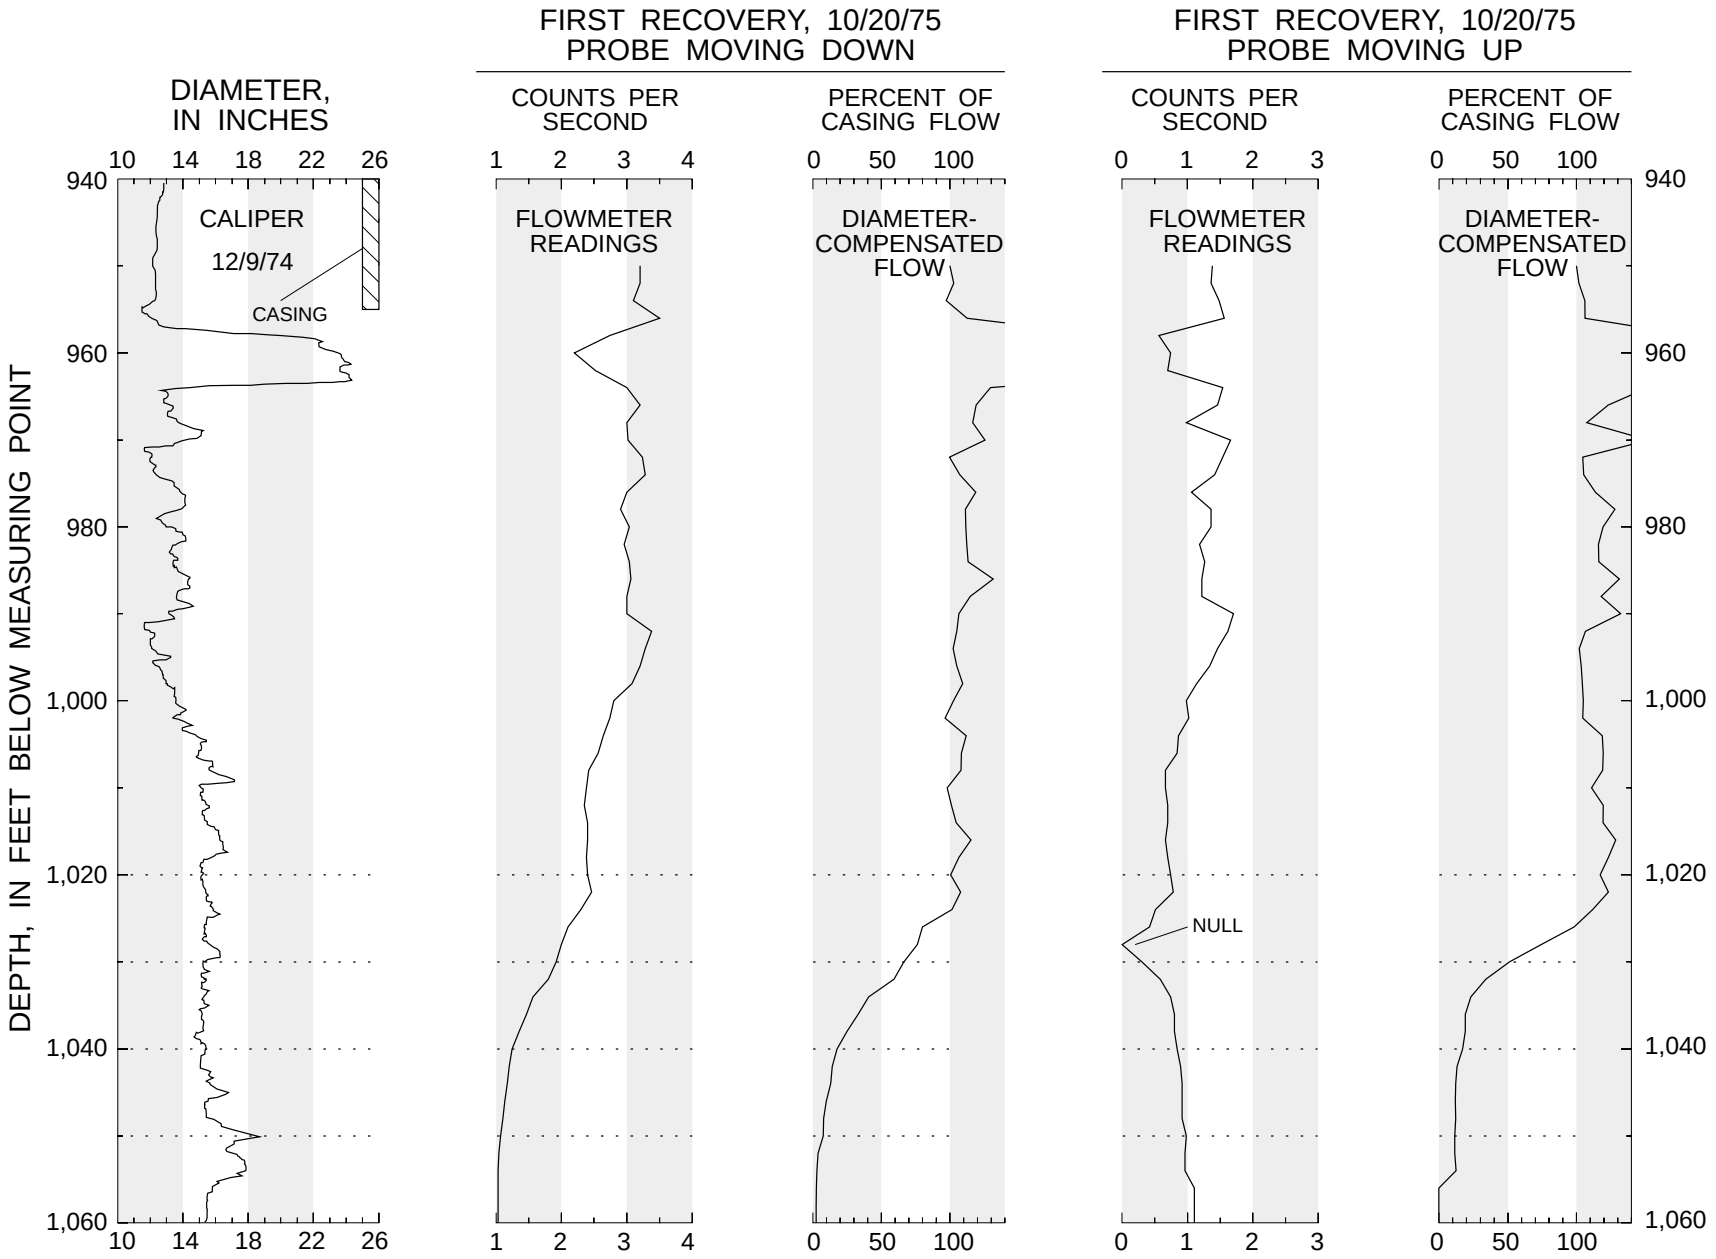

Figure 9. Conversion of a typical set of spinner flowmeter data to wellbore flow measurements.

Stationary spinner flowmeter measurements, in which the rotation speed is observed while the probe is hung at a fixed elevation, are more reliable than continuous readings that must be corrected for tool velocity, but often fail to clearly show the depths at which changes in flow occur. During the Hialeah tests, stationary flowmeter measurements were obtained during the logging sequences of May 25, 1976, and April 20, 1978 (fig. 10). On May 25, 1976, the stationary reading at 1,046 ft was only 7 percent of that measured in the casing, and a zero reading was obtained at 1,059 ft. On April 20, 1978, a zero reading was obtained at 1,040 ft. These measurements proved that flow in the bottom of the hole was negligible and aided in interpreting other geophysical logs.

Whether spinner flowmeter measurements are continuous or discrete, the measured velocity varies with the diameter of the borehole as well as with the quantity of flow produced. Therefore, in quantitative analyses, flowmeter data must be adjusted to compensate for borehole diameter. For example, the flowmeter data values recorded as the probe moved downward on October 20, 1975, show a decline below 992 ft. However, the borehole diameter increases, and the diameter-compensated flow values remain nearly uniform to a depth of 1,024 ft.

Quantitative analysis of flowmeter data consists of the diameter compensation and an adjustment for the velocity of the probe during descent or ascent. Flow at a given depth $Q(h)$ can be expressed as a percentage $\Delta Q(h)$ of flow within the lower part of the casing Q_0 where the radius r_0 is considered to be locally uniform. The computation can be written as

$$\Delta Q(h) = 100\frac{Q(h)}{Q_0} = 100\ \frac{\pi r(h)^2}{\pi {r_0}^2}\left(\frac{C(h)\beta - V_t(h)}{C_0\beta - V_0}\right) \qquad (1)$$

where: $r(h)$ is the borehole radius at depth h,
$C(h)$ is the measured counts per second at depth h,
C_0 is the measured counts per second in the casing,
β is a conversion factor relating counts per second to velocity,
$V_t(h)$ is the velocity of the tool at depth h, and
V_0 is the velocity of the tool at the depth where C_0 is measured in the casing.

In flowmeter logging in long boreholes, the probe velocity can vary appreciably, and a record usually is made of the tool velocity at regular depth intervals. In the flowmeter logging conducted during the Hialeah ASR tests, however, the logged interval was short (generally 940–1,100 ft), and at best, a single value for probe velocity is noted on the logs. Therefore, the assumption was made in the analysis that the probe velocity was uniform throughout; that is,

$$V_t(h) = V_t = V_0 \qquad (2)$$

Furthermore, because stagnant water is present in the bottom of the borehole, the probe velocity is related to counts recorded in the bottom of the hole C_b; that is

$$V_t = \beta C_b \qquad (3)$$

Equation 1 now reduces to

$$\Delta Q = 100\frac{r(h)^2}{{r_0}^2}\frac{[C(h) - C_b]}{(C_0 - C_b)} = 100\frac{r(h)^2}{{r_0}^2}\frac{\Delta C(h)}{\Delta C_0} \qquad (4)$$

In this formulation, counts at depth h, $C(h)$, are referenced to counts in the bottom of the hole (C_b) and adjusted by the ratio of the squares of the radii. This provides a simple formula for digital computation.

Many problems are associated with the quantitative analysis of spinner flowmeter logs. When the probe passes through thin zones of larger diameter, the moving fluid often apparently does not develop a uniform velocity throughout the enlarged borehole; thus, the diameter compensation can lead to error. When the probe moves in the direction of well discharge and the spinner reverses direction, the counts do not always read zero, or null, on the chart; thus, errors can occur in computing the degree of flow augmentation in this interval. Depth errors can occur as a result of cable stretch or errors in depth orientation. Such errors can be critical in making diameter compensations and in precise evaluation of the depths at which significant flow augmentation occurs. Errors can be introduced related to the physical operation of the spinner device; the device may be more sensitive to flow from one direction than the other, and a time lag can occur in the response of the device to changes in borehole flow, depending on the probe velocity.

Each of the 18 spinner flowmeter logs run during the ASR cycles was digitized at 2-ft depth increments and converted to relative volumes of flow using equation 4. Nulls were identified and assigned $C(h)$ values of zero, while data from lower depths were considered to be negative values and data from higher depths were considered to be positive values. Depth errors due to cable stretch or calibration error were identified by comparing low count intervals with the large-diameter interval centered at 960 ft in the injection well, and depth adjustments ranging from 0 to 6 ft were made to all recorded depths in the logged interval. Results of the analyses are shown in figure 10.

Examination of the computed flows indicates a depth of 1,024 ft to be the top of the flow zone. Evidence identifying the bottom of the flow zone is less clear, but the bottom is most likely at 1,036 ft, indicating a flow-zone thickness of only 12 ft. On the basis of some logs, the zone might extend to a depth of 1,040, 1,044, or 1,050 ft, indicating possible flow-zone thicknesses of 16, 20, or 26 ft.

A slight amount of flow between depths of 955 and 965 ft was noted during drilling (App. A), but the flowmeter log analyses show no evidence of it; thus, the amount of flow from this depth interval apparently is negligible compared with that from the principal flow zone (1,024–1,036 ft). No appreciable contribution to flow seemed to originate from the indicated bedding interface at 986 ft. Any slight contribution would have been masked by the effect of irregularities in the borehole diameter.

Spinner flowmeter logs in the observation well could have been used to verify that the narrow flow zone in the injection well was similar in character at the location of the observation well, and in supporting the hypothesis that the zone was similar throughout the region of injected freshwater flows. A flowmeter log was attempted in the observation well on January 27, 1975, but the probe would not pass below a depth of 983 ft. The installation of multidepth samplers in the observation well at the beginning of the ASR cycles rendered subsequent flowmeter logging of this well infeasible.

The flowmeter logs of August 27, 1976, as previously noted, are useful in assessing the degree to which the vertical permeability distribution may be affected by borehole plugging during injection. The spinner was raised and lowered during (1) injection before a backflush, when plugging had substantially reduced injectivity; (2) the backflush; and (3) injection immediately following the backflush, after most of the natural injectivity had been restored. An examination of the converted logs (fig. 10) shows more apparent difference between the up and down logs of each set than between any sets of logs. All tend to confirm the previously accepted hypothesis that the flow zone lies between depths of 1,024 and 1,036 ft, and there is no indication that any change in the vertical distribution of injectivity has occurred.

The flowmeter logs shown in figure 10 cover a period of injection, storage, and recovery lasting nearly 4 years. The similarity of the results throughout this time period indicates that no long-term changes in the vertical distribution of injectivity have occurred.

Interpretation of Data From Temperature and Fluid-Resistivity Logs

Logs of temperature and fluid resistivity run before and during the ASR cycles are used as additional means to corroborate the delineation of the flow zone. These logs are also used to aid interpretation of interesting facets of the injection and recovery process and the effect of the process upon water quality.

Temperature and fluid-resistivity logs run in the observation well on January 27, 1975 (fig. 8) were for the purpose of establishing background conditions prior to ASR cycles. The fluid-resistivity log, probably run during artesian flow, shows inflows of increasing resistivity (fresher water) between 1,011 and 1,042 ft, an interval which corresponds to 1,015 and 1,046 ft in the injection well because of the different elevations of the measuring points. The interval also correlates with the interval of shelly limestone (fig. 7) that contains the flow zone.

One possible interpretation of a zone of fresher water surrounded above and below by more saline water is that the zone is sufficiently permeable to be partly flushed by flow from upgradient areas of freshwater recharge. The Floridan aquifer system crops out in central Florida, where it receives atmospheric recharge and contains potable water (fig. 5). The peak resistivity in the log of January 27, 1975, is at a depth of 1,020 ft (1,024 ft in the injection well, the probable top of the permeable flow zone). The temperature log, run as the well flowed under artesian pressure, shows temperature to be nearly uniform from land surface to about 1,010 ft, below which the temperature decreases about 0.2 °C in 50 ft, an indication that inflow occurs in this interval.

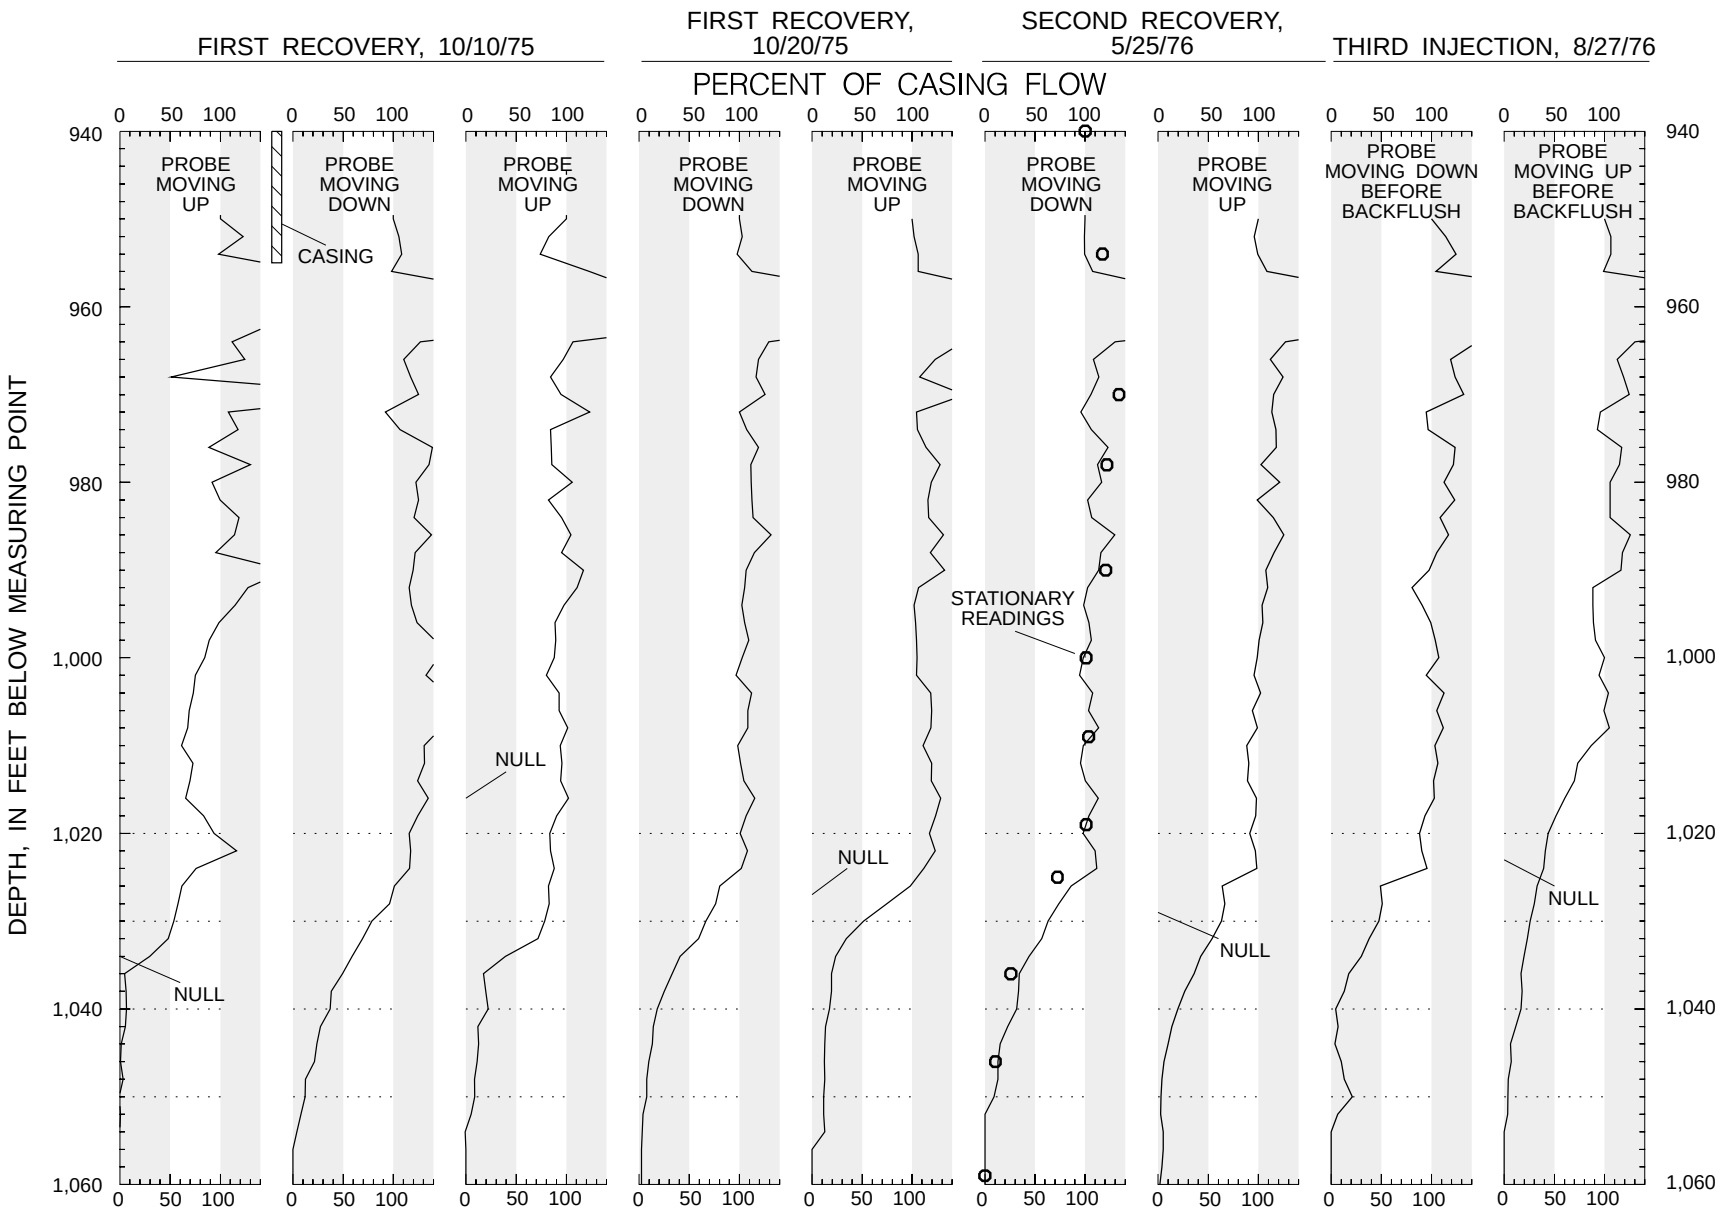

Figure 10. Wellbore flow measurements from conversion of spinner flowmeter logs of the injection well (G-3061) during three injection and recovery cycles (1975-79).

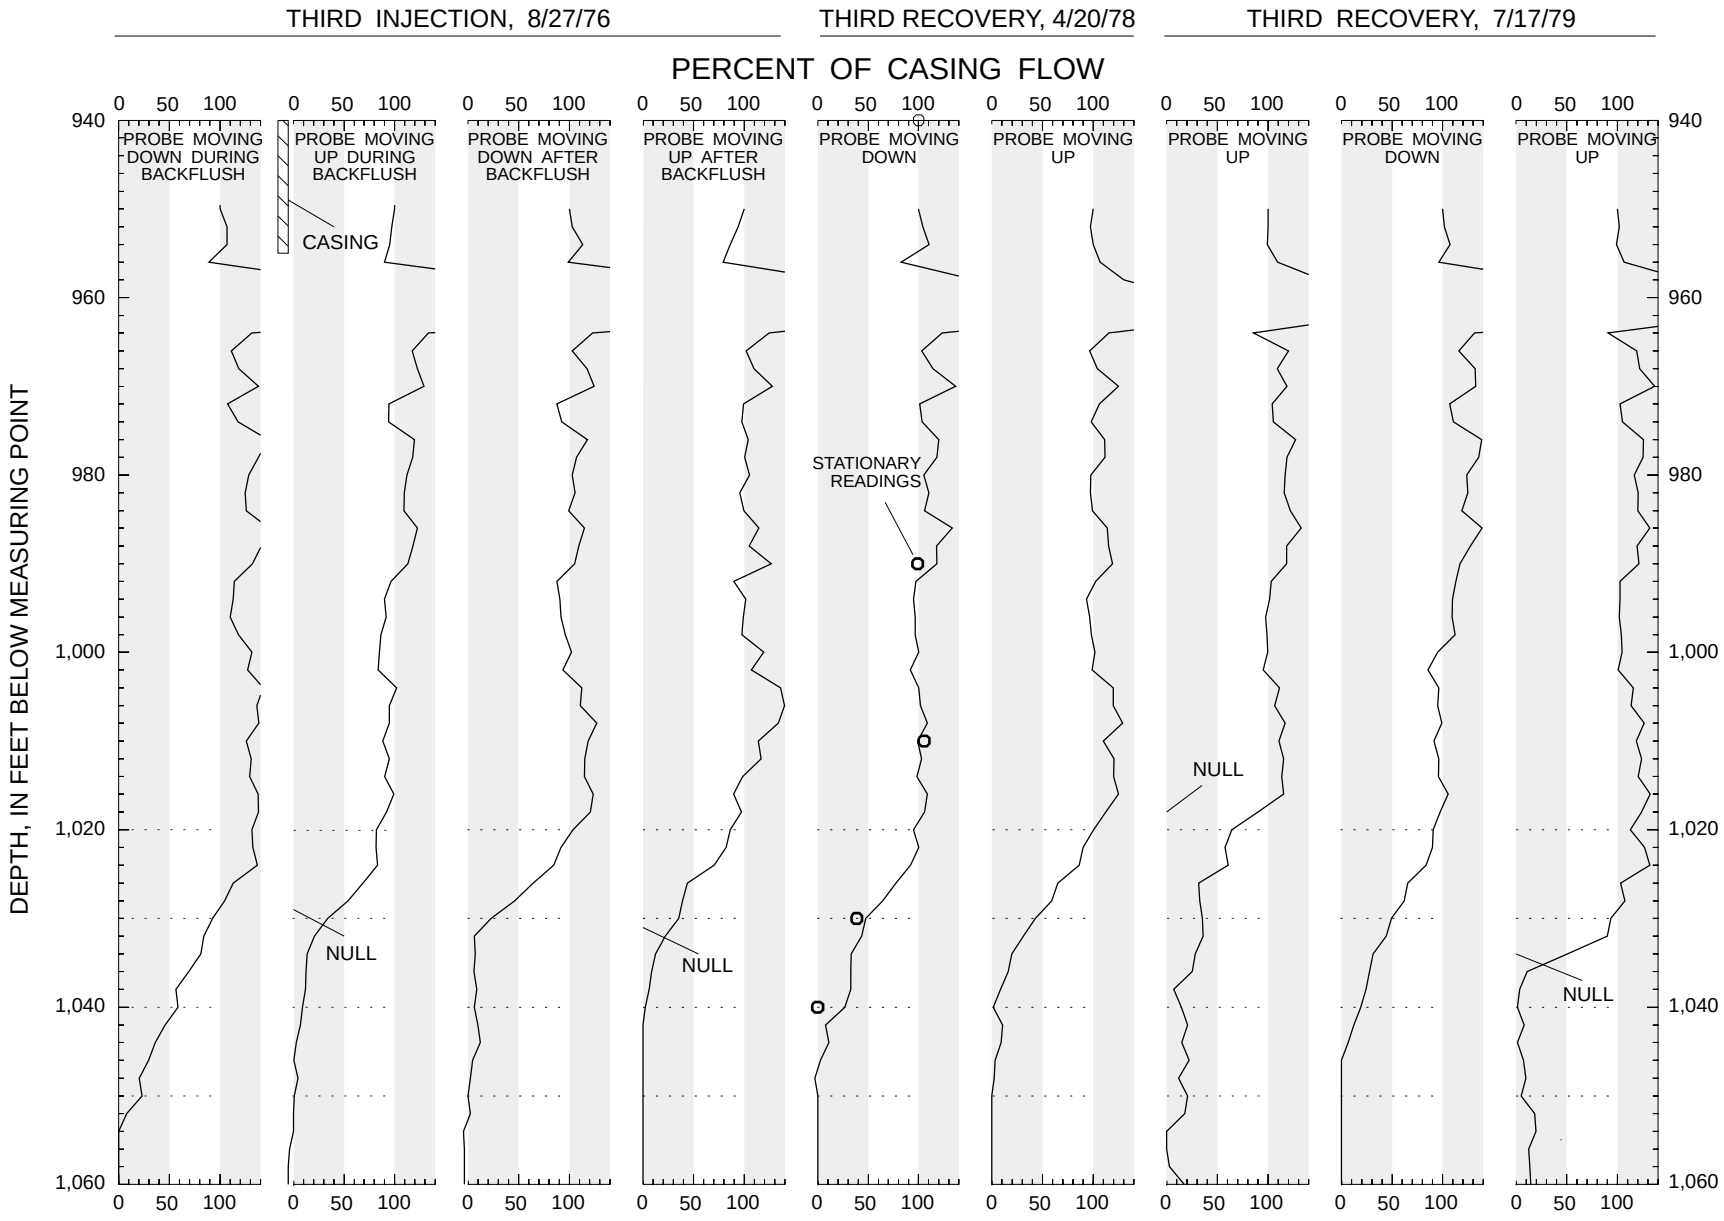

Figure 10. Wellbore flow measurements from conversion of spinner flowmeter logs of the injection well (G-3061) during three injection and recovery cycles (1975-79)--Continued.

Selected logs of temperature and fluid resistivity in the injection zone obtained as water backflowed during the three recovery phases are shown in figure 11. For comparison purposes, the temperature log run on October 10, 1975, 30 days into the first recovery, when the chloride concentration of recovered water had reached 300 milligrams per liter (mg/L), is shown together with the observation-well temperature log of January 27, 1975, which depicts preinjection conditions. Measurements of the temperature of water from the supply well during the three injection phases are shown in figure 12. The temperature of injected water in the first ASR cycle averaged 25.55 °C, in contrast with the preinjection temperature in the injection zone of about 21.2 °C. The temperature of recovered water on October 10, 1975, was about 24 °C, but the temperature increased rapidly to about 25 °C below 1,047 ft (fig. 11). Fluid resistivity on the same date also increased markedly below 1,047 ft. Below 1,047 ft, therefore, is a zone of warmer, fresher water that is likely stagnant injected water either forced into the zone of relatively low permeability underlying the flow zone during the previous injection or forced downhole by turbulent convection. At 300 mg/L of chloride concentration, recovered water contains about 22 percent native water. The temperature decrease from 25.5 °C to 24 °C probably is caused by mixing and thermal diffusion.

A break in the fluid-resistivity trace of October 10, 1975, and a slight break in the temperature trace of the same date, occurs just below 1,025 ft, indicating a concentration of flow at this depth. That the water becomes relatively more saline and slightly cooler above this elevation also suggests more rapid recovery of injected water from cavities at this elevation.

The fluid-resistivity log run on May 25, 1976, 22 days into the second recovery phase, when the chloride concentration of recovered water had reached 124 mg/L (about 6.5 percent native water), shows a more gradual resistivity increase with depth, beginning at about 1,018 ft and becoming more pronounced after about 1,047 ft (fig. 11). No temperature log was obtained. Again, there seems to be stagnant freshwater in the bottom of the hole, particularly below 1,047 ft.

The temperature and fluid-resistivity logs of April 20, 1978, 276 days into the third recovery, when the chloride concentration of recovered water had reached about 600 mg/L (about 48 percent native water), again show stagnant, warmer freshwater in the bottom of the hole below 1,043 ft. The average temperature of the injected water in the third ASR cycle was 25.93 °C. On April 20, 1978, recovered water above 1,020 ft had a temperature of about 22.8 °C (fig. 11), close to the preinjection background of 21.2 °C, apparently a result of both mixing and at least 457 days of thermal diffusion (the storage period was 181 days). A slight break in the trace of the fluid-resistivity log at about 1,022 ft suggests a concentration of inflow, possibly correlating with similar indications at 1,025 ft during the first recovery and at 1,018 ft during the second recovery. The slight difference in elevations could easily be attributed to depth measurement error. The temperature log of July 17, 1979, 729 days into the third recovery, when the chloride concentration of recovered water was 1,060 mg/L (about 88 percent of that in the native water), shows the recovered water temperature to have dropped to about 22.0 °C, even closer to that of the native water before injection. The fluid-resistivity log of the same date shows slightly more saline water below 1,030 ft. Apparently, recovery has been of sufficient duration to have flushed the stagnant freshwater from the bottom of the hole and surrounding rocks, though some of the thermal energy remains.

All of the temperature logs show some cooling of the warmer water near the bottom of the hole. This could be due to the closer proximity of stagnant warm water in the bottom of the hole to the vast thermal sink below.

On the basis of temperature and fluid-resistivity logs and the preceding analysis of the spinner flowmeter logs, it seems that a depth of 1,024 ft approximately marks the top of the flow zone and may be a point source for much of the flow. The bottom of the flow zone now seems to be in the 1,043- to 1,047-ft range. However, the proportionate amount of flow that occurs below 1,036 ft may be insignificant.

Porosity

A review of data that leads to estimates of aquifer porosity is useful because the generic simulator used in this study implicitly represents aquifer storativity with input specifications of effective porosity, rock and water compressibility, and thicknesses of permeable flow zones. Effective porosity, which changes slightly as pressure varies and the aquifer pores expand or contract, is a direct measure of the amount of injected freshwater that can be accepted by a unit pore volume of the aquifer. Total porosity is a measure of the amount of water contained within a unit pore volume and may be greater than effective porosity if some of the water is contained in pores that are not connected to flow pathways.

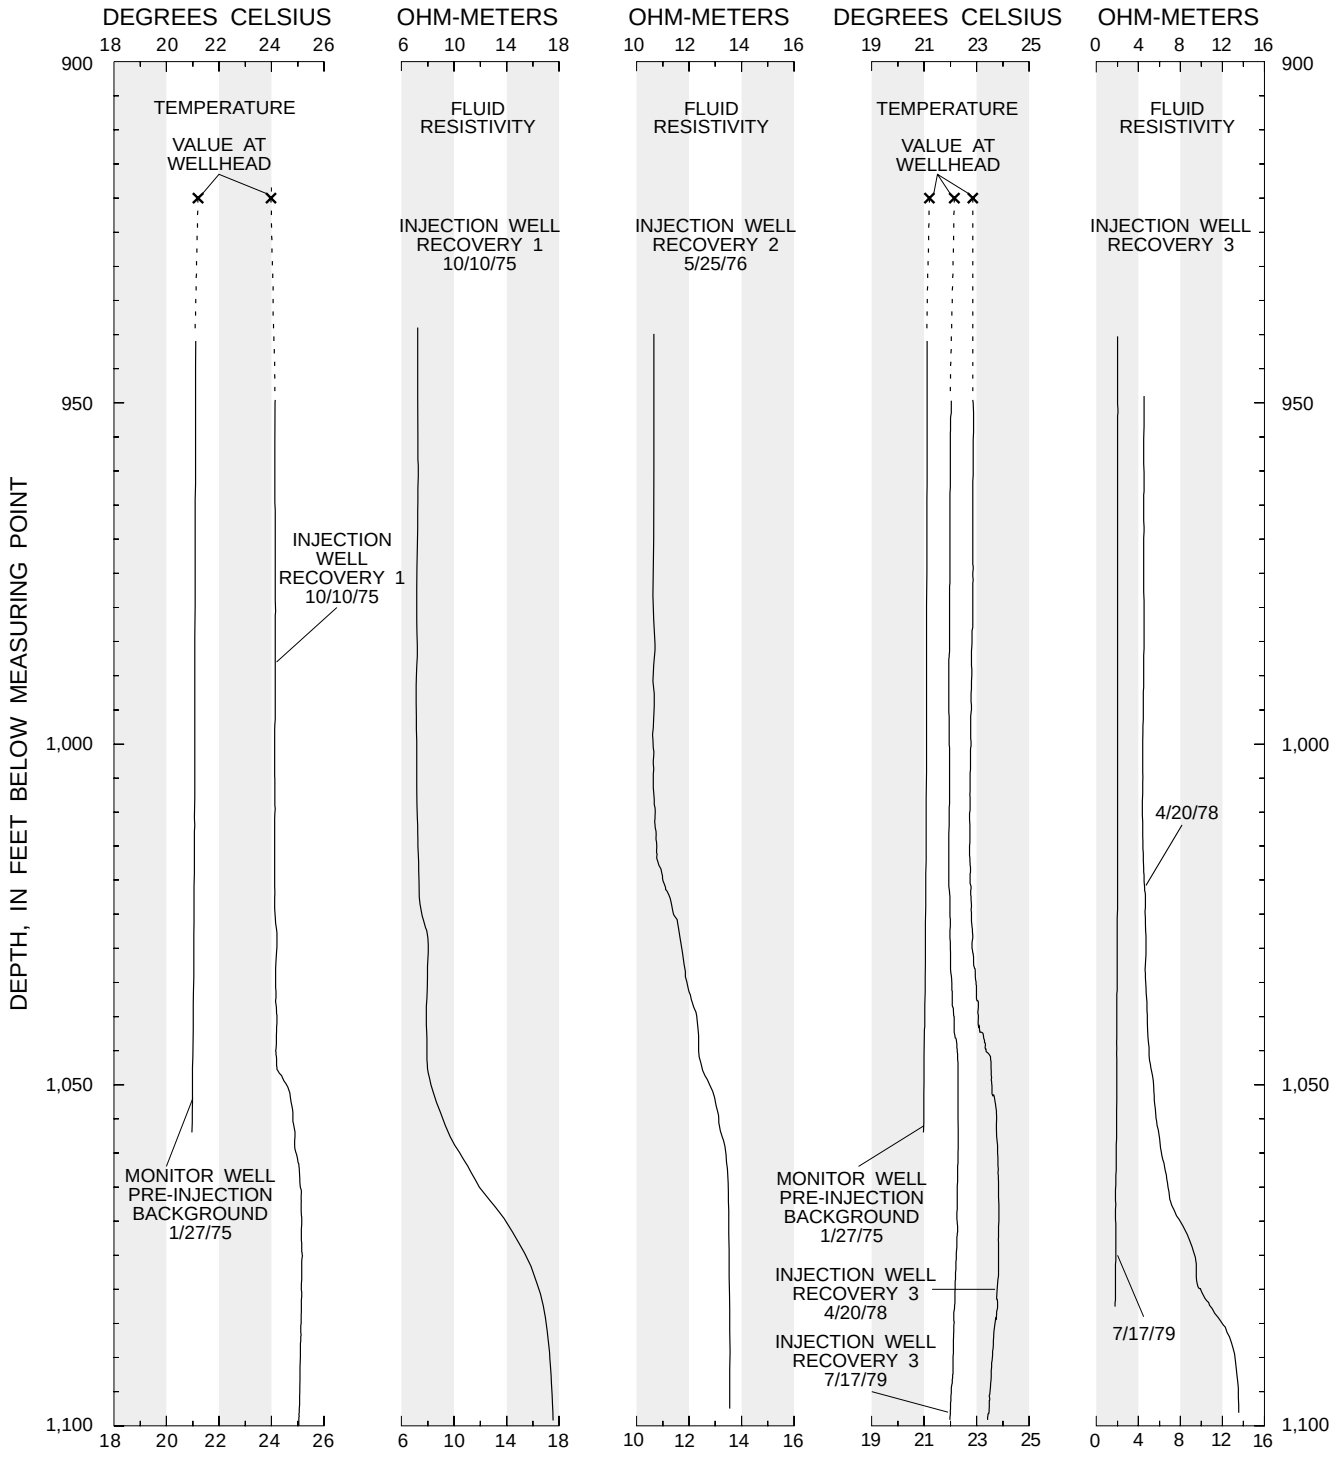

Figure 11. Temperature and fluid-resistivity logs of the injection well (G-3061) before and during aquifer storage and recovery cycles.

Direct measurements of injection-zone total porosity consist of the neutron porosity log run in the injection well by Schlumberger, Inc., on January 8, 1975, and neutron porosity logs run by the USGS in the injection and observation wells on October 10, 1975, and January 27, 1975, respectively. The Schlumberger log data, illustrated in figure 7, were stated by the contractor to have been compensated for borehole effects. Porosity seems to average about 35 percent throughout the injection zone. Large variations between extreme values of 20 and 65 percent occur within discrete intervals. Although no reason exists to

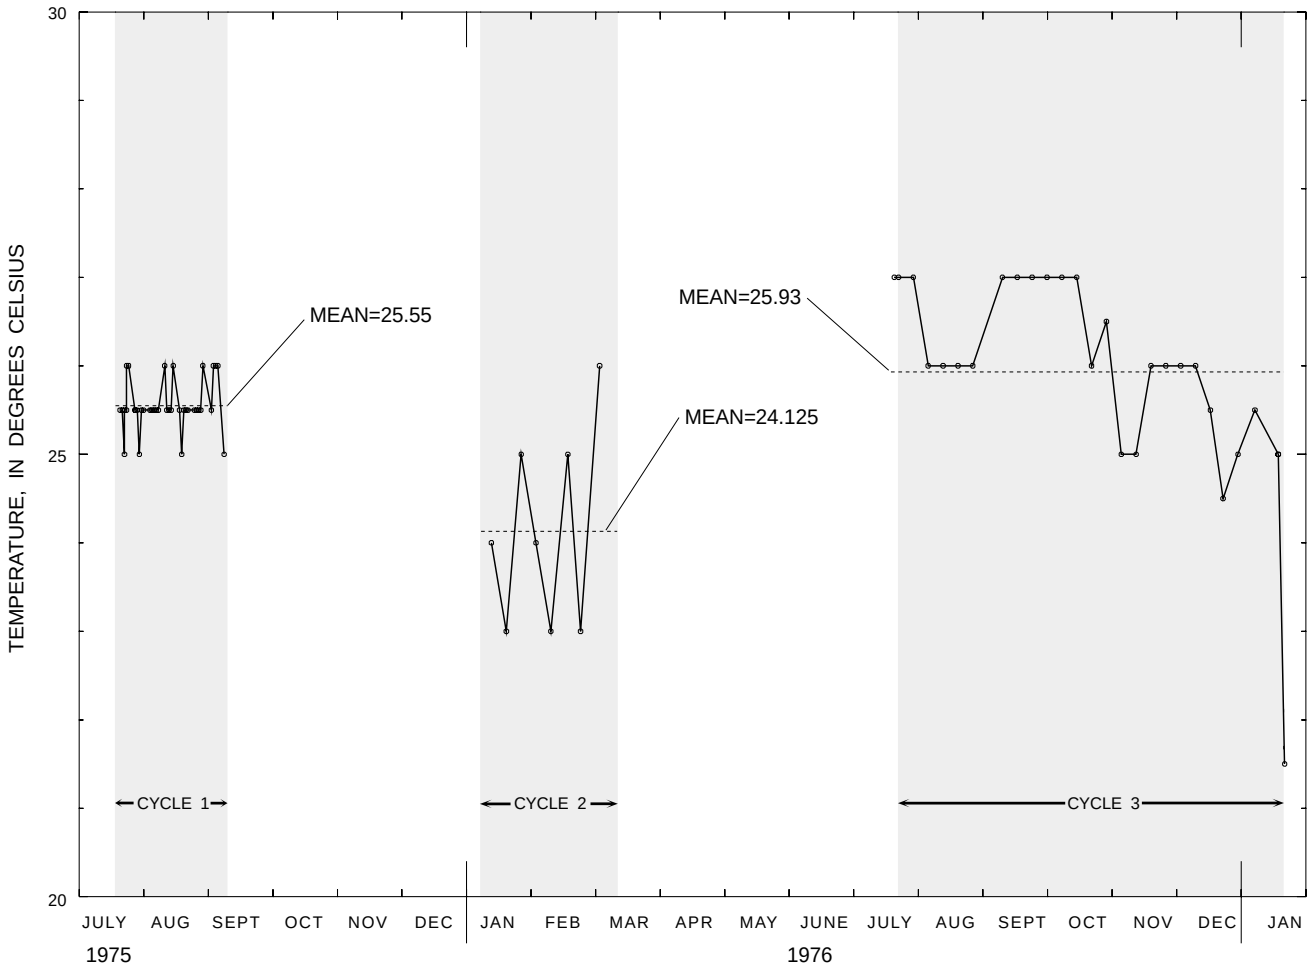

Figure 12. Temperature of water from the injection supply well during aquifer storage and recovery cycles.

question the validity of the lower values, the high-porosity spikes probably indicate where exceptional borehole irregularity has caused an overestimate of the amount of the compensation. The USGS logs were not compensated for borehole effects and were not used for porosity estimates.

Estimates of storage coefficient obtained from analyses of aquifer-test data can sometimes be used to check porosity data and corresponding estimates of rock compressibility and aquifer thickness. However, the disparity among the storage coefficients estimated from the Theis and Jacob-Lohman analyses of the February 10, 1975, aquifer test discouraged attempts to make such detailed comparisons.

The neutron porosity log measured the total water content of the formation, including that contained in either pores within the rock or in solution features. Of striking interest is the fact that the average value of 35 percent seems to be the water content not only of the solution-riddled flow zone, but also of overlying and underlying layers of negligible solution porosity. However, a 35 percent value for total porosity does seem to be consistent with the result of laboratory analyses of cores from the relatively impermeable confining layers that overlie the Lower Floridan aquifer (boulder zone). A cursory review of many core analyses performed by private laboratories for engineering consultants managing the construction of municipal waste-disposal wells indicates that porosities of 25–40 percent typically are measured on cores that are predominantly limestone. Porosities of dolomite cores, on the other hand, generally fall into a lower range of 1–15 percent.

Water Quality

A characterization of the quality of the native water is needed for an understanding of factors that affect flow processes, recoverability, wellbore plugging, and the quality of recovered water. Inclusion in

Appendix D of measurements of the chemical and biological constituents of native, injected, and recovered water provides the data to readers for many possible uses. One of the most interesting potential uses is to determine changes in the quality of the injected water after a period of residence in the aquifer. However, the interpretive scope of this report is limited to a discussion of water-quality characteristics affecting ASR flow processes and recoverability and the simulation of the ASR process with computer models. Therefore, the chemical characteristic of principal interest is density.

The degree of buoyancy stratification that occurs depends on the density contrast between injected and native water. Recoverability of injected water is reduced by buoyancy stratification (Merritt, 1985). Recoverability also is determined by the degree of dispersive mixing with the native water, another reason for accurately describing the salinity of the native water. The higher the salinity of the native water, the less the amount of mixed injected and native water that will be potable. Buoyancy stratification and dispersive mixing are processes that must be accurately represented to achieve the simulation objectives of this study.

Direct measurements of density usually lack sufficient accuracy for many purposes (Meyer, 1989a), and water density is more accurately estimated as a function of known salinity and temperature. Salinity is based herein on measurements of dissolved solids, which correlate well with chloride concentrations in brackish waters of the Upper Floridan aquifer.

A characterization of the salinity of native water in the injection zone is based on preinjection water-quality samples from the injection and observation wells, on water-quality data obtained from the observation-well monitor tubes early in the first ASR cycle, and from the preinjection fluid-resistivity log run in the observation well on January 27, 1975. The monitor-tube data obtained later in the ASR cycles help to corroborate this interpretation and also facilitate an understanding of flow processes during ASR cycles.

Preinjection Sampling and Geophysical Logging

The water-quality samples (App. D), obtained on November 20, 1974, from the observation well and on December 4, 1974, from the injection well represent a composite of water quality from all elevations within the 150-ft open borehole, dominated by the quality of water from elevations at which the formation has high permeability (the flow zone). The chloride concentration measured in each well was 1,200 mg/L, and the dissolved-solids concentration was about 2,700 mg/L.

A partial description of water-quality variation within the injection zone is obtained from a study of the preinjection temperature and fluid-resistivity logs from the observation well on January 27, 1975 (fig. 8). Before the logging, the observation well was allowed to flow on November 20, 1974, sampled, and then shut in. The well was logged on January 8, 1975, by Schlumberger, Inc. (caliper and cement bond), and the 2-in. monitor tube was perforated. The sequence of the logs run on January 27, 1975, is not known. Annotation on the temperature log indicates that the log was run under flowing conditions. The data show a temperature increase up the hole that is more rapid below about 1,015 ft than above 1,015 ft. This tends to indicate that most contributions of flow occur below about 1,015 ft. A fluid-velocity log was also attempted, but the probe would not pass below 983 ft. No annotation was found on the log to indicate that the well was flowing while the fluid-resistivity log was run. However, F.W. Meyer (written commun., 1980) has interpreted it as a production (flowing) log. The data depict an unusual description of resistivity variations within the wellbore that presents some interpretive difficulties. To describe these difficulties and their resolution, the usual method of interpreting flowing fluid-resistivity logs is briefly considered.

Generally, fluid-resistivity logs run during production (flow from the well) tend to show resistivity changes at elevations where the volume of flow from the well is augmented by appreciable amounts of water of different salinity from that of water flowing from lower zones in the well. At those elevations, the fluid resistivity changes to represent the new composite salinity of water from the new zone and from the lower zones. Often, in the Upper Floridan aquifer, salinity decreases upward, and the resistivity trace shows increases at permeable-zone elevations as the probe moves upward. The fluid-resistivity logs in figure 11 show a reverse pattern. In these logging runs, the probe was raised from a pool of stagnant freshwater at the bottom of the well and passed through permeable zones where a brackish mixture of native and injected waters flowed from the formation into the borehole under artesian pressure. As the probe passed through these zones, the measured resistivity decreased.

Because the trace of the January 27, 1975, flowing-resistivity log (fig. 8) shows both positive and negative deflections, the apparent conclusion is that water of lower salinity contributes to the flow at lower elevations and is then augmented by water of higher salinity at higher elevations. In fact, the log indicates water above 1,011 ft to be about equal in salinity to that at the bottom of the well, below 1,043 ft. Because the existence of a permeable zone containing water of higher salinity is unlikely, the data suggest that the instrument could have drifted out of calibration. The principal significance of these data is to show that a zone of low salinity at 1,020 ft (1,024 ft in the injection well) is surrounded above and below by more saline water. Possibly, water in the flow zone grades from lower salinity in the center of the flow zone to higher salinity at the upper and lower boundaries. The resistivity variation indicated by the log is not large. Water at the bottom of the well is stagnant and probably does not represent background conditions in the aquifer. This water may contain residual drilling fluid or may represent downward turbulent dispersion from the flow zone.

The resistivity values above 1,012 ft generally represent the salinity of the composite flow from the flow zone, and the actual salinity of water in the relatively impermeable rocks at those elevations might be greater. For purposes of this study, the native water in the confining zones is assumed to be more saline than water from the higher 840-ft white monitor, where the chloride concentration of samples was between 1,700 and 2,300 mg/L and the dissolved solids concentration varied from 3,900 to 5,000 mg/L. This assumption is based on the general trend of increasing salinity with depth that occurs within the Upper Floridan aquifer except in discrete flow zones flushed by fresher water.

The physical conceptual model accepted as a hypothesis for computer simulation was that of a flow zone within the interval 1,012–1,043 ft (1,016–1,047 ft in the injection well). Water is freshest in the center of the zone but may be more saline in the upper and lower parts of the zone because of greater permeability in the center and ionic diffusion or seepage of more saline water from overlying and underlying relatively impermeable rocks as flow in the zone moves downgradient from distant areas of freshwater recharge in central Florida (fig. 5). The composite chloride and dissolved-solids concentrations are about 1,200 and 2,700 mg/L, as measured in preinjection water samples. The contribution of flow from the lower part of the flow zone (above 1,043 ft) may be slight but would substantially change the salinity detected by the logger because water below is static. Therefore, this interpretation of the fluid-resistivity log generally is consistent with results of the flowmeter log analysis.

A preinjection fluid-resistivity log was run by the SFWMD at the St. Lucie County ASR site (Wedderburn and Knapp, 1983, p. 34). This log is strikingly similar to the Hialeah fluid-resistivity log of January 27, 1975 (fig. 8). A high-resistivity spike on the trace corresponds to the lower flow zone occurring at the contact between the Ocala Limestone and Avon Park Formation. Similar to the USGS log from Hialeah, no annotation is present on the log to indicate that the well was flowing; however, the log has been interpreted as a flowing log by Wedderburn and Knapp (1983, p. 32). Flowing water above the uppermost flow zone is lower in salinity (has higher resistivity) than stagnant water in the bottom of the well below the flow zones, as would be expected if the flow originates from a permeable zone containing fresher water. The fact that the lowest degree of salinity occurs near the center of the flow zone suggests a gradation of water quality within the flow zone, so that water flowing from the well will be more saline than the freshest water near the center of the flow zone.

Monitor-Tube Data From the Three Test Cycles

Interpretation of the fluid-resistivity log of January 27, 1975, is corroborated by water-quality data from the first ASR cycle taken from the monitor tubes in the observation well (pl. 1). The mean values of chloride concentration in water from tubes sampling the injection zone prior to detection of the injectant are listed in the following table:

Color code	Depth (feet)	Number of samples	Average chloride concentration (milligrams per liter)
Red	957	18	1,594
Green	978	19	1,574
Gold	999	18	1,500
Silver	1,020	18	1,211
Black	1,041	18	1,278
Blue	1,062	22	1,441

The 840-ft zone (white monitor) was sampled 41 times prior to injectant breakthrough at the observation well, and the average chloride concentration was 1,895 mg/L. This provides firm validation for the hypothesis that the flow zone is overlain by zones of more saline water.

The relation of the early chloride data from the monitor tubes to actual injection-zone water quality is better understood by considering data from the observation-well monitor tubes later in the ASR cycles. A very rapid change in water quality just after the end of the first injection on September 8, 1975, indicates the possibility that unmixed injected water has reached the observation-well borehole (pl. 1 and fig. 13). These changes are first apparent within the flow zone (fig. 8, silver and black monitors) but are detected hours later in the remaining monitors near sections of the borehole that are assumed to be relatively impermeable on the basis of the temperature and fluid-resistivity logs and the injection-well flow analysis. This indicates that the monitoring zones were not completely isolated by the rosettes holding the monitor tubes and that samples from each monitor are composites of water at that elevation and from other elevations within the borehole. Thus, water samples from the red, green, gold, and blue monitors acquired before arrival of the injected water at the observation well probably do not accurately represent the quality of water in the surrounding rocks, but partly contain lower-salinity water from the presumed flow zone. This supports the hypothesis that water in the relatively impermeable rocks overlying and underlying the flow zone is appreciably more saline than indicated by samples from the monitor tubes.

A sampling following the hiatus between the first recovery and second injection shows water in the red, green, gold, and blue monitors to have increased to concentrations of about 1,400 mg/L of chloride, unlike water from the silver and black flow-zone monitors. The increases may have been caused by ionic diffusion and are further evidence that relatively impermeable parts of the injection zone contain water of greater salinity than the flow zone.

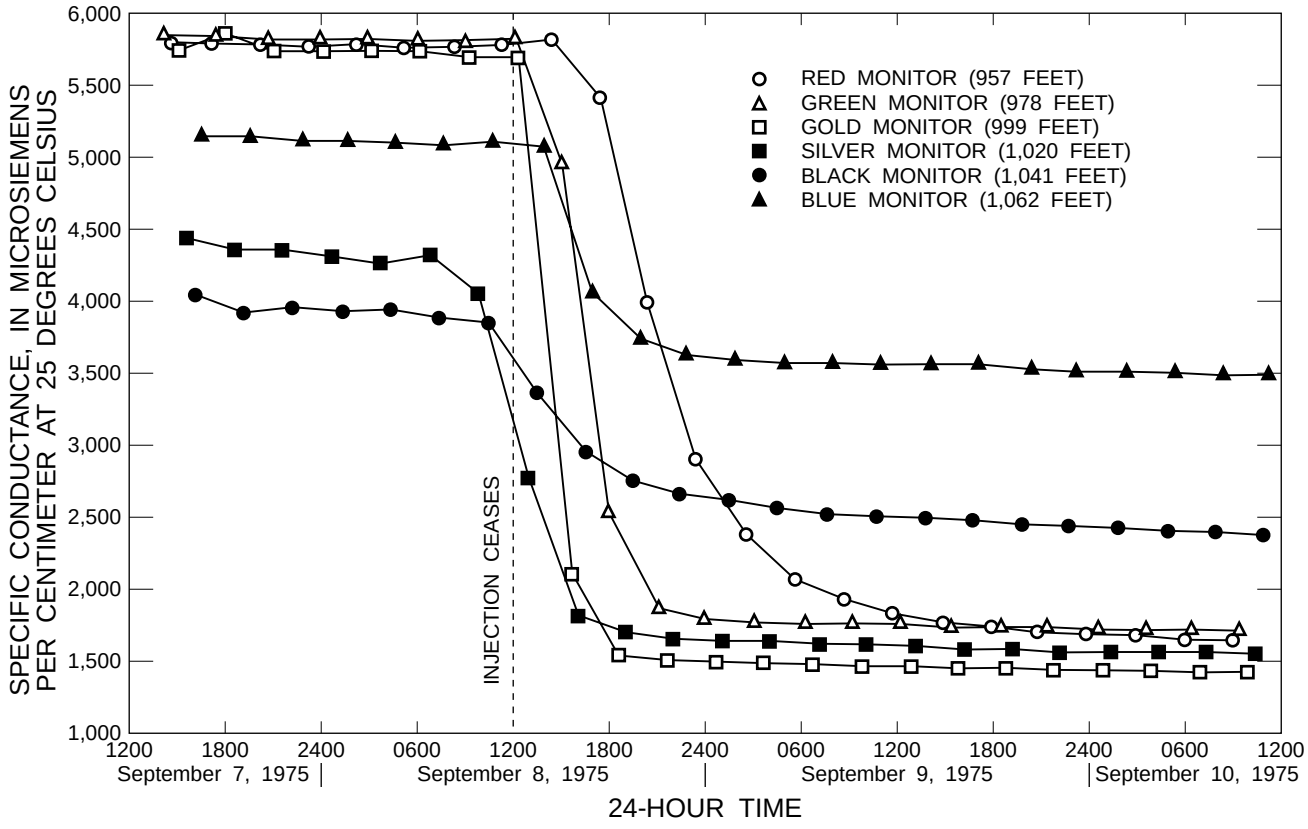

Figure 13. Automatic sampler-recorder data indicating freshening of water from monitor tubes after the first injection.

Later in the ASR cycles, the least saline water tended to be pumped from the silver and black monitors, which are the ones closest to the flow zone (pl. 1). Blue-monitor samples often were as fresh as samples from higher monitor tubes, apparently as the inflow of injected water and pumping of the monitor tube caused freshwater to move downhole. However, during storage and recovery periods, blue-monitor samples often became more saline, possibly as more saline water seeped into the well from surrounding rocks at the bottom of the well, displacing freshwater rising upward by buoyancy. This phenomenon was repeatedly reversed, possibly as a result of variation in the amount of pumping for water samples, and ceased to occur to any significant degree late in the third recovery, when water in the flow zone approached native-water salinity and the salinity contrast was reduced.

That water from all monitors late in the third recovery approached the flow-zone chloride concentration of 1,200 mg/L is further validation that water in the flow zone was appreciably less saline than that sampled from the 840-ft monitor tube. Although the salinity of water from the 840-ft zone (pl. 1) showed some irregularities that do not seem related to the ASR cycles, the salinity of water from this monitor zone remained consistently higher than that of water from all lower monitoring zones.

Dispersive Properties of Aquifer Material

The degree to which injected water mixes with the native brackish water is a key factor determining how much usable water can be recovered after subsurface storage. The mixing process is referred to as dispersion or dispersive mixing. Concepts related to dispersive mixing in radial flow from wells are developed by Hoopes and Harleman (1967). Dispersion concepts are discussed by Merritt (1985) in relation to modeling ASR cycles in the Upper Floridan aquifer.

Hydrodynamic dispersion is a term that represents the combined effects of molecular diffusion and mechanical dispersion. The concept of mechanical dispersion was formulated in the context of porous media and postulates that, because the myriad pathways through connected pores differ in size and tortuosity, radially oriented fluid movement in some will be retarded or accelerated in comparison with others. Therefore, in radial flow from an injection well, water particles will not have uniform outward speed, and in the vicinity of the interface separating injected and native water, some connected pore channels will have been flushed with the injectant, but others will still contain native water. Therefore, on a spatially averaged basis, there is a spreading, or dispersion, of the interface. Reeder and others (1976) use a simplified version of the formula derived by Hoopes and Harleman (1967) to represent the relative proportions of injected and native waters within the dispersed interface, written as

$$C/C_0 = 1/2 erfc\left[\frac{r-R}{(4/3\alpha_l R)^{1/2}}\right] \qquad (5)$$

where: erfc is the complementary error function,
α_l is longitudinal dispersivity (L),
C/C_0 is a unitless fraction having values ranging from 0 to 1 representing the relative concentration at radius r of some tracer present only in the injected water, and
R is defined by $V = \pi\theta h R^2$ (θ is aquifer porosity and h is the thickness of the injection zone).

R would be the precise radius of the injected water body if there were no dispersion. This approximation (eq. 5) is valid at large radii R and where $r \simeq R$ (in a relatively small interval surrounding the midpoint R) and assumes that molecular diffusivity is negligible in a vertically uniform aquifer. The width of the transition zone depends on the value of longitudinal dispersivity (α_l). Thus, fitting the formula to observed breakthrough data (concentration values showing the passage of a dispersed interface past an observation well) can be a method of deriving a dispersivity value from field measurements (Ehrlich and others, 1979).

Data from the very rapid apparent breakthrough at the observation-well silver monitor on September 8, 1975 (fig. 13), hours after the first injection ceased, were fitted to equation 5 for an estimate of α_l. Assuming isotropic flow in a 12-ft flow zone, an injection rate of about 80,000 cubic feet per day (ft^3/d) on September 8, 1975, and porosity of 35 percent, the rate of radial flow from the injection well would be 10.48 feet per day (ft/d) at a 289-ft radius, the distance to the observation well. The concentration of injected water within the silver-monitor sample was estimated to be 11 percent at 0955 hours and 50 percent at 1242 hours, during which time the front would have moved 1.22 ft. Setting

$$0.11 = 1/2\left(1 - erf\right)\left(\frac{1.22ft}{(4/3\alpha_l 289ft)^{1/2}}\right) \qquad (6)$$

α_l resolves to be 0.0072 ft. This value is about 3 or 4 orders of magnitude less than customary estimates of longitudinal dispersivity in large-scale tracer movement in aquifers and is, therefore, subject to considerable skepticism. In fact, it is highly unlikely for the breakthrough to have coincidentally occurred within hours after an arbitrary decision to halt injection had been implemented. Whether or not such a breakthrough could occur after injection stopped, given assumed hydrogeologic conditions, is another question subsequently considered as part of the modeling analysis.

Interpretation of Observation-Well Salinity Changes During the Three Test Cycles

Another curious aspect of the breakthrough data was the inconsistency of the apparent arrival time in the first cycle with the description of the flow zone based on evidence provided by the geophysical logs. Assuming planar isotropy, the hypothetical radius of the injected water body after 53 days of injection at an average rate of 105,661 ft^3/d (549 gal/min) can be estimated from the relation

$$V = \pi r^2 \theta h = Qt \qquad (7)$$

where: V is the volume injected (L^3);
r is the radius (L) of the injected water body at time t, ignoring dispersion;
θ is aquifer porosity (unitless);
h is aquifer thickness (L);
Q is the average injection rate (L^3/T); and
t is the time (53 days).

Assuming that q was 35 percent and aquifer thickness h was 12 ft, the radius of the injected water mass at 53 days should have been 651.5 ft. A 53-day radius of 289 ft could be achieved only by assuming a flow-zone thickness of 61 ft (35 percent porosity) or 32.8 ft (65 percent porosity). Both scenarios are very unlikely, given the evidence of the geophysical data. Assuming planar isotropy and nominal parameters of h = 12 ft and q = 35 percent, the theoretical volume injected when the freshwater radius reached 289 ft was 1,102,033 ft^3. As shown in the list of Appendix C, this volume was injected by day 8 of the first injection.

To better understand this anomaly and better visualize salinity changes in the observation well during the first and second injections, the manually collected samples shown in plate 1 are enlarged in figure 14 for the injection period and the period immediately following. Water samples collected from the silver and black monitors during the first injection show three periods of rapidly decreasing chloride concentrations before the end of the first injection. This raises the possibility that water in the observation well might have contained some injected water long before the end of the cycle. In fact, the first of the three periods of decreasing chloride concentrations falls between 6 and 12 days, close to the hypothetical arrival time of 8 days.

The salinity contrast showing breakthrough during the second and third injections was reduced because of the presence at the observation well of a residual amount of freshwater from the previous ASR cycle. Large salinity fluctuations in monitor-tube samples occurred during the second injection, as in the first. Immediately following the end of the second injection, there was a substantial lowering of chloride concentration in all monitor tubes (to 100 mg/L at the silver monitor) similar to that following the end of the first injection. However, assuming horizontal isotropy, the theoretical arrival time at the observation well (when 1,102,033 ft^3 has been injected) would have been January 12, 1976, after 7 days. Because the first observation-well sampling was on January 12, no data describing water quality in the observation well in the first 7 days of the second injection are available. Samples from the silver monitor tube showed a slight salinity decrease from 700 to 500 mg/L in chloride concentration almost immediately after the beginning of the third injection, between the second and ninth days, when samples were collected. The theoretical arrival time again should have been about 7 days, and the observed decrease may have indicated arrival of the injected water.

If the weak evidence of 7- or 8-day breakthrough times in the first and third cycles is rejected, at least two hypotheses can be postulated to explain inconsistencies between observed arrival times and the conceptual model formulated on the basis of geophysical logging. The first hypothesis is that the aquifer is horizontally anisotropic. The estimated direction of flow in the Upper Floridan aquifer at Hialeah is almost due east (fig. 5). The observation well is north-northwest of the injection well nearly at a right angle to the estimated regional flow direction. If solution porosity features have developed that favor aquifer flow in the direction of the regional gradient, horizontal anisotropy would exist, and the observation well would lie

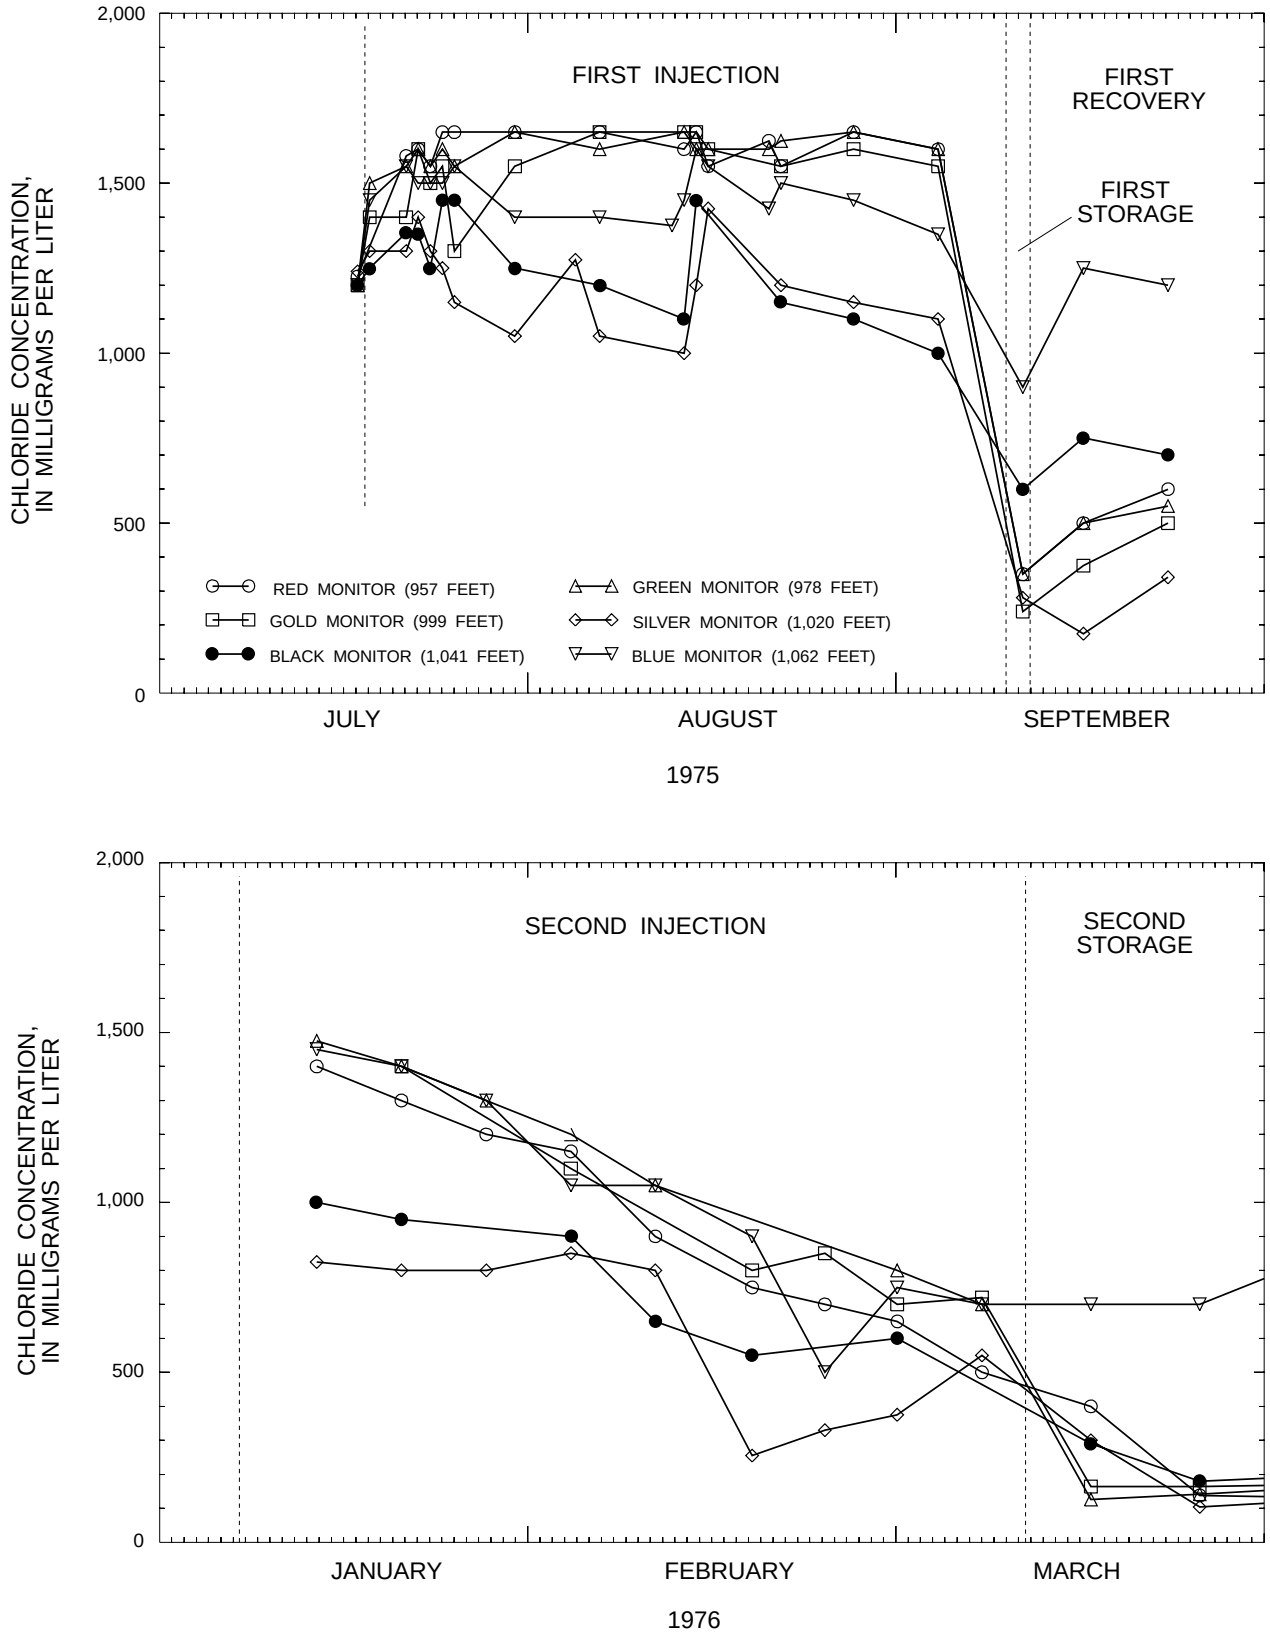

Figure 14. Chloride concentrations from observation-well monitor tubes during and after the first and second injections.

in a direction from the injection well in which the aquifer had less permeability than in the direction of the regional gradient. The flow of injected freshwater in the direction of the observation well would be slower than predicted by the isotropic conceptual model. The observed pressure at the observation well would be less than that at an equal distance in the preferred flow direction, leading to an erroneous interpretation of the aquifer-test data unless anisotropy was assumed in the analysis.

Another hypothesis is that the breakthrough data are misleading because of complex and poorly understood hydraulic properties of the aquifer in the vicinity of the observation well. The principal flow conduits might bypass the well, and complex solution features might permit the full interception of injected-water flow only after the injection pressure gradient ceases or after an extended period of time.

The latter hypothesis illustrates limitations that apply to the application of porous-media concepts of transmissivity and mechanical dispersion to secondary-porosity carbonate aquifers. The chloride concentration increases during the three recoveries were gradual, suggesting a dispersivity of many tens of feet. However, dispersivities of this magnitude may represent a more complex set of processes than considered in the development of the mechanical dispersion concept for porous media. Flow of injected water may be partly confined to an interconnected series of major and minor conduits, and mixing may occur, in part, as seepage of native water from the rock surrounding the conduits. The dispersion represented in the simulations of salinity increases during recovery, therefore, may be a representation of aquifer flow and mixing processes on a larger scale than implied by the uniform porous-media concept of solute transport. Hydraulic conductivity and dispersivity estimates may be inadequate to describe fluid movement and mixing at an isolated point, such as the location of the observation well at the Hialeah site.

Regional Flow at the Hialeah Site

An understanding of the velocity (speed and direction) of flow in the Upper Floridan aquifer in the vicinity of the Hialeah ASR site is helpful because background (regional or manmade) hydraulic gradients can substantially affect the recoverability of freshwater stored underground (Merritt, 1985). The regional gradient and the flow-zone hydraulic conductivity, thickness, and porosity determine the rate at which injected freshwater drifts downgradient, generally to the east. Thus, the influence of background gradients must be considered in the computer simulation of recovery salinity changes.

Figure 5 shows the estimated potentiometric surface and corresponding flow directions in the Upper Floridan aquifer in May 1980. The potentiometric surface in the southern part of the peninsula in the 1974–80 time period of the ASR cycles would be similar because the native water is not potable, and the only known manmade influences at that time were flowing wells located at some distance from the ASR site. Because these wells had been flowing for many years, a hydraulic equilibrium probably would have been established.

The potentiometric contours shown in southern Florida (fig. 5) are largely inferred on the basis of widely scattered data from wells containing waters of varying density. Subject to this qualification, it seems that flow in the Upper Floridan aquifer in the vicinity of Hialeah, a northwestern suburb of Miami, is maintained by an eastward hydraulic gradient of about 10 ft in 25 miles (mi), or about 0.4 ft/mi. Earlier estimates ranged from 0.1 to 0.22 ft/mi but were revised on the basis of new data and reinterpretation of data from wells in central Florida (Meyer, 1989a).

Hydrogeologic Conditions at Other Sites of Aquifer Storage and Recovery Tests

Some corroboration for the analysis of hydrogeologic conditions at the Hialeah ASR site can be obtained from a survey of data from other ASR sites where similar technical objectives dictated collection of similar types of data. The following sections present a partial evaluation of data from the town of Jupiter site and the St. Lucie County site.

Town of Jupiter Site

Tests of the subsurface storage and recovery of freshwater were performed from September 1973 to October 1976 for the Florida Department of Natural Resources at Jupiter in Palm Beach County (fig. 1, site 4). The data set collected at the Jupiter ASR site has been largely lost except for an unpublished executive summary report prepared for the Florida Department of Natural Resources by J.J. Plappert in February 1977, and suites of geophysical logs run at various times by the FGS and the USGS. The

geophysical data have not been previously published, and it was considered worthwhile to reproduce several logs for inclusion in this report.

The flow zone used for ASR cycles at the Jupiter site was found within the Avon Park Formation at about 1,220 ft. This conclusion was based on an analysis of caliper (January 30, 1975) and spinner flowmeter (July 25, 1974) logs run in the injection well by the FGS (fig. 15). Quantitative analysis of the flowmeter data was as previously described for the flowmeter data from the Hialeah site, but the diameter compensation was complicated in this case by the high rugosity of the borehole. The borehole flow, expressed as a percentage of that in the casing, is seen in figure 15 to have been generally uniform at 100 percent to a depth of 1,220 ft, below which it quickly diminishes to zero within another 10 ft.

Caliper and spinner flowmeter logs (fig. 16) were run in the observation well by the USGS on December 2, 1975. The borehole was smaller in diameter and less rugose. Results of the analysis suggest that borehole flow diminishes with depth between 1,207 and 1,228 ft, the most marked decrease occurring below a depth of 1,222 ft. Rock samples from the observation well examined by the Florida Bureau of Geology (written commun., 1975) indicate calcareous sandstone from 910 to 990 ft in depth and limestone (calcarenite) from 1,000 to about 1,250 ft in depth, except that the 1,140- to 1,200-ft depth interval is described as a foram-hash limestone. The interval from 1,200 to 1,240 ft is described as more porous than the other intervals.

The flow zone at Jupiter is, therefore, similar to the one at Hialeah in that it is also a thin, discrete zone of permeable limestone. The native water was also brackish in quality, having a chloride concentration of about 2,000 mg/L.

St. Lucie County Site

In 1981–83 the SFWMD conducted a single, low-volume ASR test in St. Lucie County (fig. 1, site 3). Results are documented by Wedderburn and Knapp (1983). Data gathered were static and flowing geophysical logs, pump tests of various depth intervals, pressure data at observation wells during ASR tests, and analysis of water-quality field parameters during recovery. The volume of injection was insufficient for the injected water to reach the observation well. Plans for further testing were canceled when analysis of results of the first test indicated that costs for recovered water were not competitive with current costs for domestic and irrigation water, and that available water for injection was of relatively poor quality because of its high dissolved-solids concentration.

Analysis of rock samples and spinner flowmeter data (Wedderburn and Knapp, 1983, p. 22) indicates appreciable quantities of flow originating from thin, discrete zones at formation contacts at depths of 650 ft (Suwannee-Ocala contact) and 740 ft (the Ocala-Avon Park contact), and small contributions of flow from four other discrete zones extending to a depth of 1,000 ft. The rock type generally was limestone (calcilutite) in elevations near the principal flow zones. However, the major flow zone at a depth of 750 ft approximately corresponded in elevation to a thin bed of dolomite. Coarse phosphate was present (about 15 percent) in an interval of high gamma counts above a depth of 650 ft. Below 800 ft are alternating beds of calcilutite, dolomite, and calcarenite. Water from the flow zones was brackish, with chloride concentrations ranging from 800 to 1,000 mg/L. The St. Lucie County data support the general conclusion that zones of significant permeability within the Upper Floridan aquifer, and potential zones for ASR, occur as discrete permeable zones often not much more than 10 ft thick.

Regional Extent of a Potential Aquifer Storage and Recovery Zone

In the present section, data from other ASR test sites and selected non-ASR site locations are considered for the more specific purpose of providing evidence for the existence of one areally extensive, brackish flow zone of moderate permeability. Besides its potential for ASR use, such a zone could also have potential for withdrawal of water to supply reverse-osmosis plants or to be used for blending with fresher water.

Some indication of the areal occurrence of a permeable zone containing brackish water in southeastern Florida can be gained by examination of natural gamma logs and related flow information from six locations (fig. 17) in southeastern Florida (section X-X' in fig. 1). These logs and others, shown later in the report, were digitized using a point cursor. At a certain depth, each log shows an interval of low natural gamma activity overlain by an interval of intense natural gamma activity.

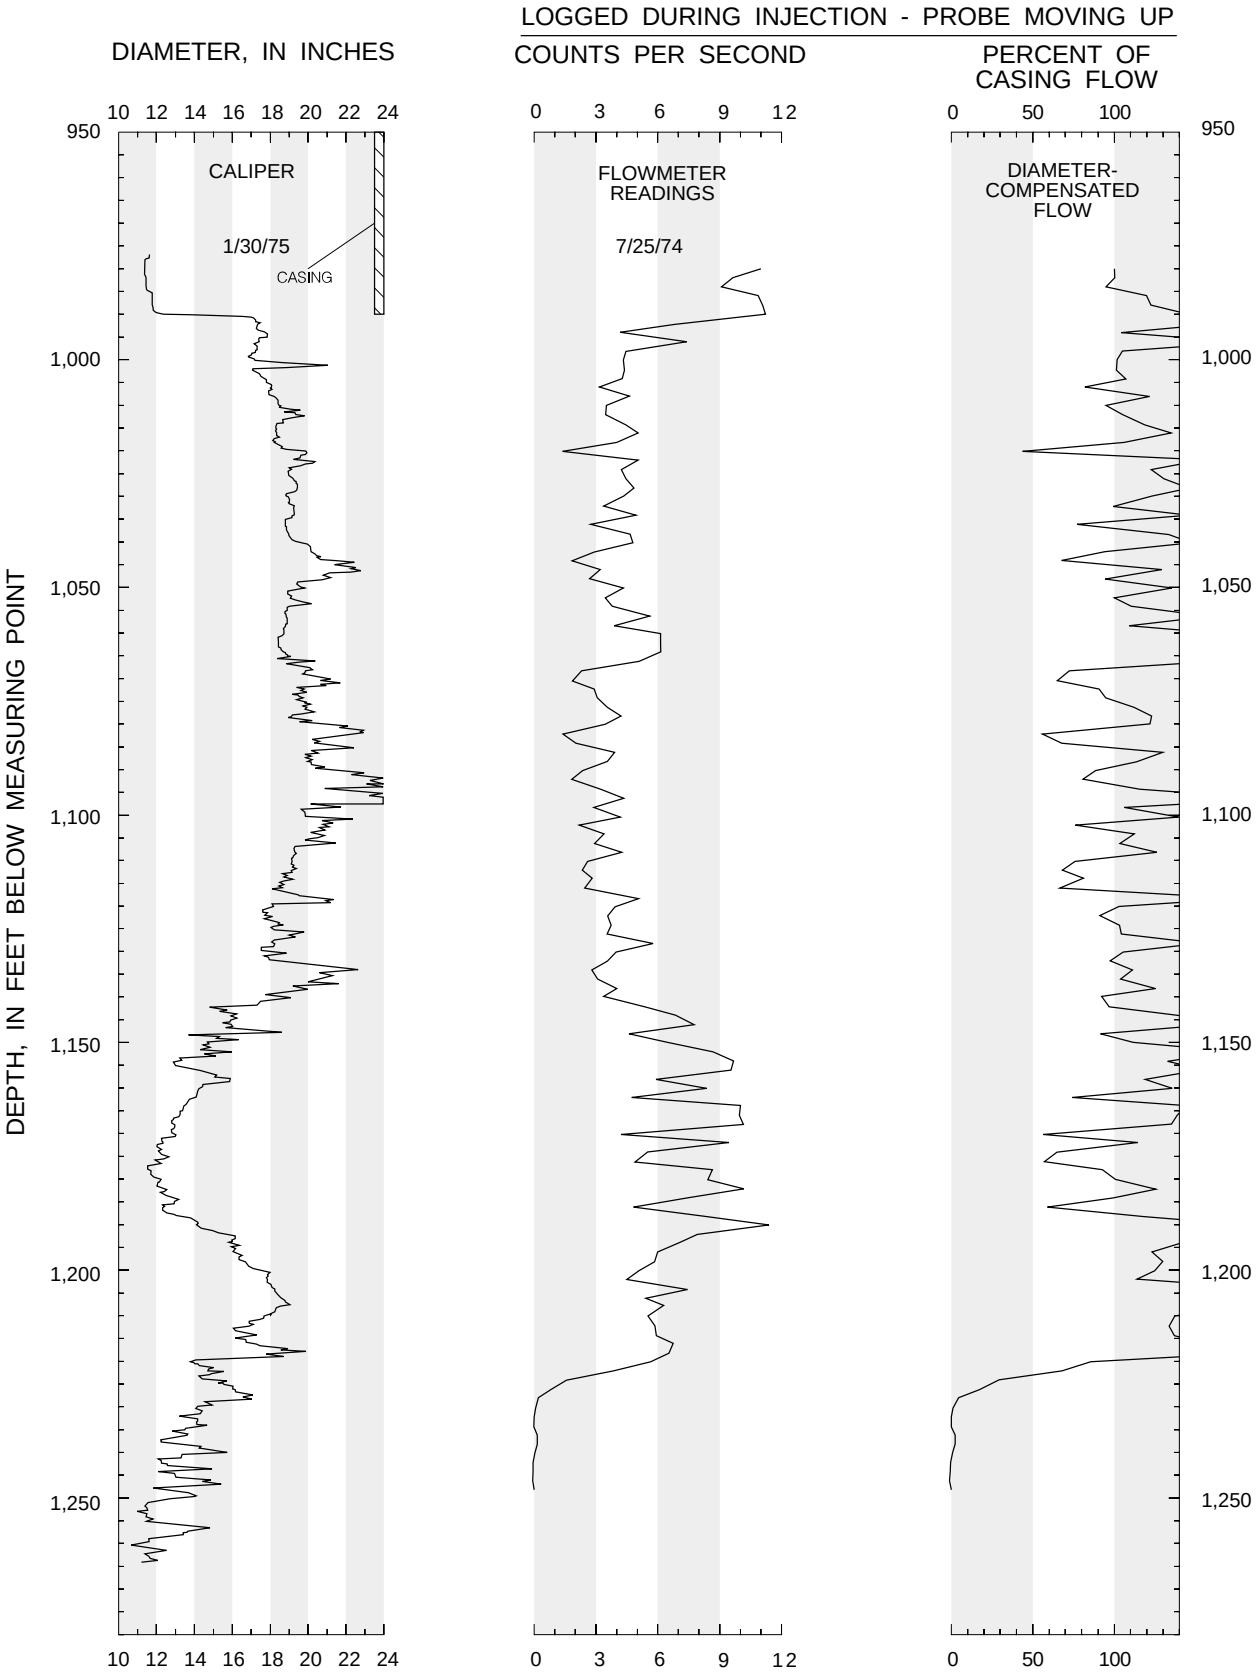

Figure 15. Results of analysis of data from spinner flowmeter logging of the injection well (PB-747) at the Town of Jupiter site.

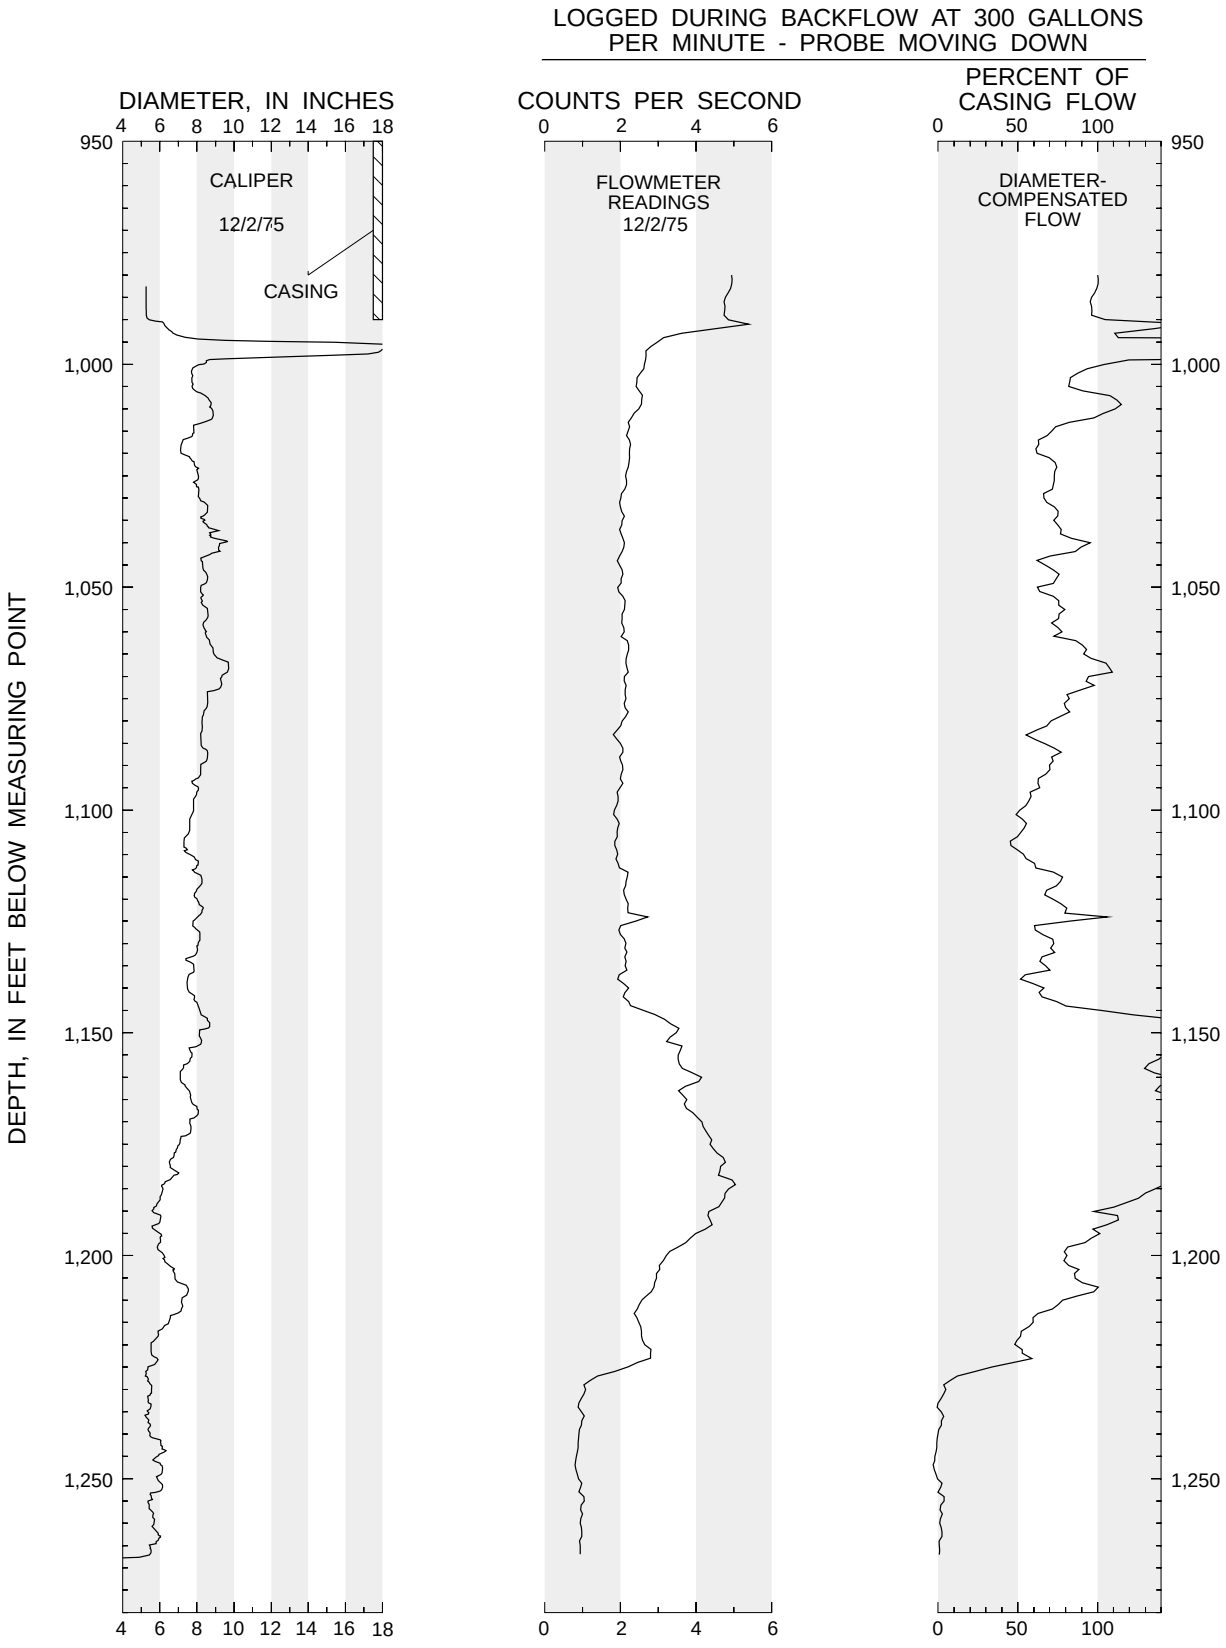

Figure 16. Results of analysis of data from spinner flowmeter logging of the observation well (PB-1145) at the Town of Jupiter site.

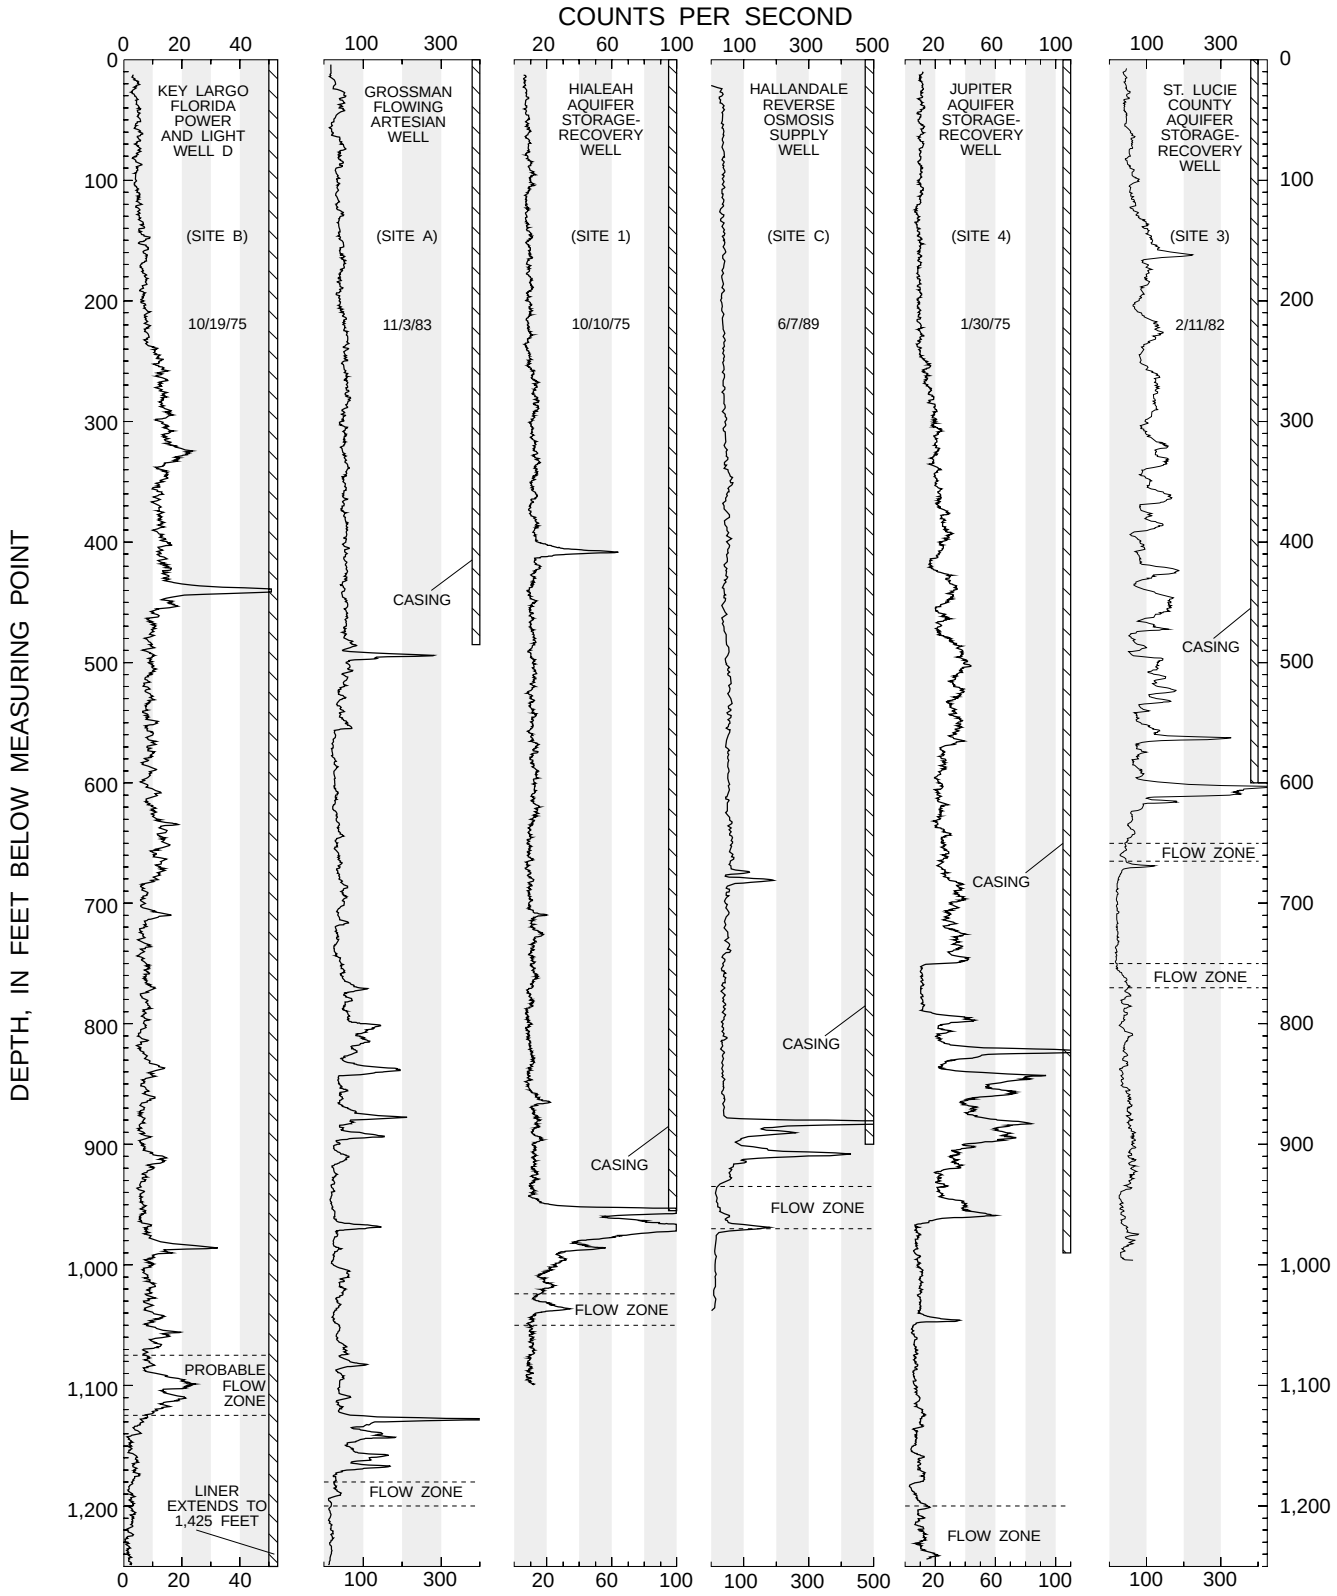

Figure 17. Natural gamma logs from selected Upper Floridan aquifer wells in southeastern Florida and elevations of known flow zones.

The high natural gamma activity usually is considered to be caused by the presence of phosphatic material containing traces of uranium. The underlying interval of low natural gamma activity is considered by some investigators to coincide with the top strata of Eocene age (the Ocala Limestone where present or the Avon Park Formation where the Ocala Limestone is absent). A clear example of this natural gamma contrast is presented by Meyer (1989a, p. 13), who correlates it with his determination of the Oligocene-Eocene contact in the Alligator Alley test well (Meyer, 1989a) near the Broward-Collier County line (fig. 1, site G).

At the site of the Florida Power and Light observation well D in undeveloped north Key Largo, Monroe County (fig. 1, site B), the interval of high natural gamma activity shown by the USGS log of October 19, 1975, is centered at a depth of 1,100 ft, and gamma activity decreases substantially with greater depth. A similar high-low activity contrast is found at a depth of 1,260 ft in the Florida Keys Aqueduct Authority reverse-osmosis supply well in Marathon (fig. 1, site D), as shown by the USGS natural gamma log of October 16, 1977. No flow information is available from well D, in which the casing extends to a depth of 1,425 ft. However, data from two reverse-osmosis plant supply wells a few miles to the southwest (fig. 1, site F) at the Florida Keys Aqueduct Authority Water Plant in the town of Key Largo (USGS natural gamma and flowmeter logs of October 16, 1975, and flowmeter log of June 14, 1978) and at a USGS test well in John C. Pennekamp State Park, just to the north of the town of Key Largo (USGS natural gamma log of October 16, 1975, and drillers log), show producing zones associated with intervals of high gamma activity centered at depths of 1,190 and 1,200 ft, respectively, that seem to correlate with the 1,100-ft depth interval in well D. However, the Florida Keys Aqueduct Authority and USGS wells were not sufficiently deep for the natural gamma logs to show an underlying interval of low gamma activity. A sample description (CH_2M HILL, Inc., written commun., 1974) picks a depth of 1,150 ft as the top of the Eocene in well D. Harbans Puri (FGS, written commun., 1965) picks a depth of 1,034 ft as the top of the Eocene in the USGS test well, which is at variance with the other finding. Water-quality data from the three wells indicate chloride concentrations ranging from 2,200 to 3,300 mg/L.

The recently plugged Grossman well was located in the Chekika State Recreation Area in central Dade County (fig. 1, site A). A sample description by L. Jordan (Sun Oil Company, written commun., November 1944) picks the top of the Eocene at a depth of about 1,150 ft; however, Jordan admits some uncertainty about the pick. Three series of readings from the stationary spinner flowmeter logs run by the FGS on June 11 and August 15, 1969, indicate a depth interval of 1,180–1,200 ft to be the sole flow-producing zone. The natural gamma log by the SFWMD shows the high-low gamma contrast at a depth of 1,170 ft.

At Hialeah the major receiving zone for injected freshwater was shown to be approximately between 1,024 and 1,036 ft in depth, and a depth of 1,045 ft was considered the approximate top of the Eocene. Thus, the flow zone at the three locations so far considered is approximately coincidental with the erosional surface of the Ocala Limestone or the Avon Park Formation as identified by several investigators. Both the Grossman well and the Hialeah ASR well produced water with a chloride concentration of about 1,200 mg/L.

A test well was recently drilled for the city of Hallandale in Broward County (fig. 1, site C) to determine whether a source of brackish water could be found for use by a reverse-osmosis plant. The plant is needed to augment supply from the municipal well field, which will soon be abandoned because of saltwater intrusion from the ocean. As in the other wells, a major flow zone was found just below the high-low gamma contrast at a depth of about 930 ft. Lithologic data are not presently available to verify that this elevation is coincidental with the top of the rocks of Eocene age. Other data indicate that most of the flow occurs at a depth of 935 ft, and an abrupt shift on a temperature log run during flow indicates that inflow at that elevation is anomalously warm compared with that from below. The chloride and dissolved-solids concentrations of water flowing from the well were 2,100 and 4,500 mg/L, respectively. These values are higher than those from the Grossman and Hialeah wells, possibly because the site is so close to the formation subcrop at the continental shelf about 3–4 mi east of the Atlantic coast.

At Jupiter, geologic sample descriptions provided by the FGS (written commun., 1974) pick the top of the Ocala Limestone at a depth of 1,060 ft in the injection well (no samples below 1,100 ft) and at a depth of 1,120 ft in the nearby observation well. A

pick of 970 ft in depth would correlate better with the top of the part of the natural gamma log run by the FGS on January 30, 1975 where low gamma activity occurred. However, the principal flow zone was found below a depth of 1,200 ft. Because the casing was set at a depth of 990 ft, if a flow zone existed near the elevation of the interval of contrasting gamma activity, it could have been cased off and remained undetected.

The top of the Ocala Limestone in the St. Lucie County ASR well was identified to be at a depth of 660 ft, and the top of the Avon Park Formation to be at a depth of 760 ft. The two depths correspond closely with the two principal flow zones identified with spinner flowmeter logging (Wedderburn and Knapp, 1983, p. 22), and the upper depth corresponds with a sharp reduction in gamma activity (fig. 17; Wedderburn and Knapp, 1983, p. 15). The well extended to a depth of 1,000 ft, but only minor amounts of flow occurred below 770 ft in depth. Water from the principal flow zone at a depth of 760 ft had a chloride concentration of about 900 mg/L.

On the basis of limited but relatively consistent evidence, it seems that formation contacts at the surface of rocks of Eocene age (the Ocala Limestone where present, or the Avon Park Formation) are the most probable depth intervals for the occurrence of permeable zones containing brackish water suitable for temporary storage of freshwater. A significant correlation exists between the elevation of the surface of rocks of Eocene age and the position of a sharp contrast in natural gamma activity (high above, low below) found in natural gamma logs at widely scattered locations along the southeast coast.

DIGITAL SIMULATION OF RECOVERED WATER QUALITY

The following sections begin with a description of the selection of a simulator and the selection of some parametric coefficients to represent aquifer characteristics based on data acquired at the Hialeah test site. A hydraulic calibration of the simulator is accomplished by a replication of data acquired during the aquifer test at the site. This is followed by a solute-transport simulation in which chloride increases during recovery are replicated by further calibration. Then various problems are considered that are related to the lack of accuracy with which aquifer characteristics are determined on the basis of field data and to the related problem of nonuniqueness of the calibration. Estimates of multiple-cycle recovery efficiency are then made. The report concludes with a comparison of model-computed solute concentrations with data collected from the observation well.

Simulation Code

The Subsurface Waste Injection Program (SWIP) code, the principal tool of investigation in this study, was developed by INTERCOMP Resource Development and Engineering, Inc. (1976), under sponsorship of the USGS. SWIP was later revised for the USGS by the same firm, renamed INTERA Environmental Consultants, Inc. (1979). Despite its intended use as a special package for waste injection problems, the SWIP code received wider use within the USGS as a general-purpose, three-dimensional simulator of solute and thermal-energy transport in ground water. The application of SWIP in USGS activities has been limited to a few users. A newer code developed by agency personnel, HST3D (Kipp, 1987), incorporated some parts of the SWIP code with adaptation. Outside the agency, the SWIP code has been adapted for special purposes by various public and private organizations.

Absolute pressure is the independent variable of the flow equation, and the model accounts for fluid density and viscosity dependence on temporal changes of pressure, temperature, and solute concentration. Solution of equations for flow and both solute and thermal transport is by standard finite-difference techniques, in which backward and central differencing in time and space are available as user options for solution of the solute- and thermal-transport equations. A Gaussian elimination technique is used to reduce the solution matrix size that results from coupling of the three equations. The aquifer simulated may be fully confined or have a free surface, and the equations may be solved in either Cartesian or cylindrical coordinates.

Fractional values (C) describe the relative concentrations of two miscible fluids ($C = 0$ and $C = 1$) in the aquifer. Any fluids present within the aquifer or entering it in simulation exercises are considered to be mixtures of these two fluids by the appropriate specification of C values. This approach works well for the problem of simulating the mixing of waters of different salinities that was a purpose of this study. $C = 0$ was used to represent pure freshwater, and $C = 1$ represented the most saline water residing within the aquifer or entering it as an influx. Injected water, the salinity of

water in some parts of the aquifer, and water in mixtures of injected and native waters were assigned or were computed to have C values that described their salinity relative to the two extreme salinities. Values of density are associated by SWIP with the extreme values of solute fraction ($C = 0$ and $C = 1$) and are used in calculations of flows driven by density gradients and in adjusting hydraulic parameters.

A more comprehensive description of the SWIP code, with reference to its application in ASR cycle modeling, has been provided by Merritt (1985). In 15 years of using the SWIP code, the author has made a number of modifications to adapt it to various applications. Most modifications have been nonmathematical in nature, and those that are revisions or extensions of the mathematical procedures of the 1979 version of SWIP have been coded as options to preserve the original solution methodology for use when needed. This study required the use of modifications affecting the computation of advective and dispersive fluxes of solute. A description of the original and experimental algorithms and their effect on computations is documented separately (Merritt, 1993), and a summary is presented later in this report.

Design of Hialeah Aquifer Storage and Recovery Simulator

The selection of parameter values and computational methods, the design of the grid, and the assignment of boundary conditions of pressure and solute fraction are described in the following sections. The rationale for design and value selections is explained, as is their basis in available data. The result of this process of selection is completion of the design of a simulator in which the process of injection, storage, and recovery of freshwater is represented, which can be used for a simulation of the salinity of the water recovered during the withdrawal stage. The substantial database acquired at the data site is used both in designing the simulator and in providing comparison data for the simulation of changes in the salinity of the recovered water.

Fluid Density and Viscosity Representation

The fluid densities assigned to injected and native waters were based on the measured or estimated concentration of dissolved solids in each fluid. Direct measurements of density were not considered to have adequate accuracy. The simulator required a density value to be associated with a solute fraction of $C = 0$, which was selected to represent pure water (zero dissolved solids). The assigned density of 62.3046 pounds per cubic foot (lb/ft^3) at 21 °C and atmospheric pressure were obtained from a standard handbook. Isothermal conditions at 70 °F (21.1°C) were assumed to prevail in all simulations on the basis of the preinjection temperature log in the observation well (fig. 8). Injected-water temperatures (fig. 12) ranged between 21.5 °C and 27 °C, but any effects of injecting somewhat warmer water were ignored. Values of density at 15 °C corresponding to various salinities were obtained from standard tables and were converted to 21 °C values by the factor 0.998892, the ratio of the densities of pure water at 15 °C and 21 °C. Measured injected-water dissolved-solids concentrations were about 400 mg/L, and the measured dissolved-solids concentrations of preinjection water samples from the injection zone were about 2,700 mg/L. As previously shown, water in the center of the flow zone may have been less saline, and water above and below more saline, than this composite value, but the composite value was assigned uniformly to the entire flow zone.

A solute-fraction value of $C = 1$ was associated with the most saline water in the aquifer, that in the relatively impermeable parts of the injection zone. The dissolved-solids concentration was estimated to be about 6,000 mg/L (about 20 percent greater than the average dissolved-solids concentration of samples from the 840-ft monitor tube). The corresponding density was 62.5414 lb/ft^3. Solute-fraction values of 0.0667 and 0.4500 were then assigned to the injected water and flow-zone water based on the ratio of dissolved solids to the estimated dissolved solids of the confining-zone water. The average chloride concentration of the injected water was 65 mg/L, and that of the flow-zone water was 1,200 mg/L. Computing the proportion of injected water in a mix of 250-mg/L chloride concentration to be 0.8370, the dissolved-solids concentration is estimated to be about 775 mg/L, using the injected- and native-water dissolved-solids values given in the previous paragraph. The corresponding solute fraction is 0.1292, and this was the maximum value of potability used in simulations in which recovery efficiency was computed. In similar fashion, chloride concentrations of recovered water were related to equivalent dissolved-solids concentrations and solute fraction for comparison with solute fraction of recovered water computed by the model.

The viscosity of injected and native waters is assumed by SWIP to vary with temperature and solute fraction. Because isothermal conditions at 21 °C were assumed to prevail, because the density contrast was low, and because viscosities of freshwater and seawater differ by only 0.06 centipoise, viscosity was assumed invariant in simulations. The assigned value of viscosity was 0.98 centipoise, the viscosity of pure water at 21 °C. The temperature of injected water ranged as high as 27 °C, at which the viscosity of injected water would have been 0.86 centipoise. Values of hydraulic conductivity in the freshwater bubble, inversely proportional to viscosity (INTERCOMP Resource Development and Engineering, Inc., 1976), would increase by as much as 14 percent. However, the simulated transport of injected freshwater was not affected by small variations in hydraulic conductivity, and simulation of viscosity variations would have been cumbersome and would have had little effect on the results.

Grid Design and Boundary Conditions

Because vertical flows caused by buoyancy stratification within the flow zone during storage might prove to have some influence on recovery efficiency, despite the low density contrast, the flow zone was discretized into six 2-ft-thick layers for calibration. Overlying and underlying relatively impermeable parts of the injection zone (the confining zones) were each represented as three layers. The layers immediately adjacent to the injection zone were thin (0.5 ft) in order to minimize the effect of the large ratio of flow-zone to confining-zone hydraulic conductivities on vertical advective flow approximations. The vertical grid discretization is shown in figure 18.

A selection of Cartesian or cylindrical coordinate systems needed to be made for the horizontal discretization in the horizontal plane. Cylindrical coordinates are well suited to problems of radial flow from wells, and solution of the equations is computationally more efficient than when using Cartesian coordinates. However, downgradient advection caused by a regional flow gradient was considered to be a likely factor explaining the quality of recovered water observed in the ASR cycles, and downgradient advection could not be represented in cylindrical coordinates. In addition, the possibility that aquifer flow was anisotropic in the horizontal plane was a hypothesis considered as an explanation of breakthrough data at the observation well and also could only be simulated in a Cartesian system. The Cartesian grid in the horizontal plane used for calibration is shown in figures 18 and 19.

The fine detail of the grid immediately surrounding the injection well cannot be shown clearly in the small-scale illustration of the 40,050-ft square horizontal grid mesh (fig. 18) but is shown in the middle-scale (7,050×5,050 ft) and large-scale (1,550-ft square) depictions of the inner mesh (fig. 19). The horizontal grid dimension of 43×31 is greater in the *x*-coordinate direction because regional flow is represented as occurring in this direction, taking advantage of special SWIP coding designed to represent regional flow. This coding provides for automatic modification of both initial pressures and specified pressure boundary conditions. Simulations of anisotropy assume the preferred flow direction to be along the *x*-coordinate axis; therefore, finer *x*-coordinate grid definition farther from the well is also needed for anisotropic simulations.

Placing the model boundaries at some distance from the region of freshwater movement confines solute movement to the center of the grid and enables constant-pressure boundary conditions to be used as an adequate approximation to actual conditions, in which a slight pressure change would occur at the boundaries during injection and withdrawal. A Theis equation calculation for an injection rate of 150,000 ft^3/d, a transmissivity of 9,600 $[(ft^3/d)/ft^2]ft$, and a storage coefficient of 2.75×10^{-4} indicates a hydraulic-head increase of 3.9 ft at the boundary after 100 days of injection. However, the known injection and withdrawal rates and estimated aquifer storage properties were the controlling factors on injected-freshwater movement, rather than transmissivity or boundary specifications.

Grid-cell dimensions in the region of freshwater movement ranged from 50 to 100 ft near the well to 250 ft farther from the well. The greatest distance in the positive *x*-coordinate direction reached by a 50 percent mix of injected and native waters in isotropic analyses was column 34 (*x*-dimension 250 ft). The injection- and observation-well nodes are both in column 22 and are five grid nodes apart (fig. 19, rows 12 and 17), providing sufficient discretization between the wells to accurately represent the hydraulic response at the injection well in simulations of the aquifer test of February 10, 1975. In some later analyses, where heads and solute fractions at the observation well were unimportant, the interwell grid definition was reduced so that the horizontal grid dimension of the model was 43×29. In special analyses designed to test various numerical approximation algorithms and value selections, the vertical discretization was enhanced, and the horizontal discretization (described in detail below) was in cylindrical coordinates.

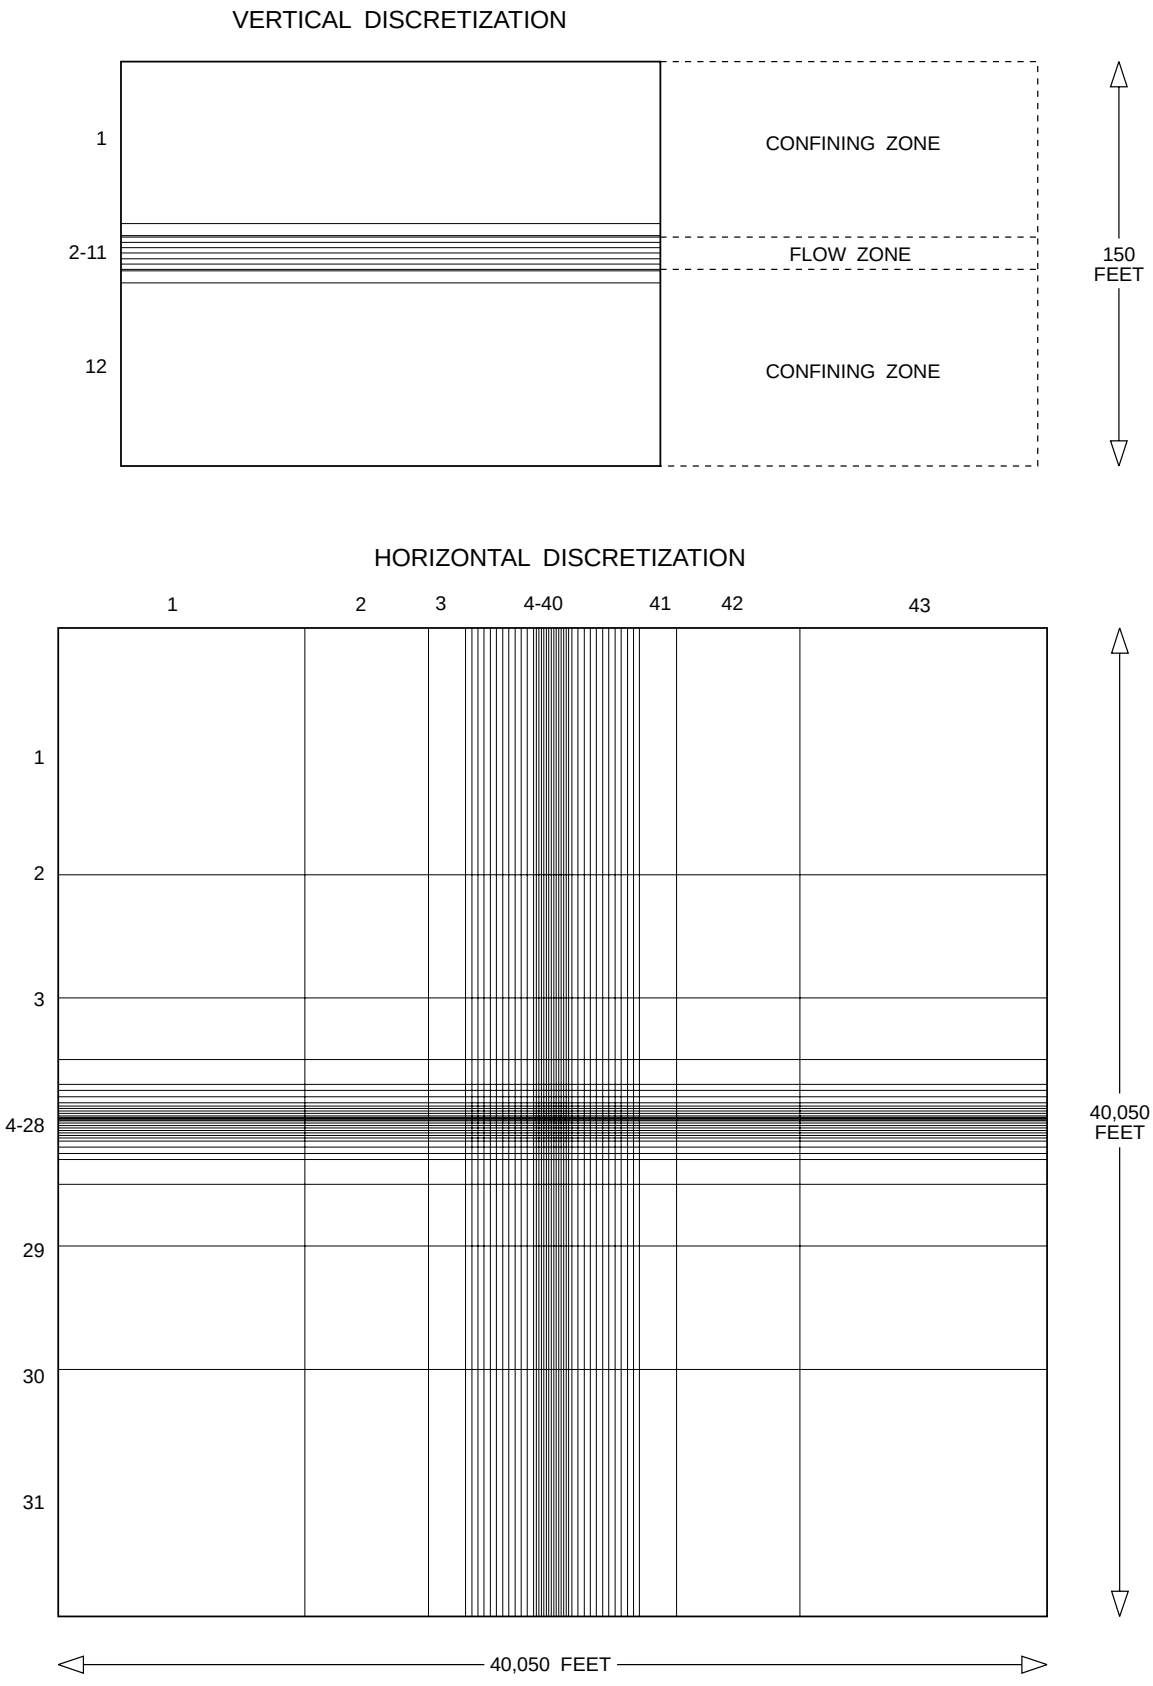

Figure 18. Vertical and horizontal discretization of the model grid used for the simulation of injection, storage, and recovery of freshwater at the Hialeah site.

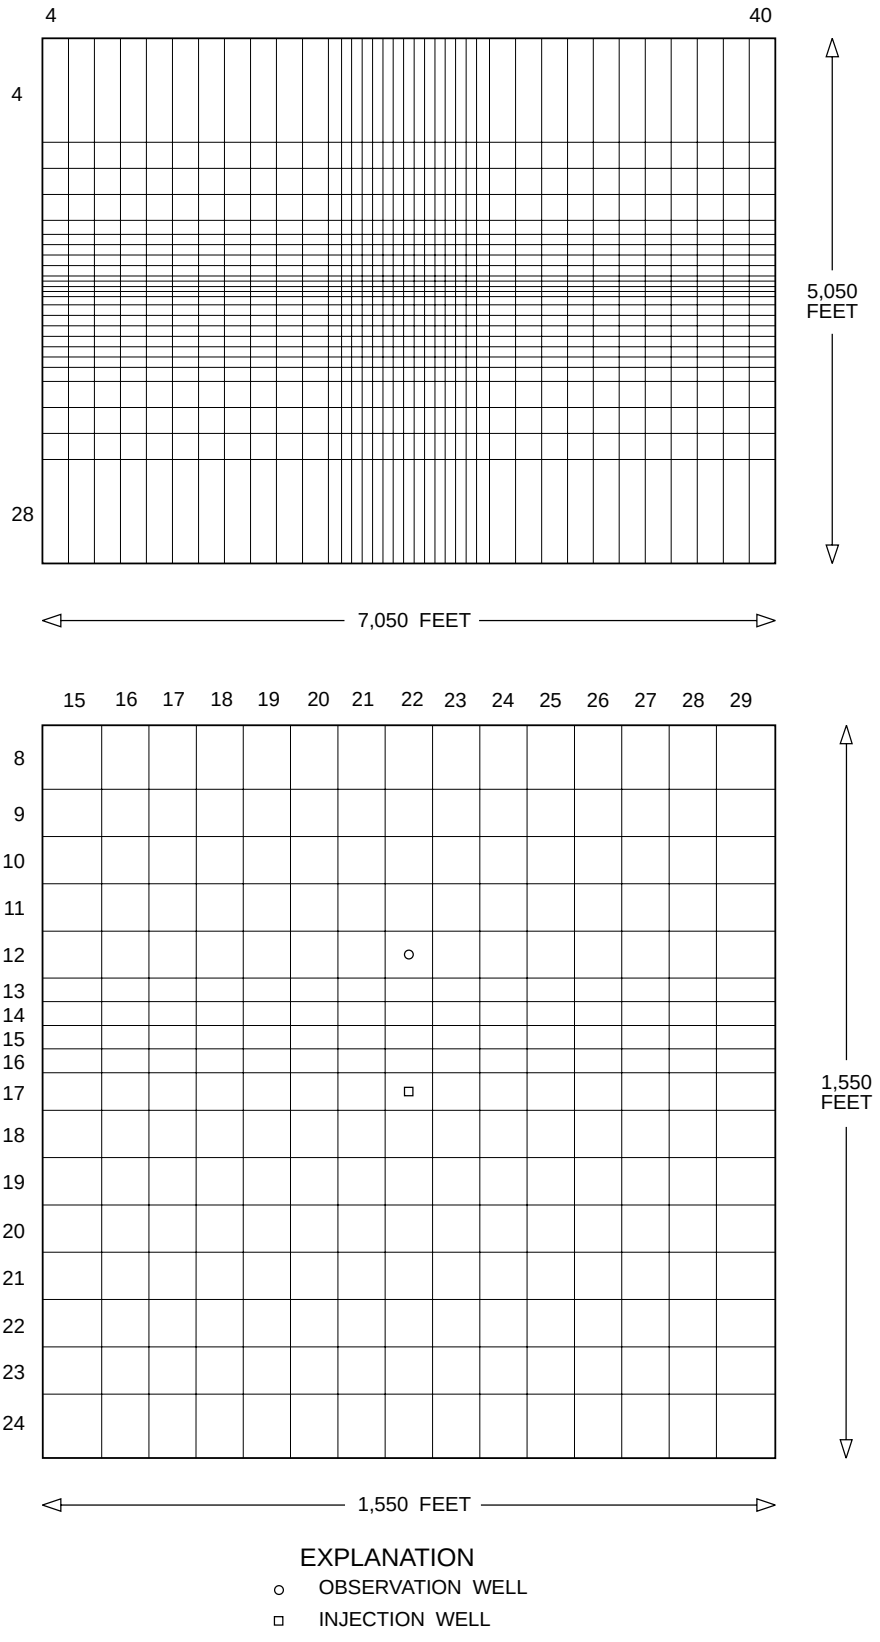

Figure 19. Horizontal discretization of larger and smaller areas surrounding the injection and observation wells within the model grid used for the simulation of injection, storage, and recovery of freshwater at the Hialeah site.

Selection of Numerical Computational Methods

Mechanical dispersion in the three coordinate directions at nodal locations is computed by the SWIP code as a function of the solute-concentration gradient, the total local fluid velocity (u), the angle of the velocity vector with respect to the coordinate directions, and longitudinal and transverse dispersivities (α_l and α_t, [L]) that specify the degree of dispersion both in the direction of flow (α_l) and perpendicular to the direction of flow (α_t). Molecular diffusion, computed as a function of the molecular diffusivity and the solute-concentration gradient, contributes additional dispersion, which in the direction of flow in large-scale grids is usually negligible in comparison with mechanical dispersion. The effect of both mechanical and molecular diffusion is termed hydrodynamic dispersion.

The numerical approximations used to represent the dispersion of solute and its relation to advective processes can, if improperly used, cause unrealistic solute-concentration values to be computed and can cause a misinterpretation of the hydrogeologic processes that are occurring. The selection of the best approximation method depends on the nature of the physical representation problem. For this reason, users of solute-transport models should consider the proposed selection of numerical algorithm methods and parameter values to determine whether the methods and values will lead to a representation that is physically realistic. Solute-transport simulation efforts often do not provide the resources for such an evaluation to be done, which is unfortunate in view of the critical nature of this aspect of the simulation problem.

The selection of the numerical approximation technique for evaluating the advective terms in the solute transport equation can be made from several optional selections, so these were tested in comparison with one another. Modifications made by the author to the model code include experimental algorithms for the computation of vertical advective and dispersive flux of solute. These new methods were tested in comparison with the original algorithms previously encoded in the 1979 version of the SWIP code.

A full description of the methods and results of the testing were documented by Merritt (1993). The following sections briefly summarize the results of this evaluation, which showed the interrelated effects of vertical mechanical dispersion and molecular diffusion from vertically adjacent confining layers to have a significant effect on the computation of recovery efficiency. This leads to a sophisticated calibration technique that accounts for molecular diffusion into the thin flow zone from overlying and underlying confining layers containing saline water.

Numerical Dispersion and Oscillatory Behavior

The SWIP code requires a user to select between backward and central methods of differencing the finite-difference approximations of the temporal and spatial derivatives in the transport equations. When backward spatial differencing is selected, a degree of first-order error is introduced into the solution that has the appearance of hydrodynamic dispersion. In one-dimensional computations the degree of numerical dispersion introduced into the solution has been shown (Lantz, 1971) to be $u\Delta x/2$, where α is the fluid velocity and Δx is the grid-cell dimension. The apparent dispersivity for the transport computation would be $(\alpha+\Delta x/2)$, where α is the dispersivity specified to represent the degree of physical dispersion that occurs. Lantz also shows in the one-dimensional case that backward differencing of the time derivative led to additional numerical dispersion of degree $u^2\Delta t/2\theta$, where Δt is the incremental time step and θ is the effective porosity. Thus, the actual degree of dispersion in the solute-transport solution would seem to be that which would be represented by a dispersivity of $(\alpha + u\Delta t/2\theta)$. In higher dimensions the numerical dispersion terms are more complex but continue to influence the apparent degree of dispersion in the solution.

When central differencing in time or space is the selected method, the corresponding finite-difference approximation is correct to the first order, and the first-order numerical dispersion terms are eliminated. Most of the degree of apparent dispersion in the transport solution depends on the dispersivities specified by the user, and is not determined by the local grid-cell size (given sufficiently fine discretization) or by a changing incremental time-step size. The different results obtained by use of the various techniques are illustrated with specific numerical examples in the aforementioned paper (Merritt, 1993). Central differencing techniques were selected for use in this study because it was desired to prevent the occurrence of numerical dispersion that would have been caused by the spatial discretization and time-step sequencing used in the simulations of injection and recovery if backward differencing techniques had been used.

The formulation of the dispersion terms in the SWIP code suggests an interpretation of the dispersion process as an interchange of equal amounts of fluid between adjacent grid nodes, with the fluid received by each having the solute concentration (or fluid mix) of the nodal center of the other cell. Intuitively, this representation may be understood to work best when a region of changing concentration is finely subdivided into many grid cells in the direction of fluid movement. Alternatively, the representation may work best in regions where the spatial variation of concentration is gradual relative to the grid spacing. Similar advisement on finely discretizing the zone of concentration change is offered by Kipp (1987, p. 116–117).

The dispersion representation does not function as effectively when concentration changes are abrupt relative to the grid spacing in the direction of flow. In this case, specification of a large longitudinal dispersivity can cause the computed concentration variation to be distributed over a larger spatial volume than is realistic. Specification of a small longitudinal dispersivity may allow spatial oscillations (caused by the tendency for the solution to overestimate the advective flux of solute between grid cells) to grow in the absence of the smoothing effect of dispersion (the overshoot and undershoot described by INTERCOMP Resource Development and Engineering, Inc.). Spatial oscillations, when using central differences, indicate an incompatibility between the selection of longitudinal dispersivity and the grid dimensions. In some models the range of values that can be assigned to longitudinal dispersivity may be restricted by a coarser than desired grid spacing mandated by the need for computational efficiency. Numerical oscillations at a grid node in sequential time steps indicate an incompatibility between the speed of solute movement and the computational time increment sequence used to simulate it.

Numerical criteria for avoiding oscillatory behavior were developed by Price and others (1966) and are cited in the SWIP code documentation (INTERCOMP Resource Development and Engineering, Inc., 1976) and in the HST3D code documentation (Kipp, 1987, p. 114). The ability to select grid-cell dimensions and dispersivities to realistically portray a zone of concentration change depends upon physical measurements or having some physical concept of the zone of dispersion based on real data, and on having adequate computational resources. In this study, data that explicitly describe the zone of dispersion are scanty, given the ambiguity of the freshwater breakthrough data at the observation well, and the spatial extent of the zone of dispersion can only be inferred on a spatially averaged basis from consideration of the chloride increases observed during recovery.

Experimental Algorithms for Dispersion and Advective Weighting

Transverse dispersivity describes the degree of dispersion in a plane perpendicular to the direction of flow without distinguishing between transverse dispersion within the plane of flow (the bedding plane) or perpendicular to it (dispersion in the crossbed or vertical direction), even though macroscopic hydraulic properties may be different or have different degrees of spatial continuity along the different directional components of fluid flow paths. In media with solution porosity, transverse dispersion may be partly related to the nonlongitudinal orientation of solution features along the flow path, but the extent to which this occurs may not be the same in the vertical direction as within the plane of flow.

When vertically adjacent layers are of different hydraulic conductivity, the more permeable layer may be partially flushed by water having a quality different from that of the other layer. This can occur as a result of flow in the more permeable layer from a recharge area or from an injection well that has not flushed the less permeable zone to a similar extent. Usually the flow direction is nearly parallel to the interface between layers. Because of common data limitations, the vertical transition of hydraulic properties and water quality usually is represented as a step function between adjacent layers of grid cells. In this case, use of central differencing for vertical advective flux of solute across the interface between layers would imply that water flowing across the interface would have a solute composition that is an average of that of the two waters. However, a more realistic conceptual model of seepage flux across the interface is as water having the quality of that in the originating layer. An upstream (backward) advective weighting scheme would seem to be more appropriate.

When vertically adjacent layers contain waters of different quality, the vertical component of dispersion implied by the dispersion algorithm may be inappropriate because the transition of water quality does not occur gradationally across the thicknesses of several grid cells and is nearly perpendicular to the direction of flow. Providing a finer vertical

discretization may not be computationally efficient, and there might not be any available data describing gradational hydraulic and water-quality variations.

Other problems can occur when there is a large difference in scale between the horizontal and vertical dimensions of grid cells. When transport processes occur over distances of several miles in aquifers a few tens of feet thick, computational economy may mandate that the ratio of average horizontal and vertical grid dimensions be as great as 1,000:1. A large longitudinal dispersivity may be required to match the coarse horizontal discretization. However, if small but still appreciable vertical flows occur, a large longitudinal dispersivity may lead to the simulation of a degree of vertical dispersion sufficient to obscure actual vertical variations in solute concentration.

Therefore, to provide the means for more physically realistic simulation of transport processes in the situation described, experimental algorithms for representing vertical advective and dispersive fluxes of solute were encoded as options in the SWIP simulator. The experimental algorithms implement the concepts described in the following statements:

- Mechanical dispersion in the vertical direction is identically zero between adjacent layers of different permeability [$K_x(k) \neq K_x(k-1)$, where K_x is the hydraulic conductivity in the x coordinate direction]. Molecular diffusion between layers occurs as before. Between layers of similar permeability [$K_x(k) = K_x(k-1)$], mechanical dispersion in the vertical direction is scaled by a user-specified factor S ($0 \leq S$).
- Vertical advective flux of solute receives upstream weighting (backward differencing) across the boundary between layers of different permeability [$K_x(k) \neq K_x(k-1)$], regardless of which weighting is used in the rest of the spatial domain of the model.

The experimental algorithms implement the conceptual view that solute flux across the boundaries between layers of different permeability occurs as molecular diffusion or as hydraulically driven seepage in which the water flux has the solute concentration of the source layer. The scaling factor is a user-specified parameter for use in application problems where bedding effects or the discretization may cause incompatibility in the description of horizontal and vertical dispersive processes within a hydraulically uniform layer.

A method of allowing longitudinal dispersivity to have a dependence on the flow direction is documented in the description of the two-dimensional SUTRA model by Voss (1984). Voss used a relatively fine vertical discretization to provide a cross-sectional depiction of a sharp freshwater-saltwater transition zone parallel to flow lines in a description of the simulation of saltwater intrusion on the island of Oahu, Hawaii (Voss and Souza, 1987). This has some generic similarities to the treatment of the problem described herein, in which the sharp transition in density occurs across flow lines parallel to a confining-zone interface. The use of the approach involving flow-dependent longitudinal dispersivity in a hypothetical cross-sectional model of saltwater intrusion is described in a paper by Reilly (1990).

Results of Testing Algorithms and Parameter Values

The tests of the original and experimental algorithms and parameter value selections consisted of a series of computer runs simulating the first injection of 53 days. A cylindrical coordinate system was used in which horizontal grid dimensions (grid annuli widths) in the region of injected-freshwater movement were less than 80 ft. The vertical discretization depicted in figure 18 was enhanced to illustrate the theoretical variation in the solute-concentration field near the boundary between the flow zone and confining layers. The assigned values of flow-zone hydraulic conductivity were 800 ft/d in the horizontal direction and 80 ft/d in the vertical direction. Confining layers were assigned values of 0.1 ft/d for horizontal and vertical hydraulic conductivity. Porosity was uniformly 35 percent. A longitudinal dispersivity (α_l) of 20 ft was assigned arbitrarily and was considered to be compatible with the horizontal discretization. Variables of the tests were (1) original versus experimental methods; (2) transverse dispersivities (α_t) of 20 ft and 0.1 ft; (3) scaling factors of 1 (no scaling), 0.1, 0.01, 0.001, 0.0001, and 0 (no vertical mechanical dispersion); and (4) molecular diffusivity (D_m) values of 0.001, 0.0001, and 0.00001 ft^2/d. In addition to a detailed description of the transition zone between fresh water and saline water at the end of injection, the effect on recovery of freshwater was assessed by simulations of withdrawal at a rate of 62,047 ft^3/d, the average rate of the first recovery at Hialeah. Results of the tests are described in detail by the author in a previous paper (Merritt, 1993).

The tests showed that when the experimental algorithm is used to eliminate vertical dispersion across flow-zone boundaries, the primary influence upon recovery efficiency and the salinization of water

at the boundaries of the freshwater mass is the degree of molecular diffusion from the more saline surrounding rocks. The magnitude of this influence depends on the degree of vertical dispersion occurring within the flow zone, and this is controlled by the transverse dispersivity (α_t) and by the size of the scaling factor specified by the user to compensate for bedding effects or for the incompatibility of horizontal and vertical discretization scales in the application problem. When the original algorithm is used and vertical dispersion across flow-zone boundaries is allowed to occur and a relatively low value of longitudinal dispersivity (α_l) is specified, the degree to which recovery efficiency is reduced depends on the size of the transverse dispersivity (α_t) specified by the user. Changing to upstream weighting for vertical advective flux had little effect in any of these tests because the amount of seepage across flow-zone boundaries was negligible in comparison with the amount of flux from molecular diffusion.

The tests of recovery efficiency revealed much about the effect of mechanical dispersion and molecular diffusion on computed recovery efficiencies without, however, leading directly to parameter estimates for the simulation model. Because a large degree of computed dispersion across flow-zone boundaries does not seem to represent any known physical process, it is probable that algorithms and parameter selections that minimize the degree of computed dispersion would lead to the most realistic simulation. Either the experimental algorithm and a scaling factor or the original method with a small transverse dispersivity should probably be used. The representation of molecular diffusion of solute from vertically adjacent confining layers into the body of injected freshwater within the flow zone is a more realistic simulation procedure than one that entirely disregards the transfer of solute between the injection zone and confining layers by treating the latter as impermeable no-flow boundaries.

Dispersion Tests in a Horizontal Plane

Additional insights into the dependence of model behavior upon dispersivity selections are gained by performing model tests with different sets of dispersivities in three-dimensional Cartesian coordinates. The 53-day first injection at the average rate of 105,661 ft^3/d was simulated in the Cartesian grid system illustrated in figures 18 and 19. The regional hydraulic gradient was set equal to zero. The experimental algorithms for computing vertical dispersion were used, and the longitudinal dispersivity (α_l) was set equal to 20 ft. The variables of the tests were the transverse dispersivity (α_t) and the vertical scaling factor (S). The aquifer was considered horizontally isotropic.

Two of the sets of values that were tested (α_l=α_t =20 ft, S=0.01 versus α_l=20 ft, α_t=0.1 ft, and S=1.0) illustrated a significant facet of model behavior. Because the mechanical dispersion term in the vertical direction resulting from the larger value of α_t was scaled by 0.01, vertical mechanical dispersion in the flow zone varied only by an approximate factor of 2 in the two cases, and the radial extent of freshwater flow was not affected by large simulated dispersive fluxes across upper and lower boundaries because the experimental algorithms were used. However, α_t also determined the degree of transverse dispersion in the horizontal plane, and between the two cases, the horizontal transverse dispersivity differed by a factor of 200. The comparison was, therefore, between relatively large and small degrees of transverse dispersion in the x-y plane.

The results of the tests are shown in figure 20 as planar views of freshwater distribution about the well (lines of 750 mg/L dissolved solids) in layer 6 (layer 3 of the flow zone). When α_t=20 ft and S=0.01, the line is virtually a perfect circle, as would be expected in radial flow from a well unaffected by a background hydraulic gradient. The line depicting the case in which α_t=0.1 ft and S=1.0, however, shows bulges of fresher water along the positive and negative x- and y-axes that have no physical meaning and are evidence of the inaccuracy of the mathematical solution for radial flow in Cartesian coordinates when horizontal transverse dispersion is small. Even when horizontal boundaries of the model grid were extended from 20,000 to more than 270,000 ft from the well to mitigate the possible effect of the nonuniform distance to the location of specified boundary pressures, there was no apparent effect upon the nonradial spatial distribution of freshwater. Requiring that at least two iterations of the solution to the solute-transport equation be performed and the use of subroutine CRSS for an alternate computation of nonaxial transport (INTERA Environmental Consultants, Inc., 1979) only resulted in a slight increase of solute movement in the positive x, positive y and negative x, negative y directions (fig. 20) without appreciably improving the depiction of radial flow.

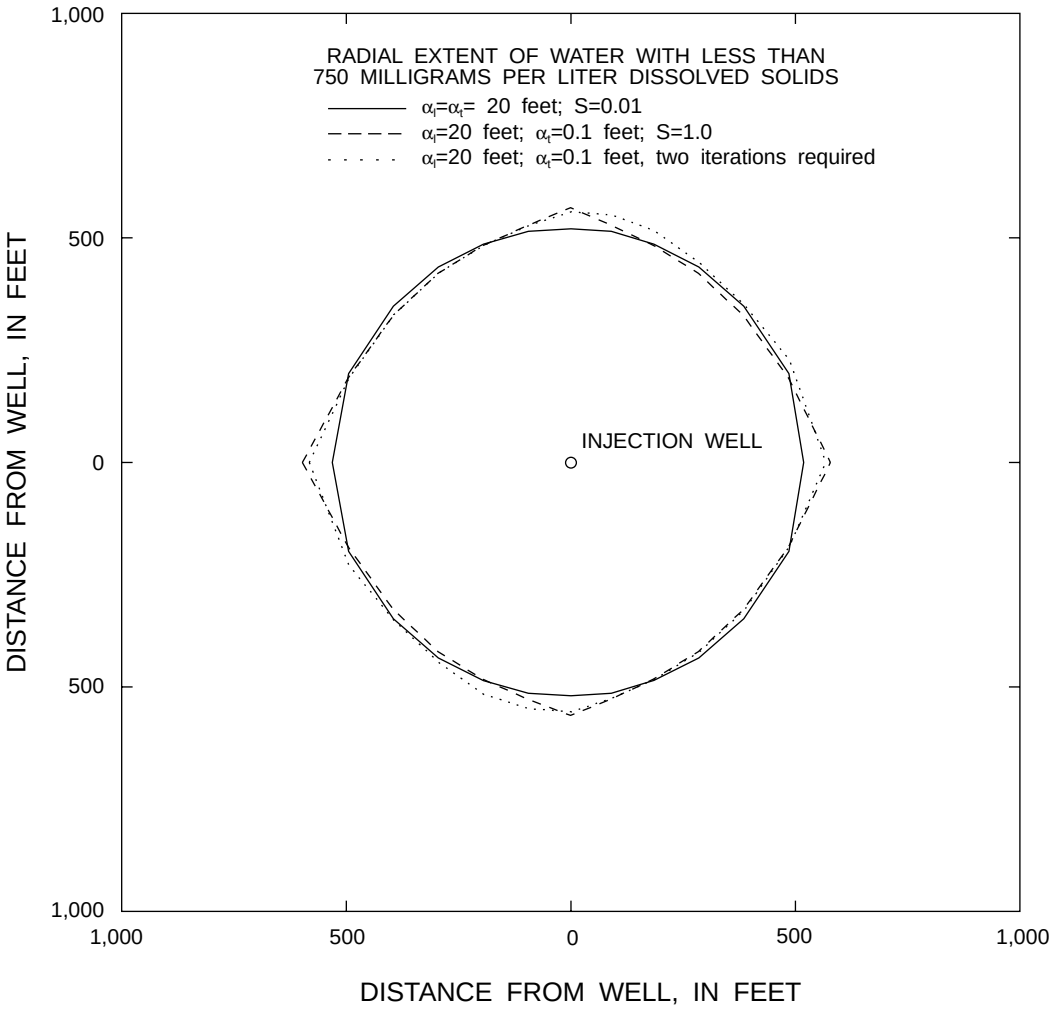

Figure 20. Plan view of the distribution of injected freshwater using two values of transverse dispersivity (α_t).

Simulations using the two sets of values were each followed by a simulation of recovery and computation of recovery efficiency. In case 1 (α_t=20 ft, *S*=0.01), recovery efficiency was 52.8 percent. In case 2 (α_t=0.1 ft, *S*=1.0), recovery efficiency was 53.1 percent. Thus, despite the apparent difference between computed freshwater distributions, the effect on computed recovery efficiency was slight. When case 2 with extended boundaries was followed by recovery, the computed recovery efficiency was 54.0 percent.

The result of these comparisons provides a basis for selecting the algorithms to be used for computing dispersion. Setting $\alpha_l=\alpha_t$, which produces the most realistic depiction of radial flow in Cartesian coordinates, is the preferred approach to the selection of values. This approach requires that some means be found to reduce the degree of vertical dispersion across flow-zone boundaries; therefore, the experimental dispersion algorithm was used for the simulations. A scaling factor of about 0.01 was used for vertical transverse dispersion within the flow zone. This selection was arbitrary but was partly based on the 100:1 ratio of horizontal to vertical grid-cell dimensions within the region of freshwater invasion of the flow zone. The value of molecular diffusivity was determined as part of the calibration process.

Hydraulic Parameter Estimation Methods

Hydraulic parameter estimates were based on data from the aquifer test of February 10, 1975. The estimates are subject to the usual reservations applying to aquifer testing in carbonate terranes, where local nonuniformities in hydraulic properties at the with-

drawal or observation points can yield estimates atypical of the average hydraulic properties of the aquifer. The results of Theis and Jacob-Lohman analyses (Lohman, 1979) were previously cited. In this section, a description of SWIP code simulations of the aquifer test is presented. The simulations were for the purposes of (1) deriving final estimates of hydraulic parameters for simulation, (2) sensitivity testing, and (3) testing alternative conceptual models of aquifer physical and hydraulic properties.

Simulation of Aquifer-Test Data and Sensitivity Analyses

The calibration of the aquifer test was based on the assumption that the flow zone was 12 ft thick and that the entire injection zone had a porosity of 35 percent. The confining-layer hydraulic conductivities were set equal to a small value (0.01 ft/d). This value was arbitrary, as no data were available upon which to base the estimate. The three-dimensional Cartesian grid design used for the calibration is shown in figures 18 and 19. Injection and observation wells were five grid nodes apart. Withdrawal from the observation well at the controlled rate of 250 gal/min was specified for a simulated period of 100 minutes. Nonvarying specified-pressure boundary conditions at a minimum of 20,000 ft from the wells were used and corresponded to uniform initial conditions within the aquifer. A Theis formula computation showed that the drawdown at 20,000 ft from 100 minutes of pumping at the cited rate was negligible.

A good match of observed and simulated drawdowns is shown as curve C in the various graphs of figure 21. Each pair of graphs shows the comparison and results of a sensitivity analysis for the entire 100-minute test period and for an early time period (first 3 minutes). The apparent stepping pattern of early time observations merely represents the limited resolution of the scale of the measuring instrument. Values of 800 ft/d for hydraulic conductivity in the horizontal (x-coordinate and y-coordinate) directions provided the best match for later time data, but the computed early time response was not highly sensitive to 25 percent changes (lines K1 and K2, fig. 21*A*) in horizontal hydraulic conductivity. The 25 percent variations caused unrepresentative later time drawdowns to be computed, the divergence increasing with time. Vertical hydraulic conductivity, for which data were not available to provide a basis for estimates, was arbitrarily considered to be 10 percent of the horizontal hydraulic conductivity in each sensitivity analysis.

The estimated values of horizontal hydraulic conductivity, integrated over the 12-ft thickness of the flow zone, give a transmissivity value of 9,600 $[(ft^3/d)/ft^2]ft$. The integration should include the confining-zone thicknesses, but because of their low estimated hydraulic conductivity, the transmissivity value would merely increase by 1.33 $[(ft^3/d)/ft^2]ft$.

Early time observations were matched by varying rock compressibility, specified in $(\text{pounds per square inch})^{-1}$. This procedure is similar to varying the storage coefficient in a two-dimensional areal hydraulic model because the storage coefficient (S) is considered (Lohman, 1979) to be a linear function of rock compressibility (C_r) according to the following formulation:

$$S = \theta\rho b(C_w + C_r) \qquad (8)$$

where: θ is porosity (unitless),
b is layer thickness (L),
ρ is fluid density ($P\,L^{-3}$), and
C_w is water compressibility ($P^{-1}\,L^2$).

Of the terms in the equation, all have been assigned values except for C_r. The value of C_w, 0.000003 $(\text{lb/in}^2)^{-1}$, is readily obtained from various handbooks. A C_r value of 0.0000400 $(\text{lb/in}^2)^{-1}$ was used to simulate the observed early-time drawdowns. Substantial disagreement occurred in the early time range when this value was increased and decreased by 25 percent (lines C1 and C2 in fig. 21*B*). The calibrated C_r value, together with the hydraulic conductivity value of 800 ft/d, also provided a good simulation of later drawdown data.

The compressibility and porosity estimates can be related to a storage coefficient value. Applying relation 10 to the flow zone (b=12 ft), an equivalent storage coefficient of 7.8×10^{-5} is obtained. Lohman (1979) states that equation 10 was derived (Jacob, 1940) by neglecting any release of water from confining beds. Because there is an assumed ratio of 80,000:1 for the horizontal permeability of the flow zone and that of the overlying 65 ft and underlying 68 ft of relatively impermeable strata, this approximation seems to be a good one. The hydraulic-head change at the observation well was 1.8 ft at the end of the 100-minute test. An inspection of the SWIP simulation shows a head change of 1.6 ft at an elevation 2.75 ft above the flow zone and a head change of 0.06 ft at an elevation 35 ft above the flow zone. Only a small part of the upper low-permeability layer has released an appreciable amount of water to the flow zone.

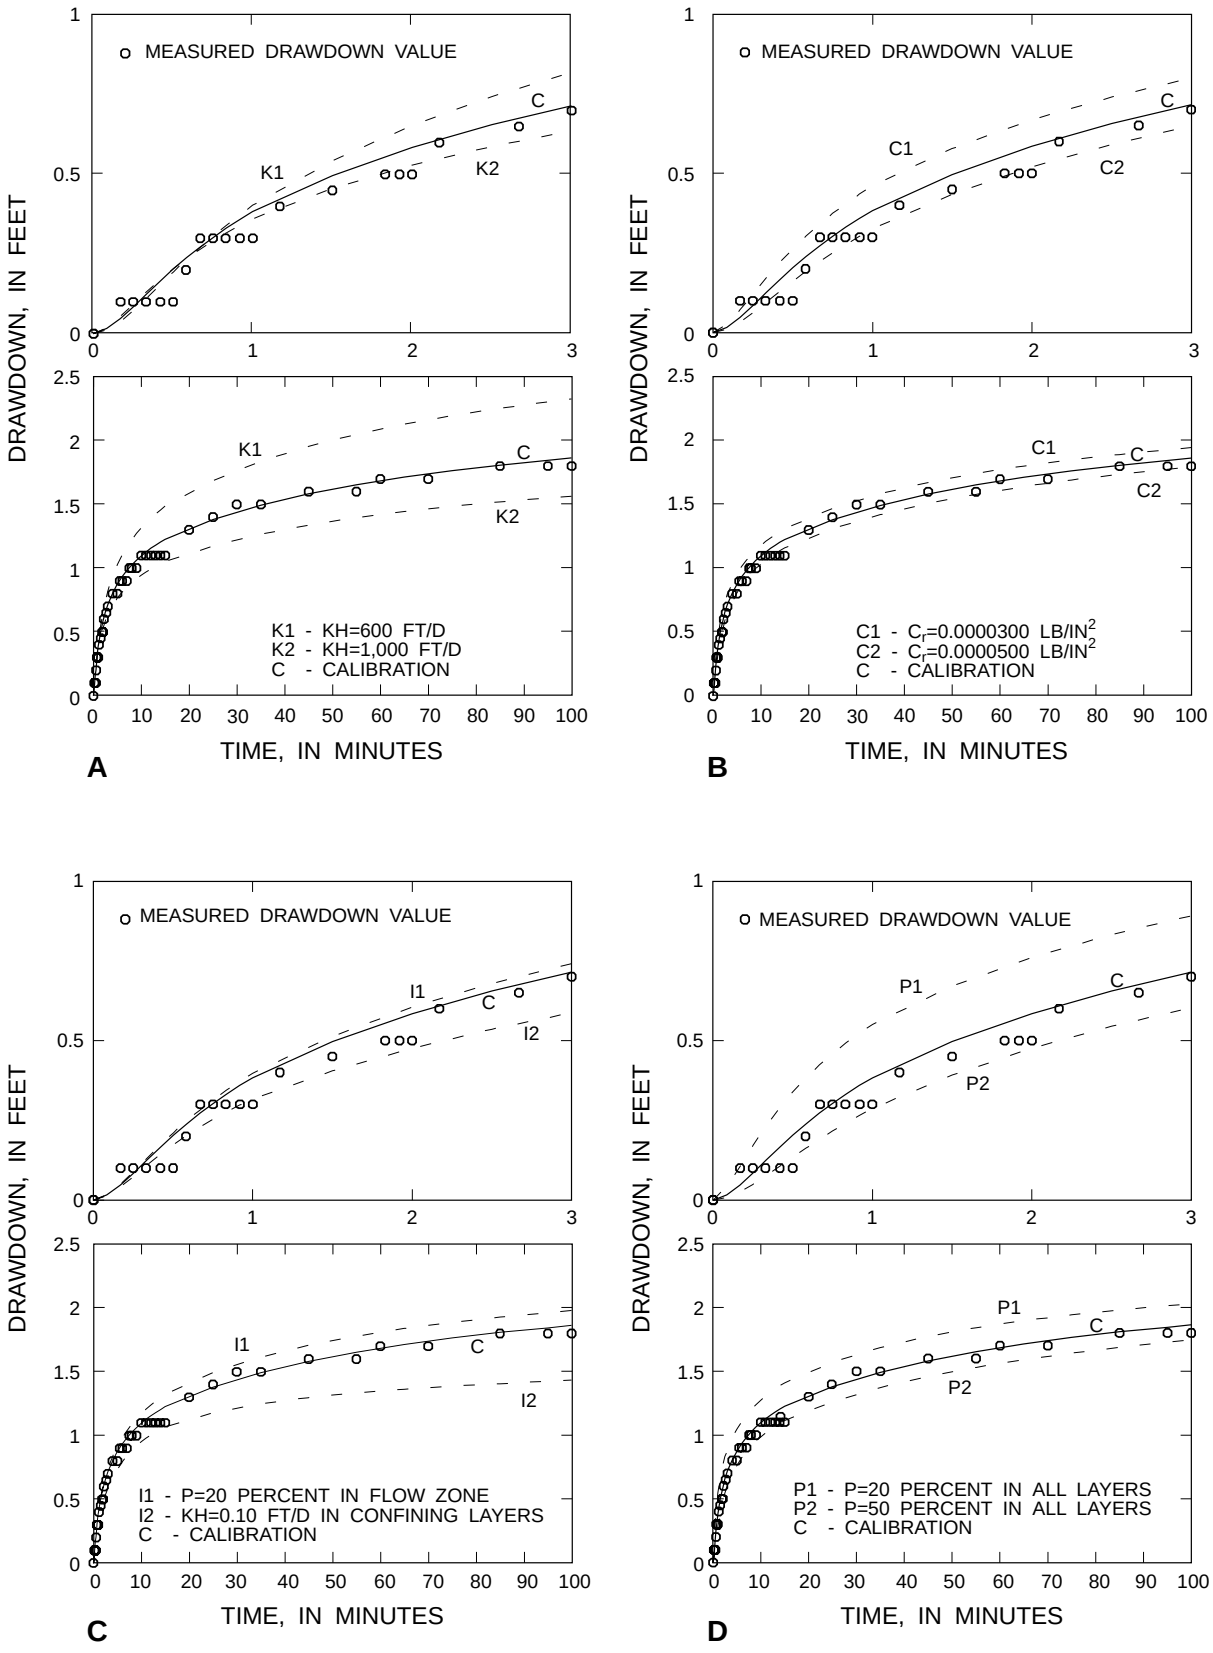

Figure 21. Simulation of the February 10, 1975, aquifer test data and sensitivity analyses. Results of sensitivity analyses are shown as dashed lines. KH, horizontal hydraulic conductivity, in feet per day (ft/d); P, porosity, in percent; CR, value of rock compressibility, in inverse pounds per square inch (lb/in^2).

As previously noted, the hydraulic-conductivity estimates for the confining layers were arbitrary, though permeability was known to be low. To gain an understanding of how much error could result by underestimating the value of this parameter, the model was run using a value of K_x=0.1 ft/d, 10 times greater than the value assigned for calibration of the aquifer test. The computed drawdowns are shown as curve I2 in figure 21*C*. Results of the test are relatively dramatic, showing a substantial underestimate of observed drawdowns at both early and late times. Thus, increasing by a factor of 10 the amount of injected water that can be accepted by 133 ft of relatively impermeable strata substantially lowers the hydraulic response of the flow zone. Other tests (not illustrated) indicated that the aquifer-test data could be simulated with flow-zone hydraulic-conductivity values of 750 ft/d and a rock compressibility value of 0.0000450 $(lb/in^2)^{-1}$ when the confining-layer hydraulic conductivity was considered to be 0.1 ft/d.

The solution dependence upon the specified porosity value of 35 percent for the entire injection zone was examined with sensitivity analyses that assumed that porosity in all zones was uniformly 20 and 50 percent. Results (curves P1 and P2 in fig. 21*D*) show significant discrepancies with observed data at early times. At later times, observed and computed data are offset to a degree that seems to change only slightly with increasing time.

Total porosity similarities between formations of dissimilar permeability, as indicated by the neutron porosity log of January 8, 1975, raise the issue of how total porosity relates to effective porosity, the pore or channel volume that is flushed by water moving in the aquifer. The SWIP code assumes that the specified pore volume of each layer receives flow from natural or user-specified sources, such as wells; thus, the specified SWIP porosity is considered to be effective porosity. Effective porosity is herein assumed to be equivalent to total porosity (35 percent) in the confining layers because the apparent lack of solution features implies that seepage through these rocks could occur at an equal rate in all pore spaces. The resistance to flow within the confining layers is accounted for by the specification of a low value for hydraulic conductivity rather than by considering porosity to be low. Specification of low values of effective porosity in the confining layers can lead to simulation error because inflow from the well is allocated to these layers on the basis of their low hydraulic conductivity, and the model would assume that even minor inflows into the confining beds were quickly distributed throughout an unrealistically large volume.

In the flow zone, a dual-porosity scenario might be more appropriate if water were contained partly within connected solution channels and partly within pores in rock surrounding the solution channels. Movement of water within pores isolated from solution channels would be insignificant relative to movement within the solution channels, and hydraulic conductivity and effective porosity would refer to the flow properties and relative volume of the latter. Effective porosity, therefore, might be less than the estimated 35 percent in the flow zone.

To test this possibility, an additional sensitivity analysis assumed that the flow-zone effective porosity was 20 percent. The result is shown in figure 21*C* as curve I1, which indicates that observed drawdowns are overestimated at late times. The later time result is similar to that when the entire injection-zone porosity is assumed to be 20 percent. The fact that some pores or solution channels admit flow and permit related solute-concentration change at a slower or faster rate than others, in either the confining layers or the flow zone, is accounted for by the mechanical dispersion concept.

Alternative Calibrations of Aquifer Test

Alternative calibrations of the aquifer test were performed to obtain separate sets of aquifer hydraulic parameters representing hypotheses that (1) the flow-zone thickness was 21 ft, (2) the effective porosity of the flow zone was 20 percent, and (3) the flow-zone permeability was horizontally anisotropic. In the third case, a 10:1 bipolar model of anisotropic hydraulic conductivity (K_x>K_y) was specified, where K_x and K_y are values of hydraulic conductivity in the two horizontal coordinate directions. These three test cases are the conceptual models of the aquifer that seem to represent the most likely errors in the accepted conceptual model or to have the greatest generic significance for model calibration. These alternative conceptual models are later used for separate calibrations of the recovery data. The accepted and alternative calibrations of the aquifer-test data are shown in figure 22 for 100- and 3-minute time periods as line C (calibration based on the accepted conceptual model of the aquifer), line C1 (21-ft flow-zone thickness), line C2 (20 percent effective porosity), and line C3 (anisotropic permeability).

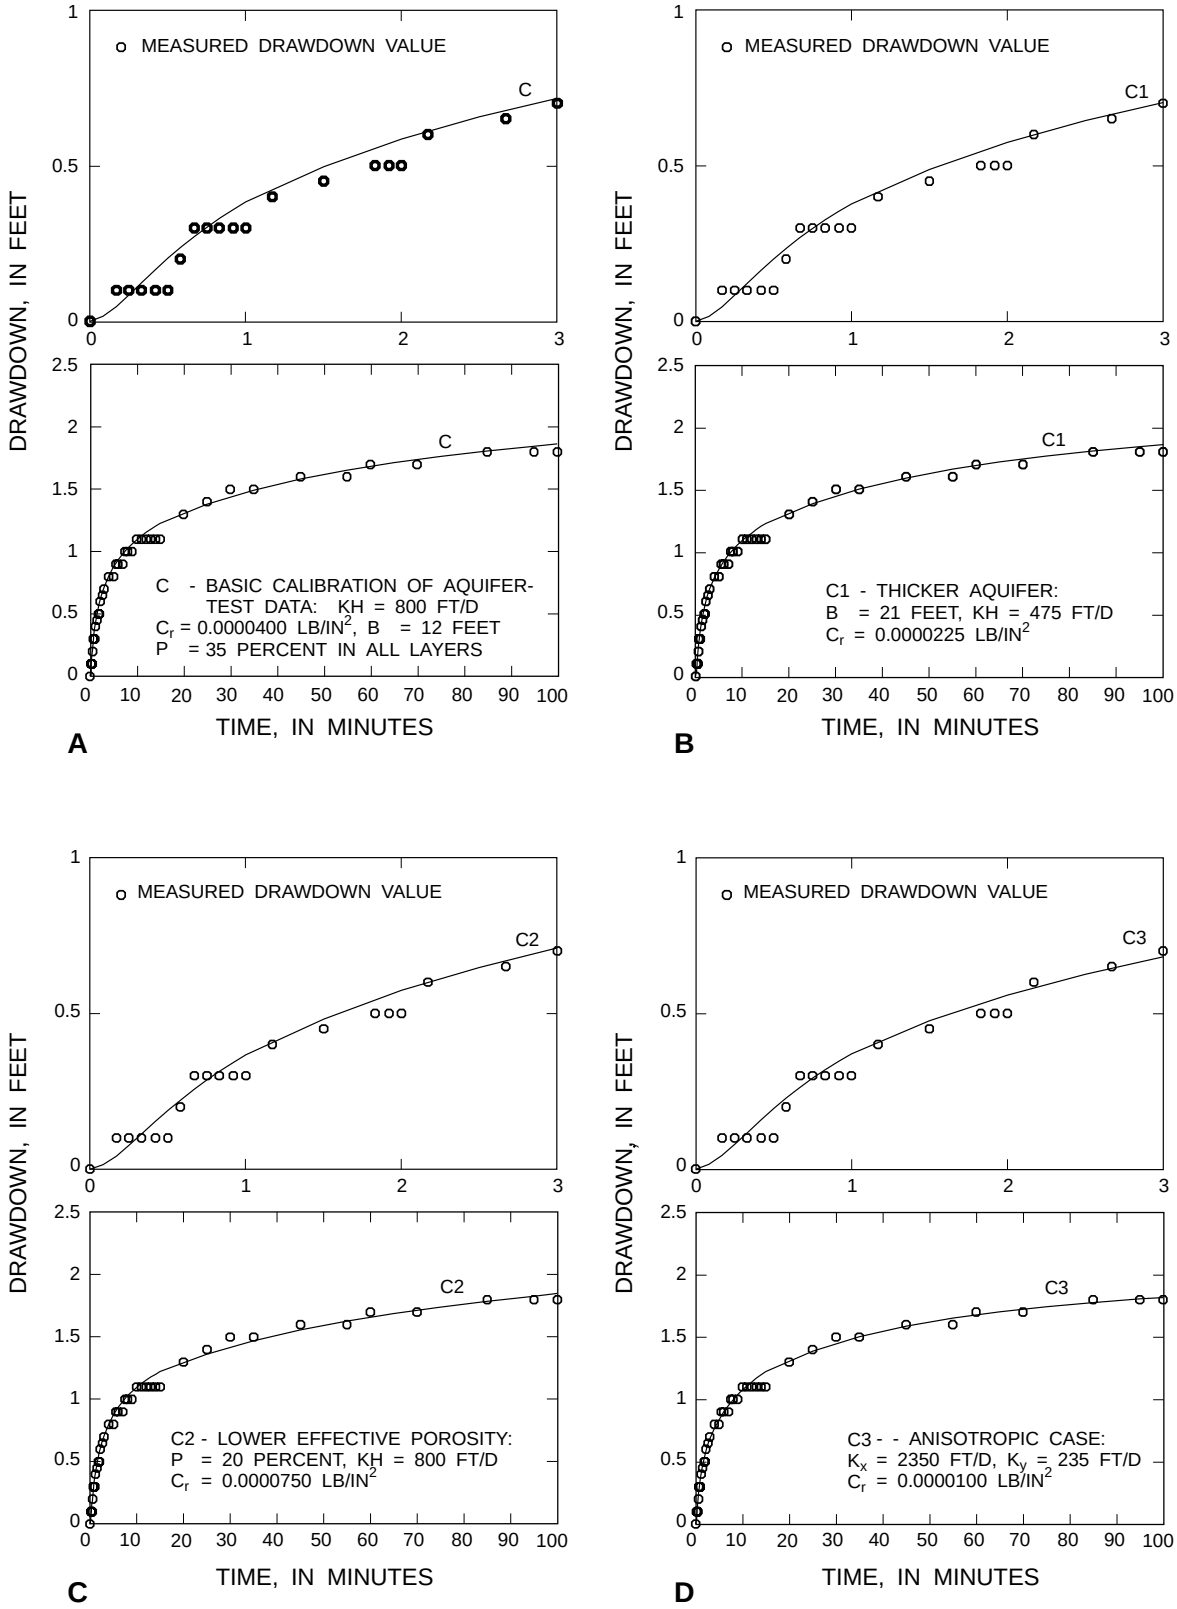

Figure 22. Alternative simulations of the February 10, 1975, aquifer-test data. KH, horizontal hydraulic conductivity, in feet per day (ft/d); K_X and K_Y, hydraulic conductivities in X and Y direction, in feet per day (ft/d); P, porosity, in percent; C_R, value of rock compressibility, in inverse pounds per square inch (lb/in^2); B, thickness of flow zone, in feet (ft).

The alternative calibrations match observed data as well as the calibration based on the accepted conceptual model. Estimating flow-zone effective porosity to be 20 percent (C2) requires that rock compressibility be increased to 0.0000750 $(lb/in^2)^{-1}$. Assuming that the flow-zone thickness is 21 ft (C1) requires that hydraulic conductivity be reduced to 475 ft/d and rock compressibility reduced to 0.0000225 $(lb/in^2)^{-1}$. Equivalent transmissivities (T) and storage coefficients (S) in the two cases are: (C2) T=9,600 $[(ft^3/d)/ft^2]ft$ and $S=7.8\times10^{-5}$, the same as for the primary calibration; and (C1) T=9,975 $[(ft^3/d)/ft^2]ft$ and $S = 7.2\times10^{-5}$.

When the flow zone was assumed to have a 10:1 bipolar anisotropy in the horizontal coordinate directions, and the observation well was assumed to be located in the direction of least permeability, calibration was achieved by setting K_x=2,350 ft/d and K_y=235 ft/d. The rock compressibility value (C_r) was 0.0000100 $(lb/in^2)^{-1}$. If expressed in bipolar components like hydraulic conductivity, then T_x=28,200 $[(ft^3/d)/ft^2]ft$ and T_y=2,820 $[(ft^3/d)/ft^2]ft$. The storage coefficient would be 1.8×10^{-5}.

Simulation of Recovery Salinity Data

Simulation of the increasing salinity (chloride or dissolved-solids concentrations) of recovered water implied a replication of the volume of withdrawal when withdrawn water reached the limiting chloride concentration used to calculate recovery efficiency and was, therefore, also a simulation of observed recovery efficiencies. The simulation required selection of values to represent aquifer hydraulic, chemical, and dispersive properties, representation of injection and recovery rates and volumes, and a method of relating simulated recovered volume to observed chloride data for matching purposes.

Parameter Value Selection and Comparison Techniques

For the initial calibration effort, parameter values were selected on the basis of an evaluation of data collected at the site, the simulation of the aquifer test, and a consideration of insights derived from the tests of dispersion models. On the basis of site data, the flow zone was assumed to be 12 ft thick, have an effective porosity of 35 percent, and contain water of 2,700 mg/L dissolved-solids concentration. The confining layers were assumed to have effective porosity of 35 percent and contain water of 6,000 mg/L dissolved-solids concentration. The hydraulic conductivity of the confining layers was set at an arbitrary low value, 0.01 ft/d. On the basis of the aquifer-test simulation, the flow-zone hydraulic conductivity was assigned a value of 800 ft/d, and rock compressibility was assigned a value of 0.0000400 $(lb/in^2)^{-1}$. On the basis of dispersion model tests, the experimental algorithm of vertical dispersion computation was selected to eliminate vertical dispersion across the boundaries between the flow zone and confining layers. Longitudinal and transverse dispersivities were assigned the same value to realistically represent radial flow from the well in the Cartesian grid shown in figures 18 and 19, and a scaling factor of 0.013 (ratio of average horizontal and vertical grid-cell dimensions) was used to reduce the degree of vertical dispersion occurring within the flow zone.

The values of longitudinal and transverse dispersivity and the molecular diffusivity could not be directly estimated on the basis of available data, but were found to be of primary importance in simulating the observed recovery salinity data. Therefore, they were determined by a process of trial-and-error adjustment and curve matching. The regional flow gradient was initially estimated to be 0.4 ft/mi on the basis of the regional potentiometric-surface map drawn by Meyer (1989a). This parameter also proved to be of major importance in matching observed data and needed considerable adjustment. Model calibration, therefore, consisted primarily of adjusting dispersivities, the molecular diffusivity, and the regional seepage velocity that depended on the regional hydraulic gradient and aquifer hydraulic parameters.

The time history of injection, storage, and recovery periods and hiatuses between cycles was represented approximately as listed in Appendix C. The time periods and corresponding rates of flow were encoded in the simulation as given in the table below, in which time 0 corresponds to the start of the first injection on July 17, 1975.

Stage	Time period (days)	Rate of flow (cubic feet per day)
Injection 1	0–53	105,661
Recovery 1	54–93	62,047
Hiatus	94–165	0
Injection 2	166–235	162,026
Storage 2	236–289	0
Recovery 2	290–367	95,333
Injection 3	368–554	147,442
Storage 3	555–729	0
Recovery 3	730–1,655	59,084

The 2-day storage period between the first injection and recovery was ignored, and the volume of the aborted second injection (App. C; pl. 1) was included in that of the subsequent successful second injection. Injection and recovery rates were represented as averages over each injection and recovery stage. Recovery efficiency and the distribution of injected water in the receiving zone were shown not to be related to injection or withdrawal rate in simulations with the SWIP code (Merritt, 1985), so use of average rates did not affect simulation of recovery salinity data. The estimated volumes of backflushes were subtracted from injection volumes (because only one flowmeter was used) before computing average rates.

Because average recovery rates were used, it was necessary to find a way to relate computed solute-fraction values of recovered water at given simulation times to the measured chloride concentrations of recovered water samples, which were recorded at various times as the actual recovery rate varied (App. C; pl. 1). This problem was resolved by using recovery volume rather than time as the common factor. The observed chloride concentrations were assigned artificial times equal to the actual recovered volume divided by the average rate. Thus, observed data times shown in subsequent illustrations differ slightly from the actual measurement times.

Chloride concentrations measured during recoveries were related to dissolved-solids concentrations by interpolation on the basis of chloride and dissolved-solids concentrations of injected-water samples and preinjection flow-zone water samples, as previously described. Based on the estimated dissolved-solids concentrations, recovered water samples were assigned values of solute fraction for comparison with the computed solute fraction of recovered water. (Solute-fraction values were 1.0 for 6,000 mg/L dissolved-solids concentration, 0.45 for native flow-zone water, and 0.0667 for injected water.) The SWIP code computes the solute fraction of withdrawn water as the weighted average of water withdrawn from each layer of the model. The weighting is a set of allocation factors that in these simulations was based on the relative thicknesses and hydraulic conductivities of the layers. Each of the six flow-zone layers had the same allocation factor, and allocation factors for the confining zone layers were so small as to make negligible their contribution to recovered volumes.

Basic Simulation

The process of calibrating the model to match observed recovery chloride data is illustrated in figure 23. An early simulation attempt (fig. 23A) was based on the supposition that the regional pore velocity had no influence on observed recovery data. The regional hydraulic gradient was set equal to zero. The dispersivity values were $\alpha_l=\alpha_t=65$ ft, and molecular diffusivity was $D_m=0.0002$ ft^2/d. A good match of the observed salinity increases was obtained in the first recovery and at the end of the third recovery, when recovered water salinity had returned nearly to the background level (the salinity of native flow-zone water). However, observed salinity exceeded computed values in the second recovery and during most of the third recovery, and the discrepancy was substantial.

To obtain a better match of observed and simulated data in the second and third cycles, the dispersivity values were increased to 100 ft (fig. 23B). The salinity increase is slightly faster in the third recovery, although computed values still are greatly exceeded by the observed data. However, computed salinity increases now substantially exceed observed increases in the first and second recoveries. It was evident that this simulation strategy could not be productive.

At this point, nonzero values of regional pore velocity were introduced, and the dispersivity values were reduced to the value of 65 ft that produced a good match in the first recovery. When pore velocity was set equal to 260 ft/yr, a good match was obtained in all three recoveries (fig. 23C). The computed salinity of recovered water in the brief first ASR cycle was unchanged by the use of a nonzero pore velocity. However, because recovery followed 54- and 181-day storage periods in the second and third ASR cycles and because the third recovery continued for 2.5 years, sufficient time elapsed for the simulation of a substantial downgradient shift of the injected freshwater mass. During the later part of the simulated second and third

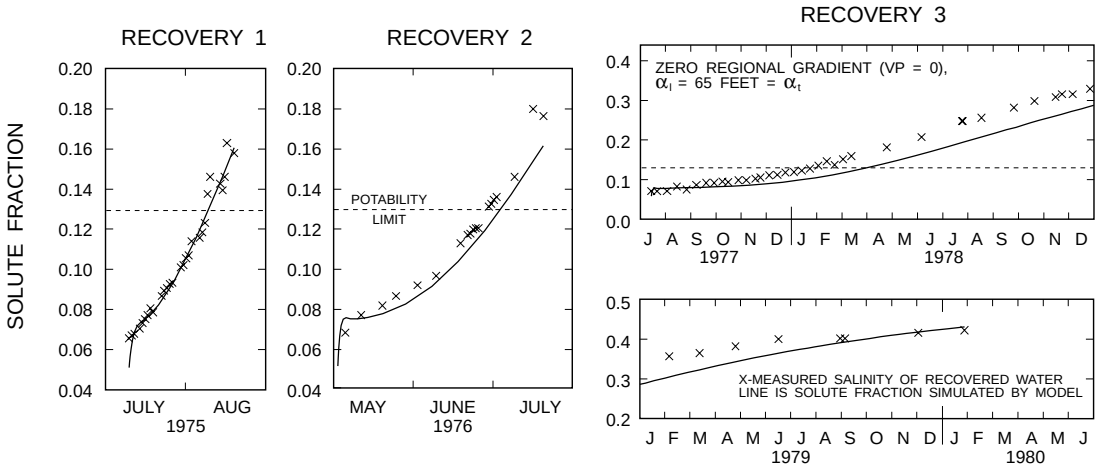
recoveries, water entering the well from the upgradient direction was more saline than water coming from the downgradient direction. Thus, the computed recovery salinities increased relative to the earlier run with no regional flow and matched measured data.

This calibration (fig. 23C) will be referred to as the basic simulation to distinguish it from later simulations in which some of the parameter values not used as calibration adjustments were revised (alternative simulations). The downgradient shifts of injected freshwater caused by simulated regional flow are shown in figure 24, which shows planar views of lines of equal solute fraction in layer 6 (layer 3 of the flow zone) at selected times during the three ASR cycles. Other lines of equal computed solute fraction within the transition zone are also shown. The illustration helps to visualize the simulated distribution and movement of injected water within the flow zone during the ASR process, and also indicates the simulated degree of dispersion around the mass of potable water. Figure 24 was generated by selecting the locations of the solute value within each row of the model grid by linear interpolation between columns and then connecting the points successively. Small bulges along the *y*-axis are a consequence of using Cartesian coordinates to simulate radial flow from a well, as previously discussed, even when a large horizontal transverse dispersivity is specified. That this does not occur along the *x*-axis is due to the influence of regional flow.

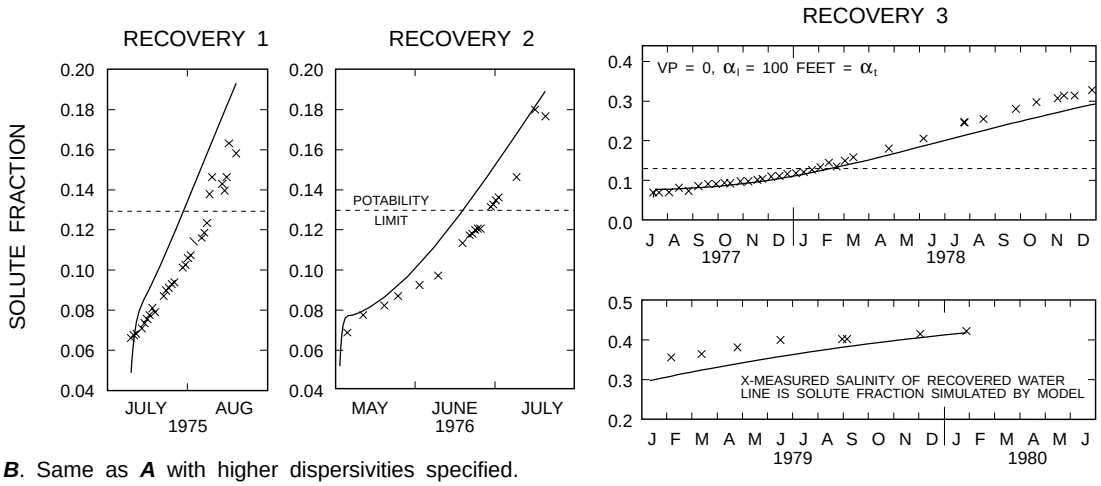
Figure 24 shows the nearly circular injected water mass after the brief first injection and the injected water at the end of the second injection, when some downgradient drift is evident. The drift becomes progressively more pronounced after the second storage period of 54 days, at the end of the third injection, and at the end of the third storage period of 180 days. The transition zone is wider (more diffuse) downgradient of the injected well. After the end of the extended third recovery, water with a lower solute fraction than that of the native water (0.45) remains in the aquifer. This fresher water is a mixture of injected freshwater and native saline water. That small amounts of the fresh injected water remain in the aquifer at this time as a result of downgradient advection is especially remarkable because the volume of the third recovery was nearly twice that of the third injection and exceeded the volume of all three injections by 22 percent.

Using a pore velocity of 260 ft/yr for calibration requires a regional gradient of 1.6 ft/mi, given the hydraulic conductivity estimate of 800 ft/d and porosity estimate of 35 percent. However, this value is 4 times that estimated on the basis of published potentiometric-surface data (Meyer, 1989a). Errors of this magnitude in the published estimates are unlikely, raising questions about the accuracy of the hydraulic conductivity estimates determined from simulating the aquifer-test data. In fact, results of individual aquifer tests in carbonate terraces are known to be unreliable because local heterogeneities are common. Thus, average flow-zone hydraulic conductivity possibly could be larger than estimated, perhaps even 4 times larger, or could be anisotropic. The unusual trends previously cited in observation-well water-quality data during the three injections, which suggest a partial early breakthrough of injected water, also suggest the possibility of local heterogeneities in flow-zone solution features that might affect results of an aquifer test.

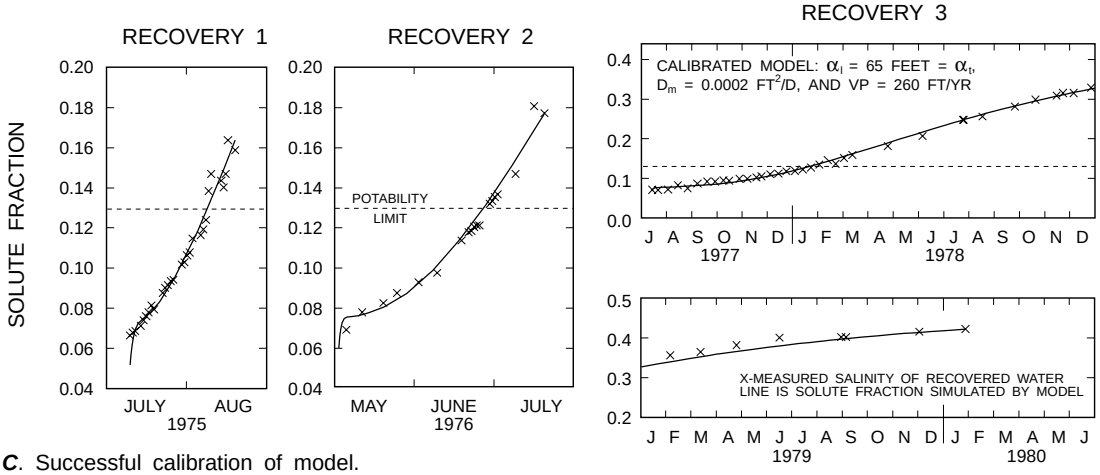
Near the end of the third recovery, computed recovery salinities were nearly the same as when the hydraulic gradient was specified to be zero, as would be expected if computed values are approaching the natural flow-zone salinity (1,200 and 2,700 mg/L concentrations of chloride and dissolved solids, respectively). The last chloride concentration measurement of recovered water, on January 28, 1980, was 1,120 mg/L. However, the magnitude of computed solute-fraction values near the end of the third recovery was highly sensitive to the molecular diffusivity value (D_m), which determined the rate at which solute ions from the more saline confining layers diffused into the injected water occupying the flow zone in the vicinity of the well. Figures 23D–E illustrate the dependence of the simulation result upon the value of D_m, as determined by additional simulation runs in which the dispersivities and regional pore velocities were the same as in the calibration (fig. 23C). D_m was increased to 0.001 ft^2/d (fig. 23D) and decreased to zero (fig. 23E). When D_m=0, no appreciable change in computed recovery salinities is observed in the first recovery, but computed salinities in the longer second and third recoveries are too small, and the salinities seem to converge to a value that is too low near the end of the third recovery. This illustrates results of the previously described algorithm tests showing that the observed recovery salinity data are highly influenced by the degree of molecular diffusion from overlying and underlying rocks



A. Unsuccessful attempt to simulate data using a zero regional gradient.



B. Same as ***A*** with higher dispersivities specified.



C. Successful calibration of model.

Figure 23. Results of the simulation of the salinity of recovered water and selected sensitivity analyses showing the calibration techniques. D. Sensitivity analysis: a higher value of molecular diffusivity is specified.

E. Sensitivity analysis: the value of molecular diffusivity is specified to be zero.

Figure 23. Results of the simulation of the salinity of recovered water and selected sensitivity analyses showing the calibration techniques--Continued.

containing more saline water. When D_m=0.001 ft^2/d, computed salinities are too large in all three recoveries and converge to a value that is too high near the end of the third recovery, indicating that the degree of molecular diffusion from adjacent layers has been overestimated.

On the basis of these observations, a convenient calibration strategy has evolved. The first recovery simulation is sensitive to the selection of dispersivities but insensitive to the selections of molecular diffusivity or regional pore velocity. The second and third recovery simulations are highly sensitive to regional pore velocity, and the computed salinity value near the end of the third recovery is especially sensitive to the specified value of molecular diffusivity, even when other calibration parameters are correct. Thus, these three parameters can be determined independently from comparison with separate parts of the observed data set. This set of conditions arises from the dissimilarity of the three ASR cycles and, particularly, from the fact that the third recovery was continued long enough to clearly show the effect of downgradient advection and the effect of molecular diffusion as the salinity of recovered water approached background levels.

Alternative Simulations

The simulation technique described in the preceding section was applied in additional calibration exercises in which flow-zone properties of the basic simulation were changed to investigate the implications of possible error in the interpretation of the field data. The same variations of the conceptual model of the flow zone that were the basis of alternative calibrations of the aquifer test, and one additional variation, were also used for alternative simulations of recovery salinity data. The objective was to determine if the

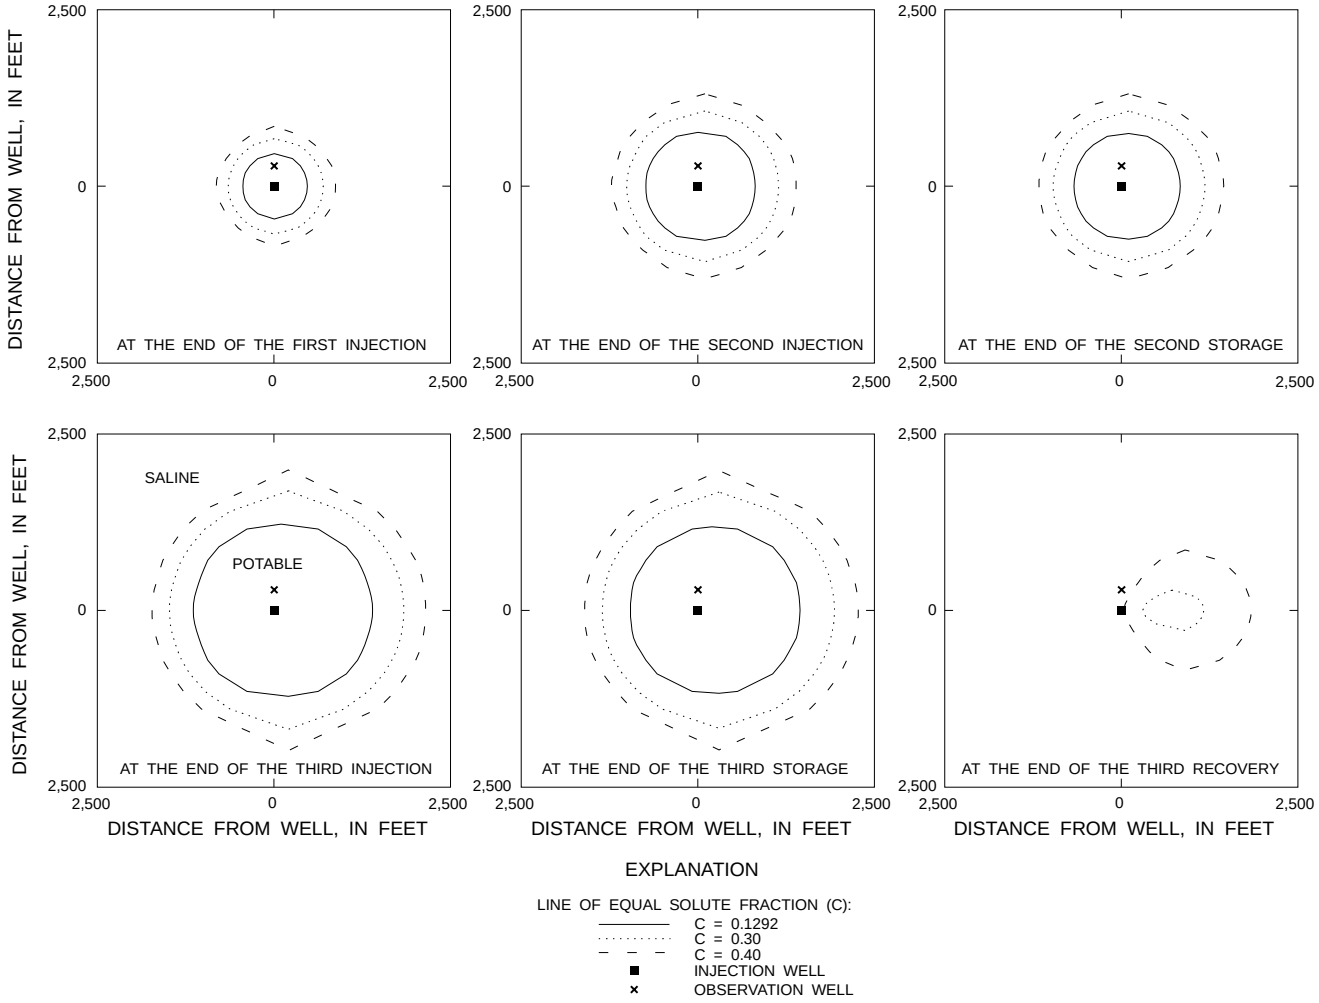

Figure 24. Horizontal distribution of injected freshwater at various stages of the aquifer storage and recovery cycles when permeability is horizontally isotropic. A solute fraction of 0.1292 corresponds to a chloride concentration of 250 milligrams per liter.

observed data could still be simulated, given the assumptions of the revised conceptual models. If so, results of subsequent predictive modeling could be strengthened by considering multiple cases that encompassed the possible range of variation of certain flow-zone properties determined from field data. This approach was the focus of a paper by Merritt (1991). The four cases considered and their significance are as follows:

- Flow-zone hydraulic conductivity was larger than that estimated from analysis of the aquifer-test data, resolving the discrepancy between calibrated model and literature estimates of hydraulic gradient;
- Flow-zone thickness was almost twice that estimated on the basis of some spinner flowmeter logs, as suggested by other flowmeter logs and some water-quality data;
- The effective porosity of the flow zone was lower than the total porosity of rock and pores measured by the neutron porosity log; and
- Flow-zone hydraulic conductivity might actually be anisotropic in the horizontal plane, the major flow direction being in the direction of the regional flow gradient and perpendicular to a line drawn between the injection and observation wells.

Excellent calibrations were achieved in all four cases and are illustrated, together with the basic calibration curve, in figure 25. Table 2 lists the assumed physical and hydraulic properties of the aquifer and parametric values used to calibrate each alternative simulation. In terms of the three parameters adjusted to calibrate the simulations, C-2 (increasing the flow-zone thickness to 21 ft) required doubling the molecular diffusivity, decreasing pore velocity by 15 percent, and decreasing the dispersivities by 23 percent; C-3

(decreasing the flow-zone porosity to 20 percent) required increasing the pore velocity by 40 percent, increasing the dispersivities by 23 percent, and decreasing the molecular diffusivity by 70 percent; and C-4 (anisotropic permeability having a 10 to 1 ratio of directional components) required increasing the pore velocity by 40 percent, decreasing the dispersivities by 23 percent, and leaving the molecular diffusivity unchanged.

In case C-1 the horizontal hydraulic conductivity value was increased to 3,200 ft/d, four times the original value determined from the aquifer-test simulation. This implied an injection-zone transmissivity increase to 38,400 [$(ft^3/d)/ft^2$]ft. The regional hydraulic gradient was decreased to 0.41 ft/mi, close to the value estimated from published literature and one-fourth the value used in the basic calibration (figs. 25A). Regional pore velocity remained the same at 260 ft/yr, and the dispersivity and molecular diffusion values were unchanged. The simulation curve (fig. 25B) is virtually identical to the previous one. This result indicates the absence of any significant degree of buoyancy stratification, which tends to increase with the value of hydraulic conductivity. However, at the prevailing density contrast, the degree of buoyancy stratification was still insignificant even when K_x=K_y=3,200 ft/d, though it did increase slightly.

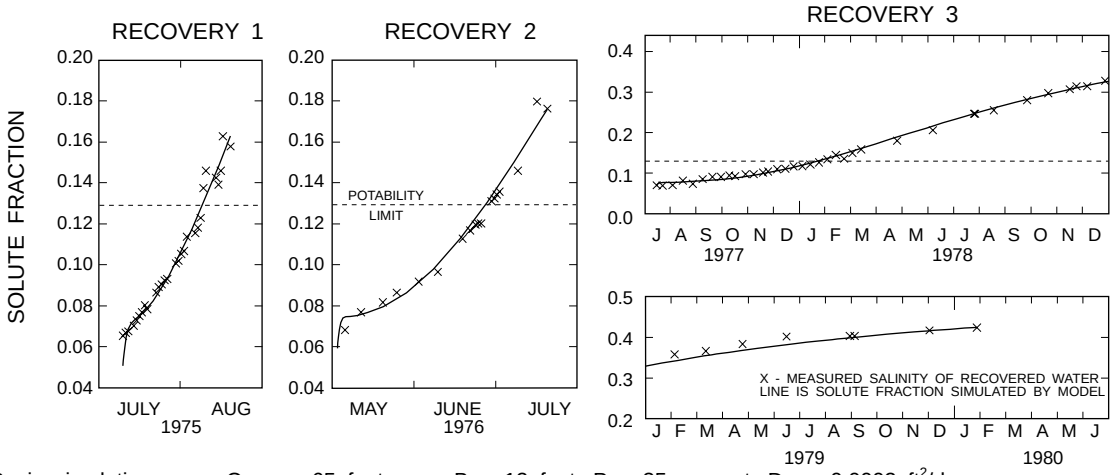
That identical results were achieved with the two sets of hydraulic conductivities and regional gradient estimates meant that each simulation of alternate conceptual models could be considered to actually represent two test cases corresponding to the two regional gradient estimates. The consequent reduction in the number of simulation runs required to test all hypotheses was especially beneficial, considering the large amount of computer time required for each simulation. The basic simulation required 20.5 hours on the PRIME 9955. When K_x and K_y were increased to 3,200 ft/d in simulation C-1, oscillatory behavior occurred in the second and third recoveries. When the maximum time step was reduced to mitigate this undesirable behavior, the computer run time increased to 48.9 hours. Run times also depend on other work being processed by the computer concurrently, but the processing times per time step did not vary much in these simulation runs. Run times for the test cases are listed in table 2, as are the horizontal hydraulic conductivities that would have been used in simulations assuming that the regional gradient was 0.4 ft/mi.

The ellipsoidal planar distributions of injected freshwater at various stages of the ASR cycles in case C-4 are shown in figure 26. The views correspond to the same times and ASR cycle stages as in the isotropic case C (basic simulation) to facilitate comparison with figure 24. At the end of the first injection, potable freshwater has just reached the observation well along the axis of minimum permeability. This would be consistent with the rapid freshening observed in the observation well in the hours following the end of the first injection. Progressive downgradient advection is evident in the second and third cycles. As in the isotropic case, some injected freshwater remains in a mix with native saline water downgradient of the injection well at the end of the 2.5-year third recovery.

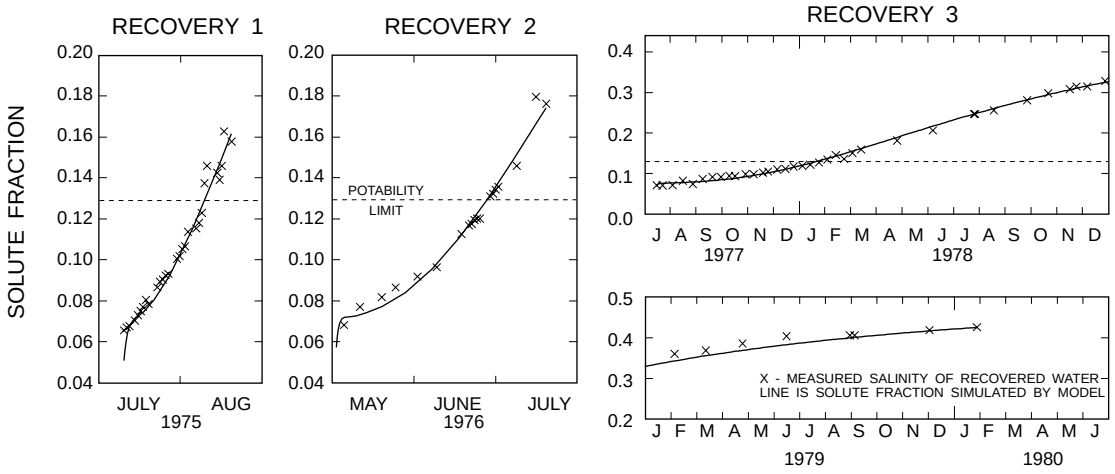
Estimates of Potential Recovery Efficiency After Several Cycles

The calibrated simulations were used for estimating the recovery efficiencies that would be achievable by operating a similar well at the Hialeah site for several annual cycles, as would be done if the ASR process were implemented by water utilities as an alternative for augmenting dry-season water supply. Merritt (1985) reported that, given favorable hydrogeologic conditions, recovery efficiency increases rapidly in early repetitions of the ASR cycle, particularly if each recovery is terminated just when withdrawn water exceeds salinity criteria for potability, leaving some injected freshwater in the flow zone in a nonpotable mix with native brackish water.

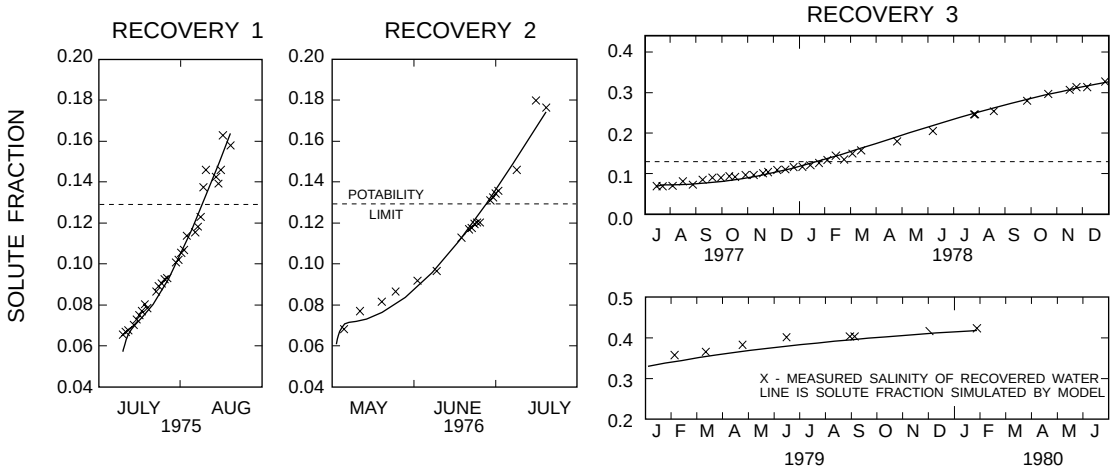
The SWIP code was used to simulate 10 successive ASR cycles, using the four sets of calibration values given in table 2 for cases C, C-2, C-3, and C-4. Each cycle consisted of 5 months of injection at 150,000 ft^3/d, 3 months of storage, and a maximum of 4 months of recovery at 150,000 ft^3/d. In southern Florida the injection period might correspond to June through October (when ground-water levels are highest), the storage period might correspond to November through January (the early months of the dry season), and the recovery period might correspond to February through May (the later months of the dry season when water shortages periodically occur in the region). The model was coded to stop recovery in each cycle when solute fraction approximately reached a value of 0.1292, corresponding to 250-mg/L chloride concentration. The pumping rate was then changed to zero until the scheduled beginning of the next simulated injection.



A. Basic simulation, case C: α_l = 65 feet = α_t, B = 12 feet, P = 35 percent, D_m = 0.0002 ft^2/d, VP = 260 ft/yr, K_x = K_y = 800 ft/d

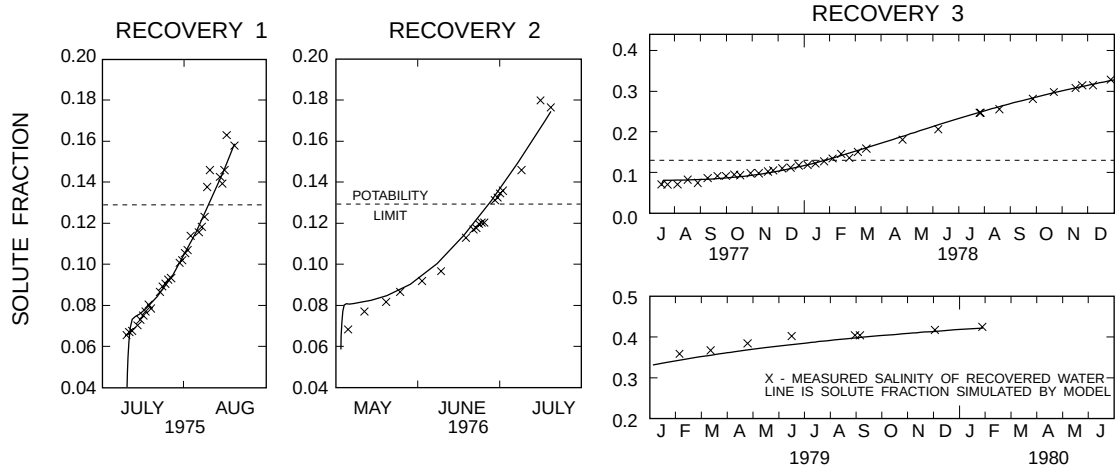


B. Higher hydraulic conductivities, lower regional gradient, case C1: K_x = K_y = 3,200 ft/d, VP = 260 ft/d, B = 12 feet, α_l = 65 feet = α_t, P = 35 percent, D_m = 0.0002 ft^2/d

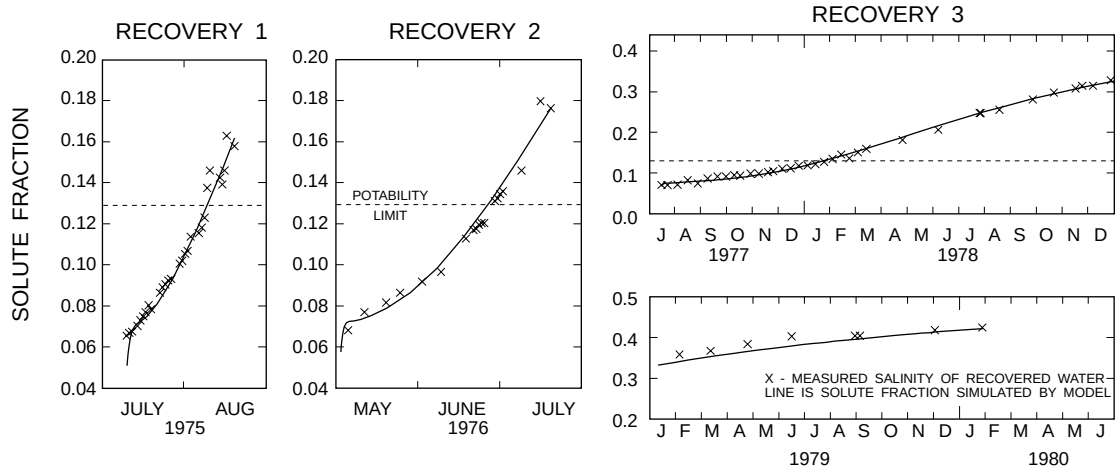


C. Increase flow-zone thickness, case C2: B = 21 feet, α_l = 50 feet = α_t, VP = 220 ft/yr, K_x = K_y = 475 ft/d, P = 35 percent, D_m = 0.0004 ft^2/d

Figure 25. Alternative simulations of the salinity of recovered water. P, flow-zone porosity, in percent; α_l, α_t, longitudinal and transverse dispersivities, in feet; B, flow-zone thickness, in feet; VP, aquifer pore velocity, in feet per year (ft/yr); D_m, molecular diffusivity, in feet squared per day (ft^2/d); K_X, K_Y, directional horizontal hydraulic conductivities, in feet per day (ft/d).



D. Lower flow-zone effective porosity, case C3: P = 20 percent, B = 12 feet, $K_X = K_Y$ = 750 ft/d, D_M = 0.0004 ft^2/d, VP = 364 ft/yr, α_l = 80 feet = α_t



E. Anisotropic horizontal hydraulic conductivity, case C4: K_x = 2,350 ft/d, K_Y = 235 ft/d, B = 12 feet, VP = 364 ft/yr, α_l = 50 feet = α_t, P = 35 percent, D_M = 0.0002 ft^2/d

Figure 25. Alternative simulations of the salinity of recovered water--Continued.

Table 2. Physical and hydraulic properties and parameter values used to calibrate basic and alternative simulations of the freshwater injection, storage, and recovery tests

[Description: 1, basic simulation; 2, increase hydraulic conductivities, decrease regional gradient; 3, increase flow-zone thickness; 4, decrease flow-zone effective porosity; 5, anisotropic permeability. Abbreviations: ft/mi, feet per mile; ft/yr, feet per year; ft^2/d, square feet per day; in^2/lb, (pounds per square inch)$^{-1}$; K_x, K_y, hydraulic conductivities in the *x*- and *y*-coordinate directions, in ft/d; K_{xa}, and K_{ya}, adjusted hydraulic conductivities in the *x*- and *y*- coordinate directions, in ft/d]

Case	Description	Flow-zone thickness (feet)	Flow-zone porosity (percent)	Regional gradient (ft/mi)	Regional pore velocity (ft/yr)	Dispersivity value (feet)	Molecular diffusivity value (ft^2/d)	Rock compressibility (in^2/lb)	Hydraulic conductivity (ft/d)				Simulation run time (hours)
									Regional gradient				
									1.6 ft/mi		0.4 ft/mi		
									K_x	K_y	K_{xa}	K_{ya}	
C	**1**	12	35	1.6	260	65	0.0002	0.0000400	800	800	—	—	18.6–20.5
C-1	2	12	35	.4	260	65	.0002	.0000400	—	—	3,200	3,200	48.9

C-4	5	12	35	.8	364	50	.0002	.0000100	2,350	235	4,580	458	17.2–17.9

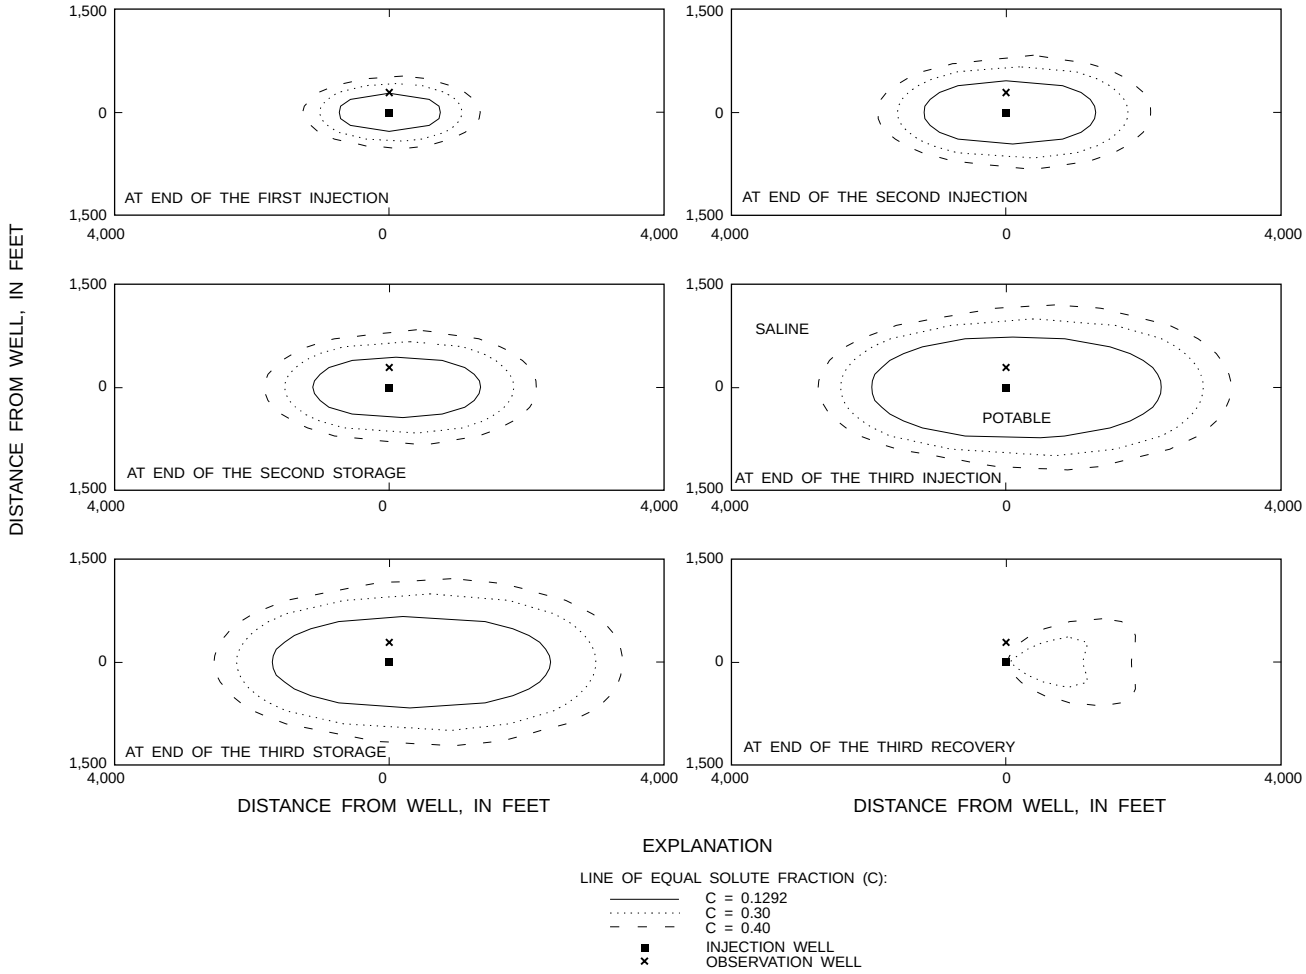

Figure 26. Horizontal distribution of injected freshwater at various stages of the aquifer storage and recovery cycles when permeability is anisotropic. A solute fraction of 0.1292 corresponds to a chloride concentration of 250 milligrams per liter.

Results of the 10 annual cycle simulations for the four cases and for an additional sensitivity analysis (case Ca) are given in the table below (values are recovery efficiency, in percent; dashes indicate not computed). Run C-2 was terminated by a power failure. As these computer runs required between 65 and 80 hours computing time on the PRIME 9955, and results of the run appeared definitive after six cycles, run C-2 was not repeated.

For each set of calibration values (C to C-4), virtually the same limiting recovery efficiency of 67–70 percent for the given schedule and rates was nearly realized after only four cycles. That the different simulations generally encompassed the likely range of possible values of true aquifer thickness, effective porosity, permeability, and permeability anisotropy enhances confidence in the result of the predictive simulations, which are shown to depend on the replication of observed changes in recovered water salinity in the three disparate ASR cycles rather than on the precise identification of aquifer parameters.

One of the principal limitations on recovery efficiency in these simulations was the high rate of regional flow, which was computed to be 260 ft/yr in

Case	Cycle 1	Cycle 2	Cycle 3	Cycle 4	Cycle 5	Cycle 6	Cycle 7	Cycle 8	Cycle 9	Cycle 10
C	40.6	58.4	63.9	66.3	67.4	68.0	68.3	68.4	68.5	68.55
C-2	41.8	58.4	63.2	65.1	65.9	66.3	—	—	—	—
C-3	42.0	58.1	62.5	64.6	65.7	66.4	66.8	67.0	67.2	67.2
C-4	40.1	58.9	65.1	67.8	69.1	69.7	70.1	70.2	70.3	70.3
Ca	45.1	67.9	76.3	>80.0	—	—	—	—	—	—

simulation C. The deleterious effect of downgradient advection is illustrated by simulation Ca, a sensitivity analysis in which the regional pore velocity was assumed to be much smaller (13 ft/yr). Substantially higher recovery efficiencies were realized, ranging from 45 percent in the first cycle to 76 percent in the third cycle. The maximum recovery efficiency possible in these simulations was 80 percent because injection was for 5 months, and recovery at the same rate was limited to 4 months. After 4 months of pumping potable water in the fourth cycle, the chloride concentration of the recovered water remained below the cutoff limit (250 mg/L), and indications were that recovery efficiency could have approached 90 percent in later cycles if a greater withdrawal rate had been specified.

Simulation of Observation-Well Data

Part of the data collected at the observation-well site during the injection and recovery cycles was considered earlier in describing the thickness and hydraulic properties of the injection zone. Generally, water-quality and pressure data from the observation well, though clearly showing qualitative changes caused by the injection and recovery process, fail to unambiguously support the conceptual model of flow and transport used as a basis for simulating water-quality changes during recovery.

A comparison of water-quality and pressure data measured at the observation well with solute fractions and pressures simulated at this location by the calibrated models described in the previous sections is helpful in (1) illustrating the similarities and dissimilarities between measurements and model computations, and (2) evaluating the accuracy of simulations of observed water-quality changes at specific locations in aquifers with solution porosity when the transport of fluids occurs near those locations.

Salinity Data

A simulation of salinity changes measured in the flow zone at the location of the observation well, 289 ft from the injection well, required a revision of the previously described simulation procedures. Because the injection rate varied as a result of wellbore clogging, there was an accompanying variation in the rate of freshwater movement toward the observation well that determined the water-quality changes occurring at the well. Therefore, valid synthetic times could not be assigned to observation-well samples, as was done for recovered water-quality data, and the transport of freshwater toward the observation well could not be accurately simulated using average rates. To provide the desired accuracy, the injection and recovery time periods were subdivided into shorter periods, during which rates remained approximately uniform. The three injection periods were subdivided into 9, 12, and 25 subperiods with corresponding average well rates. The aborted second injection was also explicitly simulated as a 7-day event. Because withdrawal rates varied less than the injection rates, the three recovery periods were subdivided into three, two, and nine subperiods for assignment of average rates.

The simulations were performed using the four sets of calibration values (C, C-2, C-3, and C-4) representing the basic calibration and three alternative calibrations. Chloride concentration values from the silver monitor (1,020 ft) were converted to solute-fraction values based on interpolated dissolved-solids estimates, as previously described, for comparison with the simulated solute-fraction values. The grid spacing that placed four nodes between the injection-well and observation-well nodes (fig. 19) used for aquifer-test simulations was employed again in these simulations.

Computed solute-fraction values and solute-fraction values based on measured data are shown on plate 2. Comparing the four computed curves, it seems that the 21-ft-thick aquifer simulation (C-2) and the horizontally bipolar anisotropic simulation (C-4), in which the observation well is in the direction of lowest permeability, each show a later arrival time of injected freshwater and a less rapid decrease in salinity at the observation well during the first injection, compared with the basic simulation (C, 12-ft thick horizontally isotropic aquifer, 35 percent flow-zone porosity). The observation-well salinity computed by C-2 and C-4 remains higher than that computed by C during the increase of the first recovery and the decreases of the second and third injections. In the simulation where porosity is decreased to 20 percent in the injection zone (C-3), the computed salinities are lower than when porosity is 35 percent (C), representing an earlier arrival and greater proportion of injected freshwater at the well. All simulations indicate a substantial decrease of computed solute fraction during the 7-day aborted second injection of December 1975. The approximate arrival time of freshwater at the observation well in the first cycle, assuming isotropy, was previously observed to be 7–8 days.

None of the four simulations of observation-well salinity matches the measured salinity data except when nearly 100 percent freshwater surrounded the

observation well. Because large dispersivities (65 ft in simulation C) were used to match chlorides measured during recovery at the injection well, the model portrays the observation-well salinity as beginning a rapid decrease at the start of each injection. Computed curves are smooth and monotonic during each injection. Generally, the measured salinity is higher, undergoes more abrupt changes, and occasionally fluctuates considerably, showing no clear trend, as in the first and second injections. The measured data show the changes predicted by the model in a qualitative sense, but do not validate the simulated salinity changes in a quantitatively precise way. As previously noted, salinity fluctuations between 6 and 8 days could indicate the arrival of part of the injected water at the observation-well location during the three cycles.

Pore-Velocity Computations

In an attempt to resolve previously cited difficulties in explaining observed water-quality changes at the observation well immediately following the first and second injections, the model was used for an analysis of aquifer flow rates immediately following the end of the first injection, after the injection pump had been turned off. The simulation addressed the possibility that a sharp interface existed between injected and native waters near the observation well, and that the interface had nearly reached the observation well when the first injection was stopped. If a slight hydraulic gradient prevailed within the flow zone for a short time thereafter, breakthrough of fresh injected water could occur even after the injection pump was turned off. In addition, continuous pumping of the observation well at 5 gal/min for the automatic sampler/recorder could have influenced a nearby sharp interface to approach the observation well by accentuating or maintaining a lingering hydraulic gradient.

Hydraulic-head values at the observation-well node (22, 12) and the immediately adjacent node (22, 13) on the axis toward the injection well (fig. 19) were used to compute approximate pore velocity at the observation-well location just before and following the end of the first injection. The computation was based on Darcy's equation and on assumptions of 800-ft/d horizontal hydraulic conductivity and 35 percent effective porosity. The hydraulic gradient was estimated as the difference in head between the two nodes, 75 ft apart. Darcian flow estimates are not strictly accurate in environments of varying density (Hickey, 1989) but were considered an adequate approximation for this analysis, given the low density contrast. When 5-gal/min pumping was specified, the nodal value representing a grid-block head average, and not a wellbore drawdown value, was used for the value of the well node head in the analysis. The subdivision of the first injection period into nine subperiods was used for the analysis to increase the accuracy of the computed flow rates in the aquifer near the observation well at the end of injection.

Assuming no pumping at the observation well, the computed pore velocity between the two nodes just before the end of the first injection was 14.08 ft/d. Fifteen minutes after injection pumping stopped, the simulated pore velocity dropped to 0.9 ft/d. After 24 hours, the pore velocity was 0.03 ft/d. The total distance traveled by water particles during the 24-hour period would have been about 0.05 ft. When the observation well was pumped at 5 gal/min in the simulation, the head simulated at node (22, 12) was about 0.1 ft lower during the first injection. The final injection pore velocity of 14.72 ft/d dropped to 1.55 ft/d 15 minutes after injection ceased, and to 0.67 ft/d after 24 hours. The total 24-hour travel distance was about 0.75 ft. Clearly, these simulations do not provide support for the hypothesis of substantial postinjection movement of a sharp interface between injected and native water. The movement of an interface in 24 hours under influence of the 260 ft/yr regional flow used in the basic calibration (C) would only be 0.71 ft. Furthermore, the direction of regional flow was approximately perpendicular to the radial-flow vector extending from the injection well to the observation well.

Pressure Data

Flow and transport processes between the two wells in the injection zone are further elucidated by comparing observation-well head changes during the ASR cycles with simulated head changes. Head changes at the observation well are determined by the injection-well inflow rate and aquifer characteristics, and are affected by injection-well borehole clogging only indirectly, through the effect on injection rate.

Observed and computed head changes at the observation-well location are shown on plate 2. Observed data are recorded pressures referenced to the preinjection value and converted to heads. The simulations shown are the basic calibration (C), the 21 ft-thick flow-zone calibration (C-2), the 20 percent flow-zone porosity calibration (C-3), and the

10:1 bipolar anisotropic calibration (C-4), each of which used a set of hydraulic parameters that replicated drawdowns observed at the injection well during the aquifer test of February 10, 1975. Hydrographs representing simulations C, C2, and C-3 depict similar head changes at the observation well. The C-2 head change is slightly less than that of simulation C, and the C-3 head change is slightly greater.

In harmony with theory, when anisotropy is assumed (curve C-4), computed head changes at the observation well located in the direction of least permeability are appreciably less than those computed by the isotropic basic calibration (C). The hydraulic response at the observation well is most rapid in the anisotropic case, in which the rock compressibility value was only one-fourth that of the isotropic case (C). A lower value of rock compressibility implies lower storativity and a more rapid transmission of hydraulic stresses through the aquifer.

Comparison of computed head changes with the observed data is difficult because the observed data seem to be affected by instrument calibration shifts and other errors occurring during the three ASR cycles. Unexplained pressure variations were recorded during the second storage period, and average heads during the four major inactive periods show variations of as much as 3 ft. Cessation of pumping water for the automatic sampler after the first cycle can only explain about 0.1 ft of the difference.

Arrival of warmer injected water at the observation well and consequent warming of water in the sampling tube in which pressure was monitored would have caused measured pressures to increase slightly at the wellhead. If the warmest injected water (27 °C) did not cool as it approached the observation well and entered the monitor tubes, the head increase at land surface could have been as much as 1.5 ft.

The observed hydraulic response to changes of stress is even more rapid at the observation well than predicted by the anisotropic model (C-4), lending some credence to the anisotropic hypothesis. Generally, the range of head variation in the second and third cycles is less than predicted by either isotropic or anisotropic models, though the difference is less with the anisotropic model. Possibly, a simulation with an even greater degree of anisotropy and using a smaller rock compressibility value would have better simulated the head data.

A comparison of injection and recovery hydraulic responses at the observation well in each cycle leads to an interesting result. Because the hydraulic response at a point within the aquifer is linearly related to the rate of inflow or outflow at the injection well, the ratio of inflow and outflow rates should be the same as the ratio of corresponding head changes at the observation well. Between August 28 and September 2, 1975, during the first injection, the inflow rate was approximately constant at 455 gal/min, and the head at the observation well was about 4.1 ft higher than the preinjection value. In the initial 14 days of the first recovery, the withdrawal rate averaged 335 gal/min, and the head at the observation well was about 4.8 ft lower than the preinjection value. Measured heads did not vary appreciably during these periods. The ratio of the injection and recovery rates is 1.36, and the ratio of the corresponding head changes is 0.85. This analysis was repeated for selected time intervals in the second and third ASR cycles, when rates were relatively constant. Results are given in the table below. To offset the apparent calibration drift after the first cycle, a head higher by 1.9 ft was accepted as representing a static (non-stress) condition in the second and third cycles.

Cycle	Injection			Withdrawal			Rate ratio	Head ratio
	Time period	Average rate (gallions per minute)	Average head change (feet)	Time period	Average rate (gallions per minute)	Average head change (feet)		
1	Aug. 28, 1975–Sept. 02, 1975	455	4.1	Sept. 10, 1975–Sept. 24, 1975	335	4.8	1.35	0.85
2	Feb. 20, 1976–Feb. 23, 1976	820	6.2	July 01, 1976–July 19, 1976	485	5.5	1.69	1.13
3	Oct. 22, 1976–Oct. 29, 1976	785	7.2	Nov. 04, 1977–Dec. 09, 1977	435	4.6	1.81	1.57

Subject to the difficulty in compensating for calibration errors in the pressure data, the results do not support the description of head changes measured in the observation well as being proportional to the inflow or outflow rate at the injection well. In fact, the head increases during injection seem to be damped in comparison with those observed during withdrawal, suggesting that some process retards flow between well locations during injection, compared with that occurring during withdrawal.

Directionally biased wellbore plugging, in which pores in the less permeable flow direction in an anisotropic aquifer would be plugged to a greater relative extent than in more permeable flow directions, was considered as a possible explanation. However, model simulations designed to test the hypothesis tended to refute rather than confirm it.

The difficulty in simulating observation-well pressure and salinity data illustrates the generalizing nature of porous-media models as applied to problems in secondary-porosity terranes. Simulating the salinity of recovered water merely requires a general representation of the diverse mixing processes occurring within the entire volume of aquifer occupied by injected freshwater. However, simulation of salinity changes at the observation-well location requires the correct representation of flow and mixing processes at all points between the two wells. If these processes differ from the generalizing assumptions of the recovery salinity model, a highly accurate simulation of observation-well data will likely not be achieved. In secondary-porosity media, such local departures from any generalized scenario of flow and mixing processes might be the norm rather than the exception.

SUMMARY

To deal with increasing water demands in a region characterized by seasonal surplus and deficit of water supply and limited reservoir capacity, water-management officials and others in southern Florida have sponsored operational testing of ASR, a water-conservation method in which subsurface formations containing brackish water are used for temporary storage of potable water. As part of a study conducted in cooperation with the SFWMD and the MDWSA, the USGS performed operational ASR tests at the Hialeah Well Field in Dade County.

A well for injecting freshwater and a second well for observing the hydraulic response and water quality were drilled 289 ft apart in late 1974 to depths of 1,105 and 1,064 ft. The injection- and observation-well casings extended to depths of 955 and 953 ft, respectively, so that the uncased part of the injection well was open to consolidated limestone of the intermediate confining unit and the Upper Floridan aquifer assigned to the Tampa Limestone, Suwannee Limestone, Ocala Limestone (if present), and Avon Park Formation. During drilling, a substantial augmentation of flow occurred between 985 and 1,065 ft.

Between July 1975 and January 1980, three ASR cycles were performed. In the first cycle, 41.9×10^6 gal of freshwater were injected. Recovery began after a 2-day storage period, and a recovery efficiency (volume of potable water recovered, expressed as a percentage of the volume injected) of 32.9 percent was realized. In the second cycle, 85×10^6 gal were injected and stored for 54 days. Recovery efficiency was 47.8 percent. In the third cycle, 208×10^6 gal were injected and stored for 181 days. Recovery efficiency was 38.5 percent, less than that of the second cycle. Recovery in all three cycles was by natural artesian flow.

Data acquired during the three ASR cycles include pressure-gage readings at the injection wellhead and in two monitor tubes within the observation well. Volumetric data on quantity of inflow and outflow were regularly obtained during the three cycles. A system of sampling tubes extending to various depths was installed in the open part of the observation well, and water samples were obtained both manually and also, during the first cycle, by means of an automatic sampler/recorder. Before the ASR cycles and at several times during the cycles, water samples from injection and observation wells and from the shallow well used for injection supply were analyzed for major inorganic ions, bacteria, chemical oxygen demand, biochemical oxygen demand, nutrients, total organic carbon, metals, field pH, alkalinity, and specific conductance. The chloride concentration and specific conductance of recovered water were measured frequently. Volumetric readouts from the in-line flowmeter were also recorded at the same time to establish a relation between volume of flow and water quality. Special analyses were made for algal species, nitrate-reducing bacteria, sulfate-reducing bacteria, iron bacteria, dissolved gases, and uranium isotopes.

Plugging of the wellbore occurred during the injections, causing the wellhead pressure to increase and the inflow rate to decrease. Injectivity was

restored by 2- or 3-hour backflushes at the natural artesian flow rate. These backflushes were performed at weekly intervals during the third injection, and well-head pressure and inflow rate remained generally uniform. An X-ray diffraction analysis of the back-flushed sediment showed very fine particles of calcite and iron (not scale).

At Hialeah the top of vertically contiguous consolidated limestone of the Floridan aquifer system is about 975 ft below land surface within the Suwannee Limestone. A shelly interval within the interval from 1,015 to 1,050 ft contains the principal flow zones. Data from an aquifer test at the site were analyzed using various methods, providing transmissivity estimates that range from 8,825 to 12,600 ft^2/d. A slight drawdown was measured in the 840-ft monitor tube during the aquifer test, indicating minor leakage across the confining beds separating it from the injection zone.

Data from spinner flowmeter logs were analyzed to delineate the flow zone by identifying intervals within the injection zone yielding the larger proportions of flow from the well. One such zone was found after analysis of 18 flowmeter logs. The top of the flow zone seemed to be about 1,024 ft below land surface in the injection well. The bottom of the flow zone seemed to be about 1,036 ft below land surface on the basis of some flowmeter log analyses. Temperature and fluid-resistivity logs run during recovery of injected water suggested that minor quantities of freshwater could enter the formation to a depth of about 1,047 ft below land surface. A diameter-compensated neutron porosity log showed porosity to average about 35 percent, there being wide variation in thin, discrete intervals.

Because of its importance for ASR feasibility, injection-zone salinity was the water-quality characteristic of most significance for this study. The chloride and dissolved-solids concentrations of water in the principal flow zone were 1,200 and 2,700 mg/L, respectively. Water from the 840-ft monitor tube had chloride and dissolved-solids concentrations of 1,700–2,300 mg/L and 3,900–5,000 mg/L, respectively, considerably higher than those of the flow zone 180 ft below. The dissolved-solids concentration in relatively impermeable rocks overlying and underlying the flow zone was assumed to be about 6,000 mg/L, and the relatively low salinity of the flow zone was assumed to be the result of flushing from areas of recharge in central Florida, 150 to 200 mi upgradient.

Data from widely scattered locations indicate that permeable strata in the Upper Floridan aquifer are present near erosional surfaces at the tops of the Ocala Limestone, if present, and Avon Park Formation, both of Eocene age. The top strata of Eocene age seems to correspond to a marked contrast in natural gamma activity (high above, in beds containing phosphatic materials, and low below). The chloride concentration of water at this contact increases from less than 900 mg/L at the St. Lucie County ASR site, to 1,200 mg/L in central and northeastern Dade County, and to more than 2,200 mg/L on the island of Key Largo in Monroe County.

A solute-transport code was used for simulating the salinity of water recovered after injection of freshwater. The model is fully three-dimensional, and solution of the equations is by standard finite-difference techniques. Fractional values ranging between 0 and 1 describe the relative concentrations of two miscible fluids in the aquifer. Values of density are associated with the extreme values of solute fraction, and water density within the modeled domain is considered to be a time-varying linear function of solute fraction, temperature, and pressure.

A Cartesian coordinate system was selected for the simulations so that downgradient advection and anisotropy could be represented. Boundaries were 20,000 ft from the injection well at their nearest point, and time-invariant pressure values were specified at the boundaries as an approximation that did not affect simulated freshwater flows during the ASR cycles. Central differencing techniques were used to eliminate first-order numerical dispersion related in degree to grid-cell sizes and the length of time increments.

A series of numerical tests was devised to examine the importance of the vertical component of mechanical dispersion and of molecular diffusion from the confining zones and their effect on recovery efficiency. The original 1979 SWIP code algorithms for vertical dispersion and advective weighting were compared with experimental techniques, and various values were assigned to transverse dispersivity, molecular diffusivity, and a scaling factor for vertical dispersion. The tests showed that when the experimental methods were used to eliminate vertical dispersion across flow-zone boundaries, a significant influence on recovery efficiency is the degree of molecular diffusion from the more saline confining zones. The magnitude of this influence depends upon the degree of vertical dispersion occurring within the

flow zone, which is under user control by use of the scaling factor. When the 1979 methods were used, vertical dispersion across flow-zone boundaries reduced recovery efficiency.

Observed drawdown data from the aquifer test of February 10, 1975, were simulated to derive estimates of hydraulic parameters for use in simulations of recovery chloride increases. Based on the assumption derived from interpretation of geophysical and water-quality data that the flow zone was 12 ft thick, isotropic, and had an effective porosity of about 35 percent, the drawdown data were calibrated by setting values of horizontal hydraulic conductivity equal to 800 ft/d and the value of rock compressibility to 0.0000400 $(lb/in^2)^{-1}$. The calibrated hydraulic parameters were used to derive estimates of composite hydraulic parameters (transmissivity and storage coefficient) for the injection zone. The transmissivity was computed to be 9,600 $[(ft^3/d)/ft^2]ft$, and the equivalent storage coefficient was computed to be 7.8×10^{-5}.

Alternative calibrations of the aquifer-test data were obtained to give consideration to the possibility that assumptions concerning the aquifer physical properties were in error. Alternative assumptions were that (1) the flow zone was 21 ft thick; (2) flow-zone effective porosity was 20 percent; and (3) flow-zone hydraulic conductivity had a 10:1 horizontal anisotropy, the preferred flow direction being at a right angle from a vector pointing from the injection well to the observation well. Each aquifer-test calibration showed excellent agreement with observed data.

The hydraulic parameters determined from the aquifer-test calibration that assumed a 12-ft flow zone having a 35 percent effective porosity were used as part of a simulation of the chloride increases observed during the three recoveries. A simulation was completed by setting the longitudinal and transverse dispersivities equal to 65 ft, by setting the molecular diffusivity equal to 0.0002 ft^2/d, and by assuming a hydraulic gradient in the aquifer of 1.6 ft/mi, about 4 times as large as estimated from regional hydraulic-head measurements. The computed regional pore velocity was 260 ft/yr. When results of simulating the aquifer test were disregarded and hydraulic conductivity values were assumed to be 3,200 ft/d, the literature estimate of 0.4 ft/mi for the regional hydraulic gradient led to a virtually identical simulation. This result was possible because the higher estimate of hydraulic conductivity did not lead to buoyancy stratification in the simulations, given the prevailing low density contrast between injected and native aquifer water.

Sets of hydraulic parameters determined from the three aquifer conceptual models used for alternative calibrations of the aquifer-test data were again used for three additional, and equally accurate, simulations of the recovery salinity data. Each simulation used a unique set of calibration parameters different from the others. Because the conceptual models differed in parameters based on field data that could not be accurately measured, the solution dependence upon possible errors in the accepted estimates of these parameters was evaluated by this procedure.

Given the accuracy with which recovered water salinity was simulated in three disparate ASR cycles, predictive simulations were made with a fair degree of confidence. An arbitrary schedule of injection and withdrawal was specified: five wet-season months of injection at 150,000 ft^3/d, followed by three early dry-season months of storage, and then by a maximum of four late dry-season months of withdrawal at 150,000 ft^3/d. These runs showed recovery efficiency to improve from about 40 percent in the initial cycle to nearly 70 percent in later cycles. The cited figures depend on the specified rates and schedule. The predictive run was repeated with sets of calibration parameters that represented the alternative conceptual models previously described. Each case yielded results similar to those of the basic simulation, lending credence to the predictive application of the model and showing that predictive results depended on the simulation of recovered water salinities rather than on the precise identification of aquifer parameters. When regional pore velocity was substantially reduced, recovery efficiency exceeded 80 percent in the fourth cycle, demonstrating the adverse influence of the large degree of downgradient advection indicated by the calibrated models.

Additional model runs in which the temporal variation in well rates was discretized in greater detail attempted to simulate head and salinity changes at the observation well, given the same four aquifer descriptions used for the simulations of recovered water salinity and the predictive analyses. Although the general trends of the measured data and simulated values are similar, neither the observed head changes nor the salinity changes are accurately matched by the model computations. Most likely, unknown local heterogeneities in aquifer hydraulic properties in the neighborhood of the observation well rendered the generalized design of the model, developed to simulate recovery salinity changes, inappropriate for precise simulations of hydraulic or water-quality changes at an isolated point location, such as that of the observation well.

APPENDIXES

APPENDIX A—DRILLING LOG OF INJECTION WELL G-3061 AND OBSERVATION WELL G-3062

Drilling Log of Injection Well G-3061

[Lithology and remarks by W.L. Miller to 970 feet and by F.W. Meyer below 970 feet. S, soft; VS, very soft; M, medium; H, hard; VH, very hard; min/ft, minute per foot; –, no data]

Date in 1974	Depth interval (feet)	Relative drilling hardness	Drilling speed (min/ft)	Lithology and remarks
Oct. 3	0–8	S	0.375	Black top soil, tan, sandy subsoil, light-tan limestone, oolite at about 8 ft.
	12–15	S-M	3.33	Light-tan limestone, solution-riddled, shells, some dark-tan limestone.
	20–23	M	1.66	Limestone-sandstone contact about 19–20 ft, white to light-tan sandstone, fine to medium, limestone fragments. Surface casing (30 in.) set to 19.95 ft below land surface, 13 in. cut off, 25 in. above ground, original length 23.11 ft. Drove 30-in. surface casing down.
Oct. 4	25–30	S	—	Fine to very fine quartz sandstone, shell fragments.
	30–35	S	—	White to light-tan coloration.
	35–40	S	—	
	40–45	S-M	—	Fine sandstone and lenses of limestone, hard zone at 41 ft, shell fragments in limestone, 10 percent limestone in cuttings.
	45–50	S	—	Fine quartz sandstone, some large quartz sand, ream.
	50–55	—	1.0	Limestone at 54 ft, hard rock.
	56–58	H	—	Gray to white limestone, quartz sand, coarse grains.
	60–62	H	3.0	
	62–65	H	—	Limestone, concretions, little sand.
	60–65	H	2.0	Calcareous sandstone, limestone, shells, quartz sand.
	65–68	—	—	Secondary calcite, sandy limestone, a few shells.
	68–70	H	7.0	
	70–75	H	—	More calcite (secondary), hard limestone.
	75–80	H	7.1	Cavernous sandy limestone, fine-grained quartz sand.
	80–82	H	—	Large cavities, lost circulation, very sandy limestone.
	82–88	H	—	No circulation, lost mud, large cavities. Surface casing settled to 3 ft below land surface, 22.03 ft of casing in ground must seal formation and cement in additional surface casing.
Oct. 7	88–90	M	3.0	Calcareous sandstone to limestone, large percentage of quartz sand, medium- to fine-grained, white to tan, cavities.
	90–95	M	3.2	Very sandy limestone, gray to tan, some loss of circulation.
	95–100	M	—	Fort Thompson/Caloosahatchee Marl(?). Soft, dense calcareous sandstone, tan to gray.
	100–105	S	—	Same as above, fast drilling, shells.
	105–108	S	—	Same as above.
	108–110	S	—	Same.
	110–115	S	—	Some green marl in sample, coarse.
	115–120	S	—	Quartz sand.
	120–125	S	—	Green marl, barnacles, large quartz grains, shells.
	125–128	S	—	Same as above, phosphates, shells.
	128–130	S	—	Same as above.
	130–135	S	—	No sample.
	135–140	S	—	Same as above.
	140–145	S	—	Caloosahatchee Marl/Tamiami(?). Some presence of white–green clay, oyster shell, *Ostrea hytensi(?)*.
	145–148	S	—	Some quartz sand, increasing amount of green clay.
	148–150	S	—	No sample.
	150–155	S	—	Green marl, shell, green clay increasing.
	155–160	S	—	No sample.
	160–168	S	—	More green clay balls, phosphates, shells.
	168–170	S	—	No sample.
	170–175	S	—	Green marl, green clay, shells, phosphates.
	175–180	S	—	Hawthorn Formation, large quantity of green clay (first predominant clay).
	180–188	S	—	Eighty-five-percent green clay.
	188–190	M	—	Decrease in clay, green marl, little clay.
	190–195	M	—	Green marl, coarse quartz sand, shell, little clay.
	195–200	M	—	Green marl, little clay, coarse quartz sand.

APPENDIX A—DRILLING LOG OF INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Date in 1974	Depth interval (feet)	Relative drilling hardness	Drilling speed (min/ft)	Lithology and remarks
Oct . 7	200–208	M	—	Still little or no clay.
	208–210	M	—	No sample.
	210–215	M	0.6	Dense sandstone, green sandy marl, little clay, quartz, medium to coarse.
	215–220	M	—	No sample.
	220–225	M	—	Dense green shale and sandstone, shell fragments, no clay.
	225–228	M	—	Same as above.
	228–235	M	—	Green shale, fine grained to sandy, dense.
	235–240	—	—	Clayey marl, green shale, quartz sand.
	240–248	—	—	Same as above.
Oct. 8				Ream to 48 ft.
Oct . 9				Ream to 72 ft, lost some mud.
Oct. 10				Ream to 95 ft, lost circulation 82–95 ft.
Oct. 11				Ream to 167 ft.
Oct. 14				Ream to 206 ft, hole reamed to 29-in. diameter to depth of 206 ft, will set 200 ft of 24-in. OD casing.
Oct. 15				Back into hole to check depth, only 3 ft short of 206 ft.
Oct. 16				Ten yards cement used to seal casing to a depth of about 201 ft. Shut down for day to allow cement to harden.
Oct. 17				Prepared to resume drilling, opened casing, and drilled bird nest.
Oct. 18				Cemented casing to land surface, took 1 yard additional cement.
Oct. 21				Start 9 7/8-in. pilot hole.
	250–260	S	1.2	Green marl, large percent clay, fine-grained quartz sand.
	260–270	S	—	Same as above.
	270–280	S	—	Green marl, 75–80 percent clay.
	280–290	S	—	Green marl, fine-grained quartz sand, some fragments limestone.
	290–300	M	2.1	Same as above.
	300–310	M	—	Green marl, large amount of very fine sand.
	310–320	M	—	Same as above.
	320–330	M	—	Same.
	330–340	M	—	Same.
	340–347	M	—	Same.
Oct. 22	347–360	S	.46	Fine-grained sand, green clay, 90 percent sand.
	360–370	S	—	No sample has reached surface yet.
	370–380	S	—	Same as above.
	380–390	S	—	Marl, fine sand, marl breaking up and sand too fine to settle, little or no sample can be collected.
	390–400	S	—	No sample.
	400–410	S	—	Hit layer of limestone at 406 ft, sample is fine sand and green clay.
	410–420	M	1.1	Dense clayey sand, green, very fine quartz.
	420–430	M	—	Sandy limestone and green marl, very fine green quartz, increasing limestone.
	430–440	M	—	Limestone, some very fine quartz sand.
	440–450	M	—	Sandy limestone, some green clay.
	450–460	M	—	Same as above.
	460–470	M	—	Same.
	470–480	M	—	Same.
	480–490	M	—	Same.
	490–500	S-M	—	Fine, dense limestone, white, some fine quartz sand.
	500–510	S-M	—	Limestone, breaks into small fragments.
	510–520	S-M	.8	Relatively clean limestone, little sand.

APPENDIX A—DRILLING LOG OF INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Date in 1974	Depth interval (feet)	Relative drilling hardness	Drilling speed (min/ft)	Lithology and remarks
Oct. 22	520–530	S-M	—	Limestone, soft, fragments crush easily.
	530–540	S-M	—	Same as above.
	540–550	S-M	—	Same.
Oct. 23	550–560	S-M	1.4	Gray lime marl.
	560–570	M	—	Gray and green marl, large amount of gray clay, limestone.
	570–580	S	—	Gray and green marl.
	580–590	S	—	Gray marl (clay)
	590–600	S	—	Same as above.
	600–610	S	—	Same.
	610–620	M	2.1	Gray-green marl, increasing shells, limestone.
	620–630	M	—	Same as above.
Oct. 24	630–647	M	—	White limestone, mostly shells, quartz sand, fine to coarse.
	647–660	S	—	Gray limestone, shelly, some green fragments.
	660–670	S	—	Same as above.
	670–675	S	—	Gray limestone, shelly, probably Tampa Formation.
	675–680	S	—	Gray limestone, shell, tan quartz sand increasing.
	680–685	S	—	Gray limestone, fine quartz sand, clear.
	685–690	S	—	Limestone, shell, echinoid spines, sand (sample of last 40 ft).
	690–695	S	—	Mostly shell fragments, some sand.
	695–700	S	—	Same as above.
	700–705	S	—	Large shell fragments, some sand.
	705–707	S	—	Large shell fragments, echinoid spines, circulating.
	707–715	S	—	Limestone, shelly, clay increasing.
	715–720	S	—	Gray limestone, shell, some gray clay.
	720–725	S	—	Gray limestone, shell, some fine quartz sand.
	725–727	M	—	Gray limestone, gray-green clay increasing, circulating.
	727–735	M	—	Gray limestone, shell, gray clay.
	735–740	H	—	Shell, sand, green clay.
	740–745	H	—	Green limestone, gray limestone, green clay, shell decreasing.
	745–747	H	—	Same as above, circulating.
	747–755	H	—	Gray limestone, not much clay, little shell.
	755–760	H	—	Same as above.
	760–765	H	—	Gray limestone, dense, breaks into small fragments.
	765–767	H	—	Same as above, circulating.
	767–775	M	—	Softer gray limestone, some shell, little sand.
	775–780	S	—	Gray limestone, no shell or sand.
	780–785	S	—	Same as above.
	785–787	—	—	Same as above, circulating.
Oct. 25	787–795	M	—	Gray limestone, some shell.
	795–800	M	—	Same as above, some dark-green fragments.
	800–805	M	—	Same as above, large amount of mollusks.
	805–807	M	—	Same as above, circulating.
	807–815	M	—	Some green clay in gray limestone.
	815–820	M	—	Clay increasing in gray limestone.
	820–825	M	—	Large amount of gray clay in shell limestone.
	825–827	S	—	Gray-green clay, stringer of limestone at 826 ft, circulating.
	827–835	—	—	Gray clay and tan limestone.
	835–840	—	—	Tan limestone.
	840–845	—	—	Same as above.
	845–847	—	—	Same as above, circulating.
	847–855	S	—	Fine-grained tan limestone.
	855–860	S	—	Tan limestone, crushes easily.
	860–865	S	—	Same as above, some green clay.
	865–867	S	—	Large amount of light-green clay and tan limestone, circulating.
	867–875	M	—	Gray-green clay and large amount of gray limestone.
	875–880	M	—	Gray limestone, soft, crushes easily, little clay.
	880–885	M	—	Soft gray limestone.
	885–887	M	—	Same as above and gray clay, circulating.

APPENDIX A—DRILLING LOG OF INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Date in 1974	Depth interval (feet)	Relative drilling hardness	Drilling speed (min/ft)	Lithology and remarks
Oct. 28	887–895	M	—	Very sandy green marl, very fine quartz sand.
	895–900	M	9.0	Sandy green marl, little sample because most of green clay is breaking up in mud, drilling mud has changed from gray to green color, limestone fragments increasing.
	905–907	M	—	Same as above, circulating.
	907–915	M	—	Sandy green marl, phosphates in sample.
	915–920	M	—	Lime chips, green marl, forams, phosphate.
	920–925	M	—	Same as above.
	925–927	M	—	Same.
	927–930	M	—	Same.
Oct. 29	930–935	M	9.0	Green marl, forams, shell.
	935–940	M	—	Same as above, more green clay.
	940–945	M	—	Same as above.
	945–947	M	—	Lighter colored green clay, shell, phosphate, softer material.
	947–955	S	5.0	Green marl, limestone at 954 ft.
	955–960	S	3.0	Green clay, some lime, fine quartz sand.
	960–965	S	—	No sample.
	965–967	S	—	Green clay, mostly shell, mollusks, tan fossiliferous limestone.
	967–970	S	—	Tan to gray limestone, fossiliferous. Will set casing at about 970 ft (F.W. Meyer), removed all drill pipe from hole.
Oct. 30				Reaming hole to 22.5 in. at 258 ft.
Oct. 31				Reaming hole to 22.5 in. at 389 ft.
Nov. 4				Reaming hole at 436 ft.
Nov. 5				Reaming hole at 460 ft.
Nov. 22				Cemented 14-in. casing at 955.28 ft below top of 24-in. casing.
Dec. 2				Obtained gamma log from 0 to ±940 ft. On bottom with 11 7/8-in. bit, top of cement at 946 ft. First sign of returns, 25-minute lag in cuttings from cement plug.
	946–955	H	3.63	
	955–965	H-S	3.50	Slight flow. Hard to 957 ft; soft at 957 ft.
	965–970	H	1.80	Soft streaks.
	970–975	H	1.60	Limestone, gray, silty, tiny black specks, soft streaks.
	975–980	H	1.20	Same as above, *Miogypsina* sp., soft streaks.
	980–985	S	1.60	Limestone, gray-white, fossils *Operculinoides* sp. and papillate(?). Laps. Flow estimated at 10 gal/min, hard streaks.
Dec. 3				Collected 1 pint water sample, T=73.0 °F; slight H_2S. Hole filled back to about 970 ft.
	970–985	—	—	Drilling out filled-in hole. First sign of returns. 25-minute lag in cuttings. Water sample collected.
	985–990	H	10.4	Very hard streaks.
	990–995	M	3.4	Limestone, gray, sand as above, very hard streaks, 985–990 ft.
	995–1,000	S	1.4	
	1,000–1,005	S	1.4	Limestone, cream-tan, fossils of *Operculinoides* sp., and gray limestone as above.
	1,005–1,010	S	2.0	
	1,010–1,015	S	1.8	Same as above, more forams and some shell fragments.
	1,015–1,020	S	1.6	Permeability increases here.
	1,020–1,025	S	1.8	Limestone, tan-gray, some shell but many forams, barnacles.
	1,025–1,030	S	1.8	Noticeable increase in flow. Coarse fragments of echinoids and ribbed mollusks.
	1,030–1,035	S	3.4	Hard streaks, 1,032–1,035 ft. Limestone, tan-gray, coarse fragments of mollusks.
	1,035–1,040	S	1.2	Increase in flow.
	1,040–1,045	S	1.0	Limestone, cream, soft, porous, fossiliferous, miliolids.
	1,045–1,050	S	1.4	

APPENDIX A—DRILLING LOG OF INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Date in 1974	Depth interval (feet)	Relative drilling hardness	Drilling speed (min/ft)	Lithology and remarks
Dec. 3	1,050–1,055	VS	.6	Same as above, some gray shale.
	1,055–1,060	S	1.4	
	1,060–1,065	S	.6	Same as above, many *Dictyoconus* sp., Avon Park Formation.
	1,065–1,070	S	1.2	
	1,070–1,075	S	.8	
	1,075–1,080	—	.6	
	1,080–1,085	—	.4	Limestone, tan, many *Dictyoconus* sp. Terminated circulation, coming out of hole.
Nov. 4				Barbara Howie collected water samples for extended complete analysis (bacteria, standard complete, chemical oxygen demand, biochemical oxygen demand, nutrients, total organic carbon, metals, field pH, alkalinity, specific conductance, chloride). F.W. Meyer and W.A. Long logged hole (electric, caliper, gamma) and found obstruction (cement at 964 ft prevented flowmeter survey). Apparently, a piece of cement wall in overdrill below casing cracked off and lodged across the borehole. Cancel logging by Schlumberger. Jim Kern plans to return December 9 with drilling rig to drill out the cement. Estimated flow about 500–600 gal/min.
Dec. 9				Collected water sample. T=70.3 °F, moderate H_2S, flow about same. Going into hole, on top of cement slab at 964 ft.
	964–1,085	—	—	Drilled 964–1,085 ft, cement now at bottom. Decided to drill another 20 ft below cement, cuttings show greater than 50 percent cement.
	1,085–1,090	S	.6	
	1,090–1,095	S	.6	
	1,095–1,100.5	S	.8	
	1,100–1,105.5	S	1.0	Limestone, tan, microfossils, and much cement.
Dec. 10				Collected 1 L water sample. Flow about same, about 600 gal/min. Drillers cleaning up area.
Dec. 11				Construction forms for floor.
Dec. 13				Poured concrete floor.
Dec. 16				Drillers clean up site, remove equipment.
Dec. 17				Pressure measurement.

Drilling Log of Injection Well G-3062

[Lithology and remarks by W.L. Miller to 183 feet and by F.W. Meyer below 183 feet. S, soft; VS, very soft; M, medium; H, hard; VH, very hard; min/ft, minute per foot;. —, no data]

Date	Depth interval (feet)	Relative drilling hardness	Drilling speed (min/ft)	Lithology and remarks
Oct. 11, 1974	0–5	VH	0.21	Fine-grained, white Miami Oolite and gray consolidated sand.
	5–10	S	1.0	Brown limestone and gray consolidated sand; tan limestone, some fossils evident.
	10–15	S	.8	Lost circulation at 13 ft, back at 14 ft.
	15–20	S	.4	White sandstone cemented with calcium carbonate.
	20–25	S	—	Same as above. Adding drill stem. Drill stopped for day for repairs.
Oct. 14, 1974	25–30	S	—	Drilling with 7 7/8-in. bit for pilot hole. Limestone and sand grains cemented with limestone. Large fragments greater than 5 millimeters.
	30–35	S	—	Same as above. Mainly small fragments, 1–5 millimeters.
	35–40	S	—	Bit chatter at 39 ft. Limestone, not as much sand as above.

APPENDIX A—DRILLING LOG OF INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Date	Depth interval (feet)	Relative drilling hardness	Drilling speed (min/ft)	Lithology and remarks
	40–43	VH	10	Equal amounts of small and large fragments.
	43–45	VH	9.0	Small limestone fragments, more cemented sand than at 35–40 ft.
	45–50	VH	5.0	Small fragments of limestone. Larger fragments of cemented sand grains.
	50–55	S	.8	Same as above.
	55–60	S	2.0	Same.
	60–63	VS	.67	Same.
	63–65	S	1.5	Same.
	65–70	S	2.0	Same.
	70–75	S	1.6	Same as above. Lost circulation at 72 ft, back at 73 ft.
	75–80	S	2.0	Very hard at 80 ft, bit chattering.
	80–85	H	—	Lost circulation at 81 ft, mixing mud.
	85–90	—	1.4	Pumped drilling mud at a very slow rate. No circulation.
	90–95	S	1.0	
	95–100	S	.4	No sampling from 80 to 100 ft.
	100–105	—	—	Gray sand cemented with limestone, many shell fragments. Upon reaching 103 ft, pumped at a faster rate and achieved circulation.
	105–110	VS	.5	
	110–115	VS	.3	Same as at 100–105 ft.
	115–120	VS	.4	Lost circulation between 117–118 ft.
	120–123	VS	.33	Grayish-white marl, sand grains, limestone and shell fragments.
	125–130	VS	1.0	Same as above.
	130–135	VS	.4	Same as above, but grayer.
	135–140	VS	.2	
	140–145	VS	—	Lost circulation at 143 ft.
	145–150	VS	.2	
	150–155	VS	.2	
	155–160	VS	.2	
	160–163	VS	.33	No circulation from 143 to 163 ft.
	163–165	VS	—	
	165–170	VS	.2	
	170–175	VS	.3	
	175–180	VS	.1	
	180–183	VS	.17	No samples from 143 to 183 ft. Started to pick up circulation at 183 ft. Letting hole set overnight.
Oct. 15, 1974	183–185	—	2.5	Shell, dark-gray, very coarse quartz sand, some green clay. Much aquagel. Losing returns.
	185–190	—	1.0	Shell, dark-gray to white, fine to very coarse quartz sand, some gray sandstone, phosphorite, cf. barnacles.
	190–203	VS	2.6	Still losing returns; shell as above.
	203–208	VS	1.0	Some hard streaks. Added rod, lost returns. Sand, light-gray, fine.
	208–215	S	1.4	Hard streaks. No returns. Removed drill pipe to add reaming bits. Start reaming 7 7/8-in. hole to 22 3/4 in. No lag.
Oct. 16, 1974				7 7/8-in. pilot hole reamed to 187 ft (22 3/4-in. diameter), rain stopped drilling.

APPENDIX A—DRILLING LOG OF INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Date	Depth interval (feet)	Relative drilling hardness	Drilling speed (min/ft)	Lithology and remarks
Oct. 17, 1974				200-ft level reached. Preparing to set 14-in. casing. Total casing 200.52 ft.
Oct. 18, 1974				Cemented casing to 200 ft, used 390 bags (17 yards).
Oct. 21, 1974				Temperature log of 150 ft of cased, cemented hole. Gamma log to 150 ft.
Oct. 22, 1974				Drilled 7 7/8-in. pilot hole to 460 ft. Caught own samples, no log kept.
Oct. 23, 1974				Pilot hole to 740 ft. No log kept.
Oct. 24, 1974				Began to go back into hole. Bridged at ±240 ft. On bottom at 740 ft. Circulating new mud.
	740–764	S	0.416	Shell, white to gray, cf. mollusks, white sticky clay, little hard dark-green sandy clay.
	764–769	S	.6	Shell, white to gray, cf. mollusks, white sticky clay, little hard, dark-green, sandy clay.
	769–774	S	1.4	Same as above.
	774–779	S	1.8	Same as above. Shell is bluish.
	779–784	S	.4	Limestone, white to gray, soft, shelly, sticky white clay and hard dark-green sandy clay concretions resembling casts of worm burrows.
	784–789	S	.6	Same as above; casts of small snails.
	789–794	S	.8	Same as above; snail casts, shark teeth, and light-green clay.
	794–799	S	1.25	Same as above; light-green sandy clay.
	799–804	S	1.0	Same as above.
	804–809	S	1.8	Limestone, white, soft, shelly, white calcareous clay and dark-green sandy clay concretions.
	809–814	S	1.8	Same as above.
	814–817	S	3.8	Clay, white, sticky, shelly, and limestone as above.
	819–824	S	3.0	Clay, white, some shell, and stringers of limestone. Some flat branching Bryozoa.
	824–829	S	.8	Limestone, tan to white, soft, some shell.
	829–834	S	.4	Same as above.
	834–839	S	.6	Same.
	839–844	S	2.0	Limestone, tan to white, soft, clayey, some shell (less than at 824 ft).
	844–849	S	1.0	Limestone, tan, soft, porous, clayey, some shell.
	849–854	S	.6	Same as above.
	854–859	S	1.4	Same as above; some hard streaks.
	859–864	S	2.6	Limestone, tan, soft, clayey, and some green clay.
	864–869	S	1.25	Same as above; shell.
	869–874	S	.6	Same as above; light-green “slipperly” clay.
	874–879	S	1.25	Shell, mollusks, and soft light-green to tan clay.
	879–884	S	1.4	Clay, light-green, “slippery,” and pieces of hard dark-green calcareous clay or limestone, some shell as at 804 ft.
	884–889	S	3.0	Clay, light-green, sticky, and tan shelly limestone.
	889–894	S	3.6	Same as above.
	894–899	S	2.4	Same as above.
	899–904	S	3.4	Clay, dark-green, slightly sandy (very fine quartz) and large mollusks.
Oct. 25, 1974				Driller has bit stuck at 884 ft.
Oct. 29, 1974				Driller retrieved 7 7/8-in. bit.
Oct. 30, 1974				Driller repairing equipment.
Oct. 31, 1974				Driller reaming 7 7/8-in. hole to 13.5 in.
Nov. 14, 1974				6 5/8-in. OD steel casing on bottom, free and clear, 953 ft deep.

APPENDIX A—DRILLING LOG OF INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Date	Depth interval (feet)	Relative drilling hardness	Drilling speed (min/ft)	Lithology and remarks
Nov. 19, 1974				5 7/8-in. bit on bottom and circulating. On float shoe, soft cement.
	953–958	—	1.8	Drilling out cement plug.
	958–961	—	3.3	Pieces of cement and the float shoe. Well is flowing from drill pipe.
	961–966	—	1.6	
	966–971	S	1.0	
	971–976	S	.8	
	976–984	S	.8	Tan to gray shell, sand, and dark-green shale. Duplicate sample shows tan fossiliferous limestone.
	984–989	S	.6	(?) Suwannee Limestone; *Miogypsina* sp. cf.
	989–994	S	1.6	Hard streak at 989 ft. Limestone, tan, many forams cf. *Miogypsina*.
	994–999	S	.4	Soft with hard streaks.
	999–1,004	VS	.6	Same as above.
	1,004–1,009	VS	.8	
	1,009–1,014	VS	.4	Same as above.
	1,014–1,019	VS	.2	
	1,019–1,024	VS	.2	Same as above; some blue-gray limestone.
	1,024–1,029	VS	.2	
	1,029–1,034	VS	1.0	
	1,034–1,044	VS	3.3	Medium to hard at 1,039 ft.
	1,044–1,049	S	.2	Flow about 200 gal/min estimated. Slight H_2S odor.
	1,049–1,054	S	.2	Tan limestone, fossiliferous, Avon Park fauna noted.
	1,054–1,059	S	.4	
	1,059–1,064	VS	.4	Limestone, tan, fossiliferous. Many *Dictyconus* and *Coskinolinus*, few *Lepidocyclinus* and *Operculinoides* sp. Water sample analyzed by Miami Water Department. Decided to terminate drilling at 1,064 ft. All drill pipe and collars out of hole. Flow increased to estimated 250 gal/min.
Nov. 20, 1974				Water samples collected by D.J. McKenzie for complete analysis. Q=240 gal/min.
Nov. 17, 1974				Pressure gage measurement.
Feb. 6, 1975				Measured flow with 4- and 5-in. orifices.
Feb. 10, 1975				Flow tests. Monitoring well Q=250 gal/min for 100 minutes.
Feb. 24, 1975				Obstruction at 983.7 ft. Original total depth is 1,064 ft. Filled into $\pm$1,054 ft. "Clean out" needed. Rig in place and drill stems stacked. No apparent obstruction at 983.7 ft. Bottomed at 1,058 ft. Clean out to 1,064.83 ft (total depth). Pulled off well and capped. Let run overnight. Rig will leave tomorrow.

APPENDIX B—LITHOLOGIC DESCRIPTION OF ROCK SAMPLES FROM INJECTION WELL G-3061 AND OBSERVATION WELL G-3062

Lithologic Description of Rock Samples from Injection Well G-3061

[Description is by R.T. Mooney, Florida Geological Survey]

Depth interval (feet)	Description
0–5	Sand; unconsolidated quartz; pale-yellowish-brown (10 YR 6/2); grains are primarily subangular to subrounded, clear, clean quartz; very fine to fine sand size, fair sorting; above 25 percent brown-black organic-looking materials (peat?); traces (1 percent) of limestone; small gastropod shell.
8–11	Limestone, very pale orange (10 YR 8/2); evidence of solution activity; some very fine quartz grains in the limestone; trace of white clay; few shell fragments and shell molds.
12–15	Primarily limestone as above; beginning of an unconsolidated sand layer; clear, very fine sand, moderately sorted, subangular to subrounded quartz grains; also much fine sand size, limestone pieces.
20–25	Sand; unconsolidated quartz; white (N 9); very clean, clear, subangular to subrounded; very fine to fine sand grains with fair sorting; some pieces of limestone as above; piece of crab claw; few abraded shell fragments.
25–50	Same as above.
51–53	Sandstone; pinkish-gray (5 YR 8/1); calcareous cement; sand grains are primarily quartz, subangular to subrounded, fine to very fine sand size; some calcite grains are present; some pieces of limestone with evidence of solution activity is also present; few shell fragments.
55–105	Same as above; varying from a calcareous sandstone to a sandy limestone in different sample intervals, increasing shell fragments.
105–110	Same as above, increasing shell fragments.
110–115	Shell bed; pinkish-gray (5 YR 8/1) to medium-gray (N 5); many warm, abraded, gray and white shell fragments; also pieces of limestone and sand with sandstone from above; few rounded sand-size phosphorite grains.
115–145	Same as above; traces of a white clay.
150–155	Shell bed as above; beginning of a very light olive-gray (5 Y 7/1) clay.
160–175	Same as above.
175–180	Clay, yellowish-gray (5 Y 7/2); fine sand-size, rounded, quartz grains in the clay; calcareous; some large quartz and phosphorite grains, rounded; many shell fragments, bryozoan; trace of limestone.
180–188	Same as above; less shell fragments.
188–190	Mixture of shell bed, worn abraded pelecypod shells, and clear quartz sandstone with a calcareous clay matrix.
190–195	Sandstone as above, yellowish-gray (5 Y 7/2); trace of shell fragments and limestone.
195–200	Same as above.
200–208	Much sandstone as above; beginning of a yellow-gray, slightly calcareous clay; trace of shell fragments.
208–215	Clay as above; some sandstone as above; trace of shell fragments.
220–225	Clay as above; decreasing sandstone and shell fragments.
225–228	Clay as above; same sandstone and sandy limestone.

APPENDIX B—LITHOLOGIC DESCRIPTION OF ROCKS SAMPLES FROM INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Depth interval (feet)	Description
228–235	Clay, pale-olive (10 Y 6/2); marly when wet, calcareous; trace of sandstone and limestone; few shell fragments; bryozoan, echinoid spine.
235–240	Same as above.
240–248	Clay, medium-olive (10 Y 5/2); very sandy, calcareous; some shell fragments and limestone pieces; bryozoan.
250–260	Same as above.
260–270	Clay, medium-olive (10 Y 5/2); very sandy, calcareous; trace of sandy limestone.
270–280	Same as above; trace of shell fragments.
280–290	Same as above; some phosphate.
290–300	Same as above; decreasing in sand.
300–310	Same as 260–270 ft; some phosphate.
310–327	Same as 300–310 ft.
330–347	Same as above; much quartz sand (fine to medium).
347–360	Sand, unconsolidated, clear quartz and phosphorite, fine to medium, moderately sorted, subrounded.
360–390	Same as above; trace of clay, some zircon(?) present, *Globigerina ruber.*
390–410	Unconsolidated sand as above, yellowish-gray (5 Y 7/2), change of color may be due to an increase of clay.
410–420	Same as 390–410 ft; slight increase in clay and larger grains phosphorite.
420–430	Same as above; beginning of a white limestone.
430–440	Same as above.
440–450	Same as above; increase in clay content.
450–460	Clay, yellowish-gray (5 Y 8/1), very sandy, phosphorite, trace of limestone, *Rubulus.*
460–470	Limestone, yellowish-gray (5 Y 8/1); much sand and clay, phosphorite, echinoid spine.
470–480	Same as above; slightly less clay, trace of sand and phosphorite.
480–490	Same as above.
490–500	Primarily limestone as above; increase in clay and sand (very fine) content, trace of very fine phosphorite.
500–510	Limestone, yellowish-gray (5 Y 8/1); yellowish-gray clay; phosphorite; some shell fragments.
510–550	Same as above.
550–560	Limestone as above; about 50 percent, except broken into larger granule-size fragments; about 40 percent clean quartz sand, subangular to subrounded, fine to medium sand size; some polished phosphorite grains; rest of sample is composed of traces of shell fragments, dolomite, and chert(?).
560–570	Limestone, yellowish-gray (5 Y 8/1); granule-size fragments covered with a yellowish-gray calcareous clay; some quartz sand, pieces of “proto” sandstone composed of quart sand grains with a clay matrix; traces of chert; unknown hard black material (possibly phosphorite), some of it in a honeycomb pattern.
570–580	Clay, yellowish-gray (5 Y 8/1); calcareous; pieces of limestone, shell fragments, dolomite, phosphorite from above.
580–630	Clay as above.

APPENDIX B—LITHOLOGIC DESCRIPTION OF ROCKS SAMPLES FROM INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Depth interval (feet)	Description
630–647	Limestone, white (N 9) to yellowish-gray (5 Y 8/1); covered with white clay; many shell fragments; some calcite crystals, fine.
647–705	Limestone as above; decreasing clay; many shell fragments.
705–725	Same as above.
725–727	Clay, yellowish-gray (5 Y 8/1); calcareous; silt to very fine sand size phosphorite (few coarse-size grains); many limestone and shell fragments; some quartz sand.
727–747	Same as above; trace of a light-olive gray (5 Y 6/1) clay; gradually turning into a limestone with high amount of clay.
747–755	Limestone; very light yellowish-gray (5 Y 9/1); seems to be a calcilutite to a very fine calcarenite; white clay; very fine calcite crystals; few shell fragments.
755–760	Same as above.
760–787	Same as above.
787–795	Primarily as above; beginning of a clay, light-olive-gray (5 Y 6/1); clay has a high percentage of quartz sand within it; in some cases it seems to be a “proto” sandstone composed of fine sand grains in a clay matrix.
795–820	Largely as above with an increasing clay covering on the limestone.
820–825	Limestone, yellowish-gray (5 Y 8/1); soft; much yellowish-gray calcareous clay; shell fragments; traces of quartz sand grains weakly cemented with clay matrix.
825–827	Clay, yellow-gray (5 Y 8/1); calcareous; many white limestone fragments, soft; shell fragments.
827–835	Clay as above.
835–875	Same as above.
875–880	Primarily clay as above; increasing limestone and shell fragments.
880–885	Shell hash; pinkish-gray (5 YR 8/1) to yellowish-gray (5 Y 8/1); many shell fragments, primarily pelecypod; limestone fragments with very fine phosphorite grains within it; trace of white clay.
885–887	Shell bed as above, but with much more clay; covers everything.
887–895	Sand, unconsolidated, yellowish-gray (5 Y 8/1); composed of calcite, quartz and phosphorite grains; silt to fine sand size; some clay material; forams, *Rubulus*(?), *Amphistegina*(?) (very small).
895–900	Same as above.
900–905	Sand, very light olive-gray (5 Y 7/1); primarily sand-size limestone fragments and silt to very fine quartz and phosphorite grains; much clay; traces of light-olive-gray (5 Y 6/1) clay; shell fragments.
905–907	Same as above.
907–915	Sand, yellowish-gray (5 Y 8/1); primarily fine sand-size quartz and calcite grains; many pieces of light-olive-gray (5 Y 6/1) clay; silt-size phosphorite(?) grains within the clay; shell fragments.
915–920	Same as above; much light-olive-gray (5 Y 6/1) clay; 50 percent of sample.
920–927	Sand as in sample 907–915 ft; traces of light-olive-gray (5 Y 6/1) clay.

APPENDIX B—LITHOLOGIC DESCRIPTION OF ROCKS SAMPLES FROM INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Depth interval (feet)	Description
927–930	Clay, light-gray (N 7) and yellowish-gray (5 Y 8/1); much quartz and calcite sand; shell fragments; traces of phosphorite and dolomite(?).
930–945	Same as above.
945–947	Primarily as above; pieces of chert.
947–955	Sand, white to a light-olive-gray (5 Y 6/1); composed of rounded phosphorite, quartz and calcite grains, fine to medium sand size, much light-gray (N 7) clay; chert and dolomite; shell fragments.
955–960	Clay, light-olive-gray (5 Y 6/1); sample contains much quartz, phosphorite, and calcite sand; chert; shell fragments.
960–965	Clay, white (N 9); very fine black specks (possibly phosphorite) in the clay; much unknown gray material (drilling contamination?); much limonite rust from drill stem.
965–975	White clay as above; less unknown gray material.
965–967	Light-olive-gray clay as in sample 955–960 feet; many shell fragments.
967–970	Same as above; pieces of white limestone.
975–985	Limestone, white (N 9); also pieces of buff white limestone and clay; everything is covered with clay; shell fragments; forams *Operculinoides*(?), abraded *Heterostegina*(?), *Miogypsina* sp.
985–995	White limestone as above; no clay; abraded *Heterostegina*; few shell fragments.
995–1,005	Limestone, pinkish-gray (5 YR 8/1); seems to be a calcarenite, possibly bioclastic; *Operculinoides* sp., *Lepidocyclinus*(?).
1,005–1,015	Same as above.
1,015–1,025	Limestone, light-gray (N 7) and pinkish-gray (5 YR 8/1); many pieces from calcarenite above; many worn and abraded shell fragments and forams; pieces of gray dolomite and rounded phosphorite; echinoid spines; also some white limestone with black specks from above.
1,025–1,035	Same as above, but larger fragments.
1,035–1,045	Limestone, pinkish-gray (5 YR 8/1); bioclastic calcarenite; pieces of gray dolomite(?); few shell fragments; pelecypod, gastropod.
1,045–1,055	Lithology as above, but small fragments; *Dictyoconus cookei*, *Textularia*.
1,055–1,065	Same as above; *Dictyoconus cookei*(?).
1,065–1,085	Limestone; white (N 9) to pinkish-gray (5 YR 8/1); seems to be a bioclastic calcarenite; some evidence of recrystallization; *Dictyoconus cookei*.
1,085–1,105	Same as above.

APPENDIX B—LITHOLOGIC DESCRIPTION OF ROCKS SAMPLES FROM INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Lithologic Description of Rock Samples from Injection Well G-3062

[Description is by R.T. Mooney, Florida Geological Survey]

Depth interval (feet)	Description
0–5	Limestone, pinkish-gray (5 YR 8/1); about 1 percent quartz sand grains in the limestone; evidence of solution activity.
5–55	Limestone as above; slightly higher percentage of quartz.
55–60	Sandstone, pinkish-gray (5 YR 8/1); calcareous matrix (almost a very sandy limestone); sandy grains are very fine to fine, subangular to subrounded, primarily quartz with some heavy minerals (darker, honey-colored grains); trace of shell fragments.
60–63	Largely sandstone as above; also pieces of a sandy limestone; traces of a white clay; traces of shell fragments.
63–65	Same as above; slightly increasing limestone.
65–70	Limestone, very light gray (N 8); quartz sand in the limestone (varying percentages); much sandstone as above; traces of shell fragments and white clay.
70–75	Same as above.
75–80	Same as above.
80–100	No sample.
100–105	Shell bed, white (N 9) and medium-gray (N 5); many broken, worn, and abraded pelecypod and gastropod shells; medium to coarse, rounded, polished quartz and phosphorite sand grains; pieces of limestone and sandstone as above.
110–115	Same as above.
120–123	Same as above.
125–130	Primarily as above; white clay on the cuttings; some fine sand-size limestone grains.
130–135	Same as above.
135–183	No sample.
183–190	Clay, light-olive-gray (5 Y 6/1); many very fine to fine quartz and calcite sand grains; some shell fragments from above; few medium sand-size, polished quartz and phosphorite grains as above.
190–203	Limestone, white (N 9) to greenish-gray (5 GY 6/1); large amount of calcareous clay and very fine quartz sand; shell fragments; phosphorite; traces of a calcareous sandstone.
203–208	Sand, unconsolidated; light-gray (N 7); primarily very fine to fine, clear quartz grains, angular to subrounded, some polished phosphorite and heavy mineral grains; some greenish-gray-clay from above; shell fragments and traces of limestone.
220–225	Clay; many pieces of limestone, shell fragments, and drill pipe rust all covered with a gray-greenish clay.
225–230	Same as above.
230–235	Clay, light-olive-gray (5 Y 6/1); calcareous; pieces of limestone, shell fragments, etc., from above; traces of fine quartz sand.
235–240	Same as above; minor phosphorite.

APPENDIX B—LITHOLOGIC DESCRIPTION OF ROCKS SAMPLES FROM INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Depth interval (feet)	Description
240–245	Clay, olive-gray (5 Y 4/1) (slightly marly when wet); minor very fine quartz sand in the clay, minor phosphorite, limestone fragments from above.
245–270	Clay as above; increasing very fine quartz sand.
270–275	Clay as above; slight color change to about medium-olive-gray (5 Y 5/1).
275–290	Same as above.
290–295	Clay (5 GY 6/1), greenish-gray, very fine clear quartz, sandy; minor phosphate, traces of limestone and shell fragments.
295–300	Same as above.
300–305	Same as above.
305–310	Same as above.
310–315	Same as above.
315–320	Same as above; peat; *Amphistegina*(?).
320–325	Primarily as above; increasing limestone.
325–330	Same as above.
330–405	No samples.
405–410	Limestone, yellowish-gray (5 Y 8/1); covered with a grayish clay; soft limestone; trace of shell fragments; phosphorite.
410–415	Same as above; echinoid spine.
415–420	Same as above.
420–425	Same as above; increasing clay.
425–430	Limestone, yellowish-gray (5 Y 8/1); clay covering the limestone; minor phosphorite; shell fragments.
430–435	Same as above.
435–440	Limestone as above; increasing clay (about 40 percent clay).
440–445	Primarily clay-covered limestone as above; minor phosphorite; beginning of a white limestone bed.
445–450	Same as above.
450–455	White limestone as above; increasing clay; minor quartz in the limestone.
455–460	Same as above; decrease in clay.
460–465	Same as above; increasing quartz and phosphorite; shell fragments; echinoid spine.
465–470	Same as above; less quartz.
470–475	Same as above; increasing quartz (same as 460–465 ft).
475–480	Same as above; less quartz.

APPENDIX B—LITHOLOGIC DESCRIPTION OF ROCKS SAMPLES FROM INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Depth interval (feet)	Description
480–485	Same as above.
485–490	Limestone, white (N 9); seems to be a calcilutite; minor phosphate in limestone; trace of clay; some shell fragments.
490–495	Same as above.
495–500	Same as above.
500–505	Same as above.
505–510	Same as above.
510–515	Same as above.
515–520	Same as above; some shell molds in the limestone.
520–525	Same as above.
525–530	Same as above.
530–535	Same as above; slight increase in clay.
535–540	Same as above; trace of peat.
540–545	Clay, yellowish-gray (5 Y 8/1); calcareous; phosphorite in clay; about 40 percent limestone as above; trace of shell fragments.
545–550	Limestone as in 530–535 ft; about 20 percent clay (micrite?).
555–560	Micrite limestone as above; minor phosphorite.
560–565	Same as above.
565–570	Same as above.
570–575	Same as above.
575–580	Same as above.
580–585	Same as above.
585–590	Same as above; echinoid spine; decrease in phosphorite.
590–595	Same as above.
595–600	Same as above; trace of shell fragments.
600–605	Same as above; increase in shell fragments.
605–610	Same as above.
610–615	Same as above.
615–620	Same as above.
620–625	Same as above.
625–630	Same as above.

APPENDIX B—LITHOLOGIC DESCRIPTION OF ROCKS SAMPLES FROM INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Depth interval (feet)	Description
630–635	Same as above.
635–640	Same as above.
640–645	Primarily as above; beginning of a consolidated, hard, white limestone, fossiliferous.
645–650	Same as above with increase of the fossiliferous hard limestone.
650–655	Same as above; shell fragments.
655–660	Same as above.
660–665	Same as above.
665–670	Limestone, white (N 9); fossiliferous, some of the micritic limestone; shell fragments.
670–675	Same as above; evidence of secondary calcite; echinoid spines.
675–680	Same as above.
680–685	Same as above.
685–690	Same as above.
690–695	Same as above.
695–700	Same as above.
700–705	Same as above.
705–710	Same as above.
710–715	Same as above.
715–720	Same as above.
720–725	Clay, yellowish-gray (5 Y 8/1); calcareous; silt-size phosphorite; about 40 percent limestone as above; shell fragments; trace of sand-size quartz.
725–730	Same as above.
730–735	Same as above; slightly decreasing clay.
735–740	Same as above.
744–764	Primarily as above; much quartz sand within clay (25 percent); beginning of a light-brown dolomitic limestone(?); shark tooth, shell fragments.
764–769	Limestone, white (N 9); much quartzitic clay as above; some dolomitic(?) limestone as above.
769–774	Same as above; white seems to be fossiliferous.
774–779	Same as above; phosphorite.
779–784	Same as above.
784–789	Same as above.

APPENDIX B—LITHOLOGIC DESCRIPTION OF ROCKS SAMPLES FROM INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Depth interval (feet)	Description
789–794	Same as above; less clay.
794–799	Same as above.
799–804	Limestone, white (N 9); fossiliferous, some quartzitic clay as above; minor phosphorite.
804–809	Same as above; increase in calcareous, white clay (micrite?).
809–814	Same as above.
814–819	Micrite, yellowish-gray (5 Y 8/1); trace of quartzitic clay as above.
819–824	Same as above; increase in micrite clay.
824–829	Same as above; phosphorite.
829–834	Same as above.
834–839	Same as above; trace of quartz (some granules).
839–844	Same as above; increase in sand-size quartz.
844–849	Same as above; trace of phosphorite.
849–854	Same as above.
854–859	Same as above; beginning of a white fossiliferous limestone.
859–864	Limestone, white (N 9) covered with a calcareous white clay; shell fragments.
864–869	Same as above; increase in calcareous clay gives slight color change to yellowish-gray (5 Y 8/1).
869–874	Same as above; trace of quartz sand, echinoid spine.
874–879	Same as above.
879–884	Same as above.
884–889	Same as above; increasing shell fragments; trace of phosphorite, very fine.
889–894	Same as above; beginning of a gray phosphatic clay; increase in shell fragments.
894–899	Clay, white-olive-gray (5 Y 6/1), very fine phosphorite in clay, shell fragments, coarse sand-size quartz grains; some limestone as above.
899–904	Clay as above.
953–984	Limestone, yellowish-gray (5 Y 8/1); covered with a light clay, seems to be fossiliferous (forams); *Miogypsin*a, *Camerina*(?).
961–984	*Operculinoides*, *Heterostegina.*
984–994	Limestone, pinkish-gray (5 YR 8/1); covered with calcareous clay-size particles; minor phosphate; shell fragments; *Miogypsina*, *Camerina.*
994–1,004	Same as above; *Miogypsina*, *Camerina*.
1,004–1,014	Same as above.

APPENDIX B—LITHOLOGIC DESCRIPTION OF ROCKS SAMPLES FROM INJECTION WELL G-3061 AND OBSERVATION WELL G-3062—Continued

Depth interval (feet)	Description
1,014–1,024	Same as above.
1,024–1,034	Dolomite, light-gray (N 7); moldic; microcrystalline; limestone as above (but bigger cuttings); less clay; quartz in limestone; minor phosphorite.
1,034–1,044	Same as above; limestone seems to be bioclastic in part.
1,044–1,054	Limestone, pinkish-gray (5 YR 8/1); fossiliferous; 35 percent dolomite as above; phosphorite; *Cermina*.
1,054–1,064	Limestone as above; less dolomite; more forams *Camerina*, *Amphistegina*.

APPENDIX C—VOLUME AND RATE DATA FROM INJECTION AND RECOVERY CYCLES AND QUALITY OF RECOVERED WATER

Time of measurement		Days from beginning of data	Cumulative volume readout on flowmeter (gallons)	Flow rate (gallons per minute)	Chemical concentrations in recovered water		Change of activity
Date	Hour				Chloride (milligrams per liter)	Specific conductance (microsiemens per centimeter)

APPENDIX D—WATER-QUALITY DATA OBTAINED DURING WELL CONSTRUCTION AND THE SUBSEQUENT INJECTION AND RECOVERY CYCLES AT THE HIALEAH SITE

Bacteriological Analyses for Nitrogen-, Sulfate-, and Iron-Reducing Bacteria

[Nitrate, nitrate agar (14 days); sulfate, sulfate API media (14 weeks); iron, sphaerotilus agar; OW, observation well; SW, supply well; IW, injection well; —, no data]

Source	Date	Activity	Nitrate-reducing bacteria[1]	Sulfate-reducing bacteria[1]	Iron-reducing bacteria[2]	Microscopic iron bacteria[2]
OW	April 16, 1975	Preinjection background in injection zone	90	70	—	—
SW	July 22, 1975	Supply water for first injection	70	<30	—	—
OW	Aug. 04, 1975	Monitor zone, after 18 days of first injection	40	150	—	—
IW	Sept. 16, 1975	Recovered water, 6 days into first recovery	40	<30	—	—
	Sept. 23, 1975	13 days into first recovery	210	200	—	—
	Sept. 30, 1975	20 days into first recovery	110	200	—	—
	Oct. 15, 1975	35 days into first recovery				
	Mar. 04, 1976	Sampling supply water at injection wellhead during second injection	150	<30	—	—
	May 25, 1976	Recovered water, 22 days into second recovery	280	200	—	—
	July 18, 1977	Recovered water, first day of third backflow	<30	<30	<30	[2]

[1]MPN (most probable number) per 100 milliliters; MPN is based on multiple counts of bacteria colonies.
[2]Negative; considerable iron rust present.

APPENDIX D—WATER-QUALITY DATA OBTAINED DURING WELL CONSTRUCTION AND THE SUBSEQUENT INJECTION AND RECOVERY CYCLES AT THE HIALEAH SITE—Continued

Dissolved-Gas Analyses

[Analyses by D.H. Fisher, U.S. Geological Survey, written commun. (1975, 1977). ASR, aquifer storage and recovery; IW, injection well; OW, observation well;. —, no data]

Source	Date	Nitrogen	Oxygen	Argon	Methane	Carbon dioxide	Test status
			Pressures, in atmospheres, of Dissolved Gases at Sampling Temperature				
IW	Aug. 04, 1975	5.34	0.34	0.036	0.019	0.021	After 18 days of first injection (supply well water)[1]
	Sept. 16, 1975	.87	<.0001	.0104	.022	.0124	6 days into first recovery
	Sept. 30, 1975	.89	<.0005	—	.019	.0103	20 days into first recovery[2]
	Oct. 15, 1975	.99	<.0004	—	.017	.0088	35 days into first recovery[2]
OW	Apr. 24, 1975	1.05	<.001	.013	.0005	.0010	Background conditions in injection zone prior to ASR cycles
	Aug. 04, 1975	4.96	.61	.036	.007	.0047	After 18 days of first injection[1]
	Jan. 18, 1977	.89	<.002	—	.033	.019	Near end (after 181 days) of third injection
			Concentrations, in milligrams per liter				
IW	Aug. 04, 1975	99	14	2.1	.40	31	After 18 days of first injection (supply well water)
	Sept. 16, 1975	16	<.005	.61	.47	18	6 days into first recovery
	Sept. 30, 1975	17	<.02	—	.40	15	20 days into first recovery
	Oct. 15, 1975	19	<.02	—	.36	13	35 days into first recovery
OW	Apr. 24, 1975	21.4	<.05	.82	.012	1.7	Background conditions in injection zone prior to ASR cycles
	Aug. 04, 1975	96	26	2.17	.15	7.3	After 18 days of first injection
	Jan. 18, 1977	17	<.05	—	.72	29	Near end (after 181 days) of third injection

[1]High nitrogen pressures indicate atmospheric contamination (leaky stopcock or faulty sampling;, methane and carbon dioxide analyses should be relatively accurate; H_2S will have been oxidized.

[2]Argon added to the inner tube of the sampler.

APPENDIX D—WATER-QUALITY DATA OBTAINED DURING WELL CONSTRUCTION AND THE SUBSEQUENT INJECTION AND RECOVERY CYCLES AT THE HIALEAH SITE—Continued

Chemical Analyses of Water Samples

[mg/L, milligrams per liter; JTU, Jackson turbidity units; NTU, nephelometric turbidity units; Pt-Co, platinum cobalt units; µS/cm, microsiemens per centimeter; µg/L, micrograms per liter; mL, milliliter; g/mL, grams per milliliter, tons/acre-ft, tons per acre-feet; NO_2+NO_3, nitrate plus nitrite; ND, not detected; —, no data]

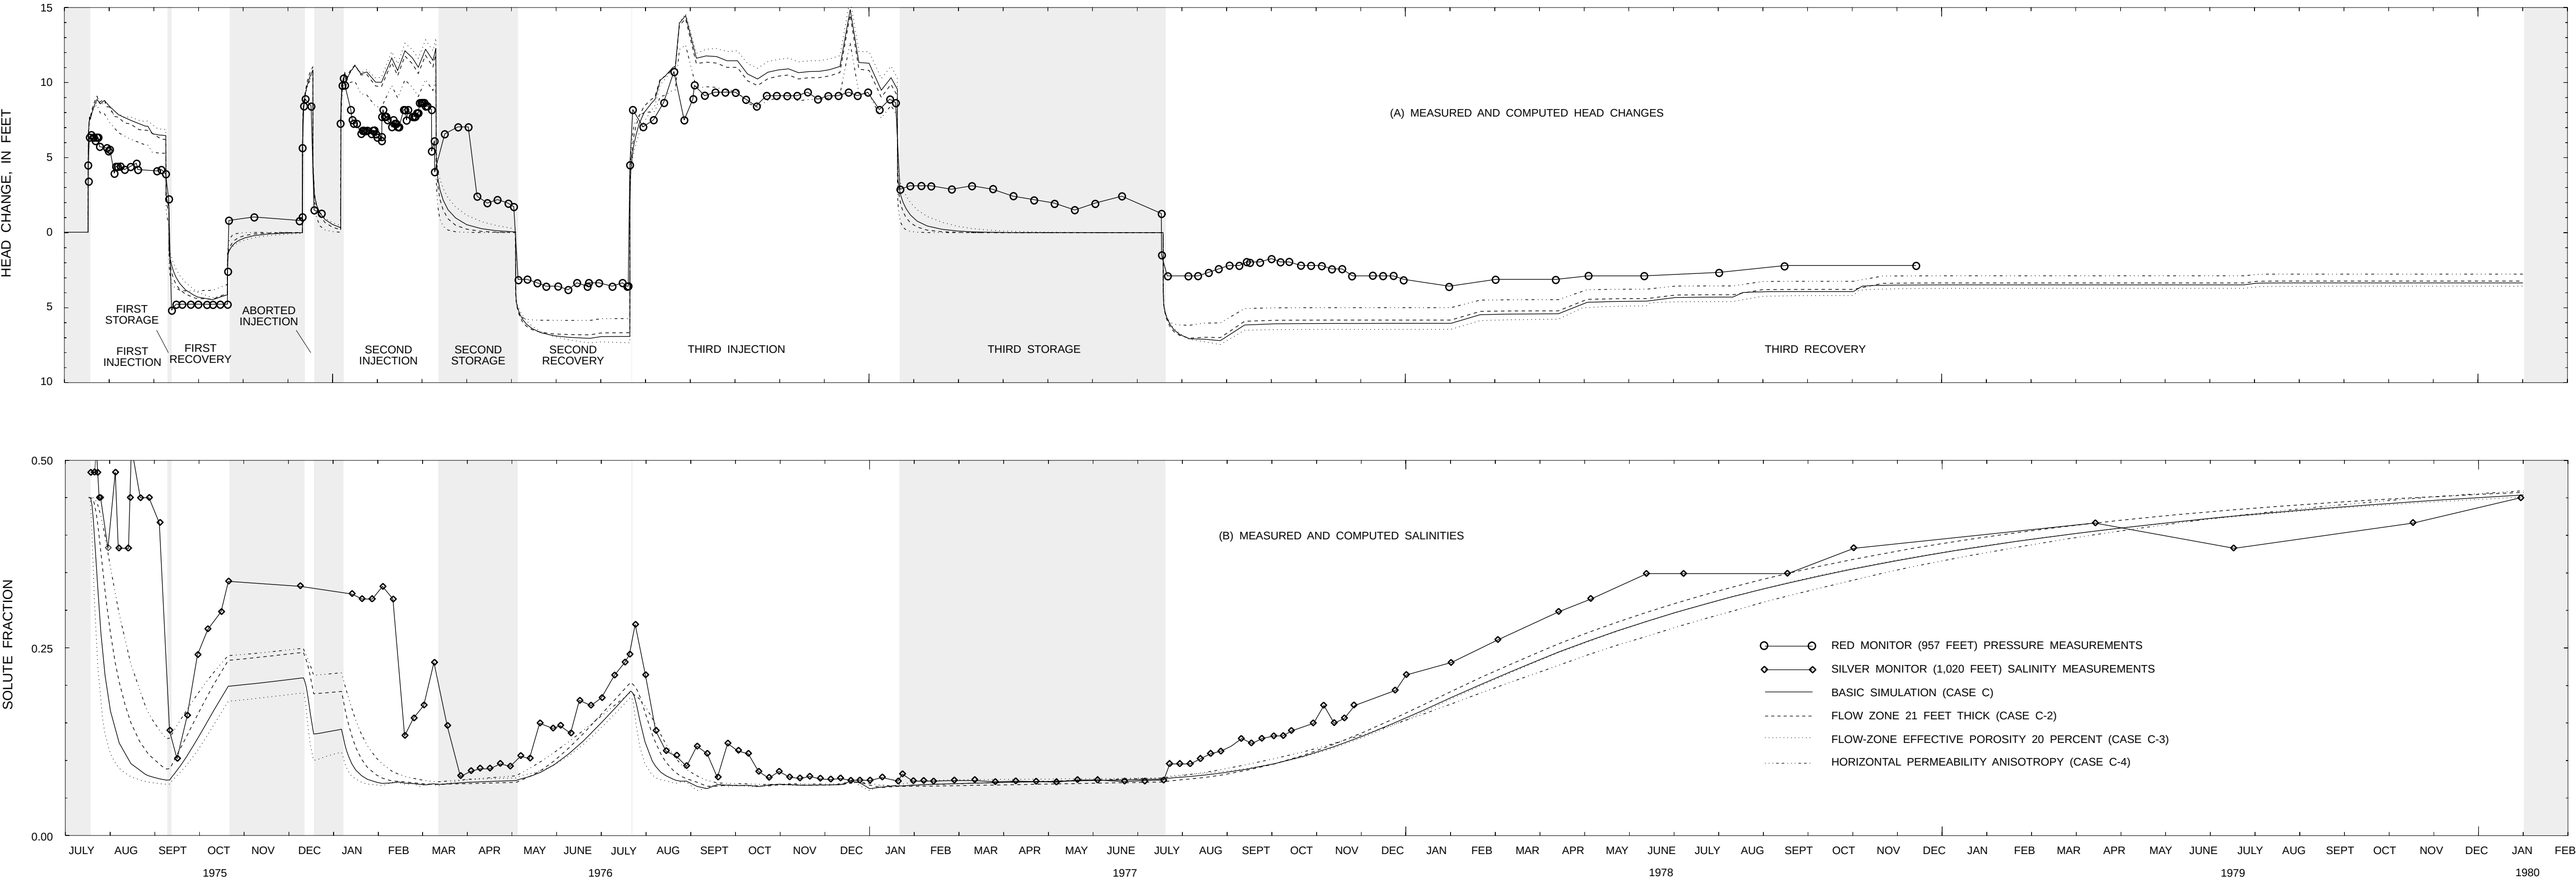
WATER SUPPLY PAPER 2437
Head changes and salinities--PLATE 2
Merritt, M.L., 1995, Tests of subsurface storage of freshwater at Hialeah, Dade County, Florida, and digital simulation of the salinity of recovered water



GRAPHS SHOWING MEASURED AND COMPUTED HYDRAULIC-HEAD CHANGES AND SALINITIES AT THE OBSERVATION-WELL LOCATION DURING AQUIFER STORAGE AND RECOVERY CYCLES

By
Michael L. Merritt
1994

SELECTED SERIES OF U.S. GEOLOGICAL SURVEY PUBLICATIONS

Periodicals

Earthquakes & Volcanoes (issued bimonthly).
Preliminary Determination of Epicenters (issued monthly).

Technical Books and Reports

Professional Papers are mainly comprehensive scientific reports of wide and lasting interest and importance to professional scientists and engineers. Included are reports on the results of resource studies and of topographic, hydrologic, and geologic investigations. They also include collections of related papers addressing different aspects of a single scientific topic.

Bulletins contain significant data and interpretations that are of lasting scientific interest but are generally more limited in scope or geographic coverage than Professional Papers. They include the results of resource studies and of geologic and topographic investigations, as well as collections of short papers related to a specific topic.

Water-Supply Papers are comprehensive reports that present significant interpretive results of hydrologic investigations of wide interest to professional geologists, hydrologists, and engineers. The series covers investigations in all phases of hydrology, including hydrogeology, availability of water, quality of water, and use of water.

Circulars present administrative information or important scientific information of wide popular interest in a format designed for distribution at no cost to the public. Information is usually of short-term interest.

Water-Resources Investigations Reports are papers of an interpretive nature made available to the public outside the formal USGS publications series. Copies are reproduced on request unlike formal USGS publications, and they are also available for public inspection at depositories indicated in USGS catalogs.

Open-File Reports include unpublished manuscript reports, maps, and other material that are made available for public consultation at depositories. They are a nonpermanent form of publication that may be cited in other publications as sources of information.

Maps

Geologic Quadrangle Maps are multicolor geologic maps on topographic bases in 7.5- or 15-minute quadrangle formats (scales mainly 1:24,000 or 1:62,500) showing bedrock, surficial, or engineering geology. Maps generally include brief texts; some maps include structure and columnar sections only.

Geophysical Investigations Maps are on topographic or planimetric bases at various scales; they show results of surveys using geophysical techniques, such as gravity, magnetic, seismic, or radioactivity, which reflect subsurface structures that are of economic or geologic significance. Many maps include correlations with the geology.

Miscellaneous Investigations Series Maps are on planimetric or topographic bases of regular and irregular areas at various scales; they present a wide variety of format and subject matter. The series also includes 7.5-minute quadrangle photogeologic maps on planimetric bases that show geology as interpreted from aerial photographs. Series also includes maps of Mars and the Moon.

Cost Investigations Maps are geologic maps on topographic or planimetric bases at various scales showing bedrock or surficial geology, stratigraphy, and structural relations in certain coal-resource areas.

Oil and Gas Investigations Charts show stratigraphic information for certain oil and gas fields and other areas having petroleum potential.

Miscellaneous Field Studies Maps are multicolor or black-and-white maps on topographic or planimetric bases for quadrangle or irregular areas at various scales. Pre-1971 maps show bedrock geology in relation to specific mining or mineral-deposit problems; post-1971 maps are primarily black-and-white maps on various subjects such as environmental studies or wilderness mineral investigations.

Hydrologic Investigations Atlases are multicolored or black-and-white maps on topographic or planimetric bases presenting a wide range of geohydrologic data of both regular and irregular areas; principal scale is 1:24,000, and regional studies are at 1:250,000 scale or smaller.

Catalogs

Permanent catalogs, as well as some others, giving comprehensive listings of U.S. Geological Survey publications are available under the conditions indicated below from the U.S. Geological Survey, Map Distribution, Box 25286, Bldg. 810, Federal Center, Denver, CO 80225. (See latest Price and Availability List.)

"Publications of the Geological Survey, 1879–1961" may be purchased by mail and over the counter in paperback book form and as a set of microfiche.

"Publications of the Geological Survey, 1962–1970" may be purchased by mail and over the counter in paperback book form and as a set of microfiche.

ABSTRACT	IN ORDER TO EVALUATE THE IMPACT OF MATRIX DIFFUSION UPON THE CLEANUP OF FRACTURED ROCK AQUIFERS, A SIMPLE MATHEMATICAL MODEL HAS BEEN DEVELOPED WHICH PREDICTS CONTAMINANT LEVELS ALONG A REPRESENTATIVE FRACTURE IN THE ROCK AS A FUNCTION OF POSITION, TIME, AND PAST HISTORY OF CONTAMINANT LEVELS IN THE GROUND WATER. THE MODEL TAKES INTO ACCOUNT THE CHARACTERISTICS OF THE FRACTURED ROCK THROUGH WHICH THE GROUNDWATER IS MOVING, SPECIFICALLY FRACTURE POROSITY, MATRIX POROSITY, FRACTURE SPACING, MATRIX DIFFUSIVITY, GROUND WATER VELOCITY IN THE FRACTURES, LONGITUDINAL DISPERSION CONSTANT, AND LENGTH OF THE GROUND WATER FLOW PATH. THE MODEL IS EMPLOYED TO EVALUATE THE EFFECT OF MATRIX DIFFUSION ON THE CLEANUP OF TYPICAL SEDIMENTARY ROCK AQUIFERS AND TYPICAL METAMORPHIC OR IGNEOUS AQUIFERS. THROUGH SENSITIVITY ANALYSES, THE MODELING REVEALS THE PARAMETERS MOST STRONGLY GOVERNING THE PROCESS. THE MODELING ALSO LOOKS AT THE EFFECT OF PUMP AND TREAT SYSTEMS AND SPECIFICALLY THE "REBOUND EFFECT" THAT CAN RESULT FROM PREMATURE CESSATION OF PUMP AND TREAT SYSTEMS. THE FOLLOWING ARE MENTIONED: AVERAGE POROSITY VALUES FOR SANDSTONE, SHALE, AND LIMESTONE; RANGES OF VARIATION IN THE MATRIX POROSITY OF SANDSTONE, SILTSTONE, QUARTZITE, CHERT, CONGLOMERATE, LIMESTONE, DOLOMITE, CHALK, MARBLE, SHALE, CLAYSTONE, SLATE, GRANITE, AND GNEISS; RANGES OF FRACTURE POROSITY FOR SANDY SHALE PETROLEUM RESERVOIRS, "FISSURED RESERVOIRS," THE CONASAUGA SHALE, "SILICEOUS RESERVOIRS," THE NOLICHUCKY SHALE, THE CULEBRA DOLOMITE, AND IGNEOUS, SEDIMENTARY, AND METAMORPHIC ROCKS; AND RANGES OF MOLECULAR DIFFUSIVITY FOR A CLAYEY SOIL, THE QUEENSTON SHALE, U.K. GRANITE

	SAMPLES, SWEDISH GRANITE AND GNEISS SAMPLES, AND SOLUTES OF LOW MOLECULAR WEIGHT IN WATER AT AMBIENT TEMPERATURE.

Abstract. Aquifer restoration has been recognized for many years to be an extremely difficult undertaking. For a variety of reasons, restoration of fractured rock aquifers appears to be especially difficult. One reason is the phenomenon of matrix diffusion. Matrix diffusion refers to the process by which contaminants diffuse into and out of the relatively immobile matrix pore water from the mobile fracture water.

In most (but not all) fractured rock, groundwater moves primarily through the interconnected network of fractures and the pore water within the matrix of the rock is relatively immobile. As contaminated groundwater moves through the fractures, the contamination is also subject to diffusion into the often stagnant matrix pore water of the rock. The diffusion of contaminants into the rock matrix is beneficial in one respect in that it retards the advance of a contaminant plume through a fractured rock aquifer. However, the diffusion-controlled release of contaminants from the rock matrix can substantially prolong aquifer cleanup efforts over what would be possible in a simple porous medium aquifer of equivalent hydraulic conductivity.

In order to evaluate the impact of matrix diffusion upon the cleanup of fractured rock aquifers, a simple mathematical model has been developed which predicts contaminant levels along a representative fracture in the rock as a function of position, time, and past history of contaminant levels in the groundwater. The model takes into account the characteristics of the fractured rock through which the groundwater is moving, specifically fracture porosity, matrix porosity, fracture spacing, matrix diffusivity, groundwater velocity in the fractures, longitudinal dispersion constant, and length of the groundwater flow path.

The model is employed to evaluate the effect of matrix diffusion on the cleanup of typical sedimentary rock aquifers and typical metamorphic or igneous aquifers. Through sensitivity analyses, the modeling reveals the parameters most strongly governing the process. The modeling also looks at the effect of pump and treat systems and specifically the "rebound effect" that can result from premature cessation of pump and treat systems.

INTRODUCTION

Much of the northeastern United States and New England, in particular, is characterized by a relatively thin, surficial mantle of glacial deposits underlain by fractured rock formations. In many areas, the fractured rock represents the only reliable source of groundwater and is heavily drawn upon for residential and municipal water supply. A number of fractured rock aquifers have been granted sole source aquifer status and have accordingly been granted special federal protection. At the same time, there has been an alarming increase in the incidence of contamination of these important aquifers as a result of improperly controlled waste disposal, leaking underground storage tanks, industrial spills, and other sources. Numerous groundwater extraction and treatment remedial

efforts have been initiated and still more are planned to control the spread of contamination and, in many cases, to clean up portions of contaminated bedrock aquifers.

Controlling the further spread of contamination plumes, while more complicated in fractured rock aquifers than in simple porous media, is not especially problematic. However, restoring aquifer water quality once the aquifer has become contaminated may be considerably more difficult. Not only are dense non-aqueous phase liquids (DNAPL) more difficult to purge from fractured rock (Mackay and Cherry, 1989), but the diffusion of contaminants from the mobile water in the fractures to the virtually stagnant water within the rock matrix can make aquifer restoration frustratingly slow at best, and, at worst, an exercise in futility. This phenomenon has become especially critical in recent years as mandated post-cleanup contaminant concentration levels have gravitated to the low parts per billion range. Since it is not unusual for initial concentration of some of the more soluble contaminants to exceed 100 or even 1,000 parts per million, expectations of 99.99 to 99.999 percent improvement in aquifer water quality are not uncommon. We here examine the parameters which govern matrix diffusion and discuss the implications of this process for aquifer restoration and groundwater protection.

As contaminated groundwater moves through the fractures of a bedrock aquifer, diffusion of contaminants will occur into the essentially stagnant matrix pore water of the rock, as illustrated in Figure 1. The extent of the diffusion and its hydrogeologic significance will depend upon the concentration gradient, the matrix diffusivity and porosity, the fracture spacing of the rock, and the duration of exposure. From one perspective, the diffusion of contaminants into the rock matrix is beneficial in that it retards the advance of a contaminant plume through the fractured rock. Lever and Bradbury (1985) reported that matrix diffusion can lead to effective retardation factors in excess of 100 and can reduce peak concentrations by three to four orders of magnitude, provided that the groundwater velocity is relatively small. However, when the objective is to purge contamination from an aquifer, the diffusion-controlled release of contaminants from the rock matrix can greatly prolong aquifer cleanup efforts over what would be possible in a simple porous medium of equivalent hydraulic conductivity.

MATHEMATICAL MODEL DEVELOPMENT

A mathematical model has been developed for the calculation of contaminant levels in groundwater as a function of the position, time, and past history of contaminant levels in the recharge water. The model includes the characteristics of the fractured porous rock in which the groundwater is moving--specifically, the fracture porosity, matrix porosity, fracture spacing, matrix diffusivity, groundwater velocity in the fractures, longitudinal dispersion constant, and flow path length. The model deals only with water movement in the zone of saturation, and assumes that advection of pore water within the porous medium itself can be neglected. In this initial study sorption was not considered.

The numerical model is for a single fracture in the zone of saturation, through which groundwater flows at a rate determined by the hydraulic conductivity and hydraulic gradient. A sketch of the system is given in Figure 2. Contaminants in the mobile fracture water are able to move into and out of the immobile pore water by molecular diffusion, and are carried in the direction of flow by advection and longitudinal dispersion. Contaminant concentrations in the recharge water can be varied to represent historical conditions and/or to simulate remedial efforts. The mathematical model's development is described in an earlier paper (Mutch, Scott, and Wilson, 1993).

PARAMETERS GOVERNING CONTAMINANT MIGRATION IN FRACTURED ROCK

The migration and ultimate fate of contaminants in fractured rock is governed by properties of both the geologic medium and the contaminant. The properties which have been incorporated into the model include advective flow rate and longitudinal dispersion in the fractures, matrix diffusivity, fracture porosity, matrix porosity, and fracture spacing. The model does not account for sorption or biological, chemical, or radioactive decay of contaminants, nor does it consider the fate of undissolved DNAPL chemicals. It also assumes steady-state water flow and no advection in the porous medium itself. The typical ranges of the hydrogeological parameters and the basic assumptions used in the modeling are discussed below.

Matrix Porosity

Virtually all consolidated rock possesses some matrix porosity, although in igneous and metamorphic rock the matrix porosity can be quite low. Sedimentary rocks tend to have fairly high porosity. Barrell (1914) reports that the average porosities of sandstone, shale, and limestone are 14.8, 8.2, and 5.3 percent, respectively. The variability of matrix porosity within different classes of rock can be quite high, however, depending upon degree of compaction, cementation, and sorting. A U.S. Geological Survey report by Manger (1963) on thousands of rock samples reveals that the matrix porosity of sandstone, siltstone, quartzite, chert, and conglomerate can vary from less than one percent to greater than 25 percent. The matrix porosity of limestone, dolomite, chalk, and marble is also reported by Manger to vary from 0.2 percent to nearly 20 percent. Shale, claystone, and slate are reported to range in porosity from 0.5 percent to 15 percent. Neretnieks (1985) studied the matrix porosity of 30 samples of granite and gneiss from Sweden and found that the porosity varied from 0.06 to 0.4 percent. In the subsequent modeling a matrix porosity of 7.5 percent was used for sedimentary rock and one of 0.1 percent for igneous and metamorphic rock.

Fracture Porosity

A review of the literature indicates that the typical range of the fracture porosity in sedimentary rocks is on the order of 1×10^{-3} to 5×10^{-3} (Streltsova, 1976a, 1976b; Walter and Thompson, 1982; Yurochko, 1982; Smith and Vaughan, 1985; Kelley et al., 1987). Streltsova (1976a) reported fracture porosities of 1×10^{-3} to 2×10^{-3} for sandy shale petroleum reservoirs and a range of 1×10^{-3} to 5×10^{-3} for "fissured reservoirs" in general (Streltsova, 1976b). Walter and Thompson (1982) noted a fracture porosity of 2×10^{-3} for the Conasauga Shale of Tennessee based upon field tracer studies. Yurochko (1982) reported a range in fracture porosity from 1×10^{-3} to 5×10^{-3} for "siliceous reservoirs". Based upon aquifer test analysis, Smith and Vaughan (1985) concluded that the fracture porosity of the Nolichucky Shale in Tennessee was on the order of 1×10^{-3}. Kelley et al. (1987) reported a fracture porosity of 2×10^{-3} for the Culebra Dolomite of New Mexico. Igneous and metamorphic rocks often have fracture porosities of approximately 1×10^{-4}, according to Freeze and Cherry (1979), who suggest a range of 10^{-2} to 10^{-5} for fracture porosities. In the subsequent calculations a fracture porosity of 2.5×10^{-3} is used for sedimentary rock and 1×10^{-4} for igneous and metamorphic rock.

Longitudinal Dispersion

Longitudinal dispersion refers to the process by which contaminants are spread in a direction parallel to groundwater flow by variations in flow velocity brought about by variations in fracture aperture and intrafracture velocity profiles. The longitudinal dispersion constant, D_L, is defined as the product of the longitudinal dispersivity, or characteristic length, α_L, and the mean groundwater velocity, V, as follows:

$$D_L = \alpha_L \cdot V$$

where D_L = longitudinal dispersion constant, m^2/sec; α_L = longitudinal dispersivity, m; and V = mean groundwater velocity, m/sec.

Dispersion has been shown to have a high degree of scale dependence; that is, the larger the scale of the transport situation studied, the larger the measured longitudinal dispersivity. Longitudinal dispersivity varies from as little as a few millimeters in laboratory column studies to more than 100 meters in large scale plumes (Anderson, 1979). In the subsequent modeling a longitudinal dispersivity of five meters is assumed.

Matrix Diffusivity

The molecular diffusivity of solutes of low molecular weight (M<500 gm/mole) in water at ambient temperatures is typically in the range of 1 to 5 x 10^{-9} m^2/sec (Rasmuson and Neretnieks, 1981). Barone et al. (1988) measured the matrix diffusivity, D_m, of a clayey soil as lying between 4.6 and 7.5 x 10^{-10} m^2/sec. Barone and his coworkers (1989) also found that the Queenston Shale of southern Ontario had a matrix diffusivity of 1.4 to 1.6 x 10^{-10} m^2/sec. In another study of the Queenston Shale of southern Ontario, Pankow et al. (1986) reported an average matrix diffusivity of 3.7 x 10^{-12} m^2/sec. These data indicate that sedimentary rocks tend to have matrix diffusivities lower than those for unconsolidated sediments. Igneous and metamorphic rocks have been shown to have even lower matrix diffusivities. Bradbury and Green (1985) measured the matrix diffusivity of granite samples from four regions of the United Kingdom and found that their matrix diffusivities varied from 2.3 x 10^{-14} to 1.6 x 10^{-12} m^2/sec. Neretnieks (1985) reported that the matrix diffusivity of 20 samples of Swedish granite and gneiss varied from 1 x 10^{-14} to 7 x 10^{-13} m^2/sec. In the subsequent modeling a matrix diffusivity of 3.1 x 10^{-11} m^2/sec is assumed for sedimentary rocks and 1 x 10^{-13} m^2/sec for igneous and metamorphic rocks.

Fracture Spacing

The mean spacing of fractures in rock can vary from a few centimeters in highly fractured rock to ten meters or more in granite and some other crystalline rocks. In the subsequent modeling a fracture spacing of one meter has been used.

MATHEMATICAL MODELING

Mathematical modeling was conducted to assess the role of matrix diffusion in retarding or attenuating the transport of groundwater contamination in fractured rock. Rock properties generally representative of a sedimentary rock such as shale were utilized in the

modeling with the exception of values of matrix diffusivity which were varied. The following properties were used in the modeling:

Mean Fracture Spacing	1 m
Fracture Porosity	0.0025
Matrix Porosity	0.75
Longitudinal Dispersivity	5 m
Hydraulic Conductivity	1×10^{-5} cm/sec

It was also assumed that the hydraulic gradient in the rock was 0.01. Combined with the above-listed hydraulic conductivity, this hydraulic gradient results in an average groundwater velocity of 0.035 m/d. Matrix diffusivity was varied from as low as 3.1×10^{-12} m^2/sec to 9.7×10^{-11} m^2/sec. These values are generally representative of those reported in the literature for sedimentary rock such as shale and fine-grained sandstone. For comparative purposes, the modeling was also conducted with matrix diffusivity set at zero. Figure 3 represents the results of the modeling, illustrating the advance of the plume of contamination through the rock after a time period of five years. Figure 3 illustrates the considerable importance of matrix diffusivity in dictating the rate of advance of a plume through fractured rock. With no matrix diffusion the plume has advanced an average (C_i/C_o = 0.5) of approximately 70 meters. By contrast, at a matrix diffusivity of 9.7×10^{-11} m^2/sec the plume has advanced an average of but seven meters. In each case, the matrix diffusivities used in this exercise resulted in some effective retardation. However, the effective retardation becomes less significant in the lower range of matrix diffusivities found to be characteristic of sedimentary rock.

It can be seen that the effect of matrix diffusion is to retard the advance of a plume of contamination through fractured rock. The extent of this retardation can be calculated by determining an effective retardation factor. The effective retardation factor can be thought of as the velocity of the contamination, represented by a particular value of C_i/C_o, with no matrix diffusion divided by the velocity of the contamination with varying levels of matrix diffusion. Table 1 presents effective retardation factors at C_i/C_o values of 0.8, 0.5, and 0.2.

TABLE 1
EFFECTIVE RETARDATION FACTORS

	Matrix Diffusivity - m^2/s			
C_i/C_o	3.1×10^{-12}	9.7×10^{-11}	3.1×10^{-11}	9.7×10^{-11}
0.8	2.2	6.2	13	20
0.5	1.3	2.5	5.2	9.7
0.2	1.1	1.6	2.9	4.7

It can be seen that the effective retardation factors vary considerably, ranging from as low as 1.1 to as high as 20. The effective retardation factor decreases with decreasing concentration ratios (C_i/C_o). This suggests that matrix diffusion is not as effective in retarding the advance of the leading edge of a plume as it is in retarding the higher concentration portions of the plume. As expected, effective retardation factors also decrease

with decreasing values of matrix diffusivity. It should be noted that the effective retardation factors are not a constant for a given fractured rock but rather vary significantly with the properties of the rock, the hydrogeologic system, and over time.

Further mathematical modeling was conducted to compare the effectiveness of a typical igneous and metamorphic rock versus a typical shale in retarding the advance of the contaminant plume. The hydrogeologic properties and physical properties of the rock were the same as in the previous modeling with the following exceptions. In modeling the behavior of a typical igneous and metamorphic rock, a matrix porosity of 0.001 was used and a matrix diffusivity of $1x10^{-13}$ m^2/sec. The typical shale was modeled using a matrix porosity of 0.075 and a matrix diffusivity of 3.1×10^{-11} m^2/sec. As depicted in Figure 4, there is a profound difference in the way the two rock types effectively retard the advance of a plume. The fractured rock with the properties of a typical shale significantly retards the plume. However, the typical igneous rock and metamorphic rock affords essentially no effective retardation as a result of matrix diffusion. The matrix diffusivity and porosity of this class of rock are simply too low to significantly retard the plume in the relatively high velocity, although not atypical, situation modeled herein.

In order to assess the impacts of matrix diffusion upon the cleanup of contaminated bedrock aquifers, the following two examples were modeled.

EXAMPLE 1

A fractured shale has been subject to groundwater contamination by a non-adsorbing, non-degradable contaminant at a concentration of 10000 units (the actual units are arbitrary, perhaps parts per billion) for a period of 20 years. During that time the contaminated water has moved in a fracture laterally a distance of 100 meters to a nearby sewer which has intercepted the plume and serves as a groundwater discharge point. The average groundwater velocity is 0.35 m/day (4.05×10^{-6} m/sec) and the shale has the following properties:

mean fracture spacing	1 m
fracture porosity	0.0025
matrix porosity	0.075
matrix diffusivity	3.1×10^{-11} m^2/sec
longitudinal dispersivity	5 m

If the source of the contaminant were removed, how long would it take the contaminants to be naturally flushed from this section of aquifer? One can apply the mathematical model to this situation to estimate the progressive flushing of contaminants from the representative fracture. The results of this modeling are presented in Figure 5. The plotted concentrations represent the highest concentration within the fracture, which, in this simple example, occurs during the cleanup at the downgradient side of the fracture, at the sewer. It is seen in Figure 5 that approximately 120 years is required to reduce the maximum fracture water concentration to 100 units, which represents a 99 percent improvement in water quality. It requires fully 650 years before the maximum fracture water concentration is reduced to one unit, representing a 99.99 percent improvement in water quality. The reason for this exceedingly lengthy cleanup time becomes clear as one examines what is occurring in the rock matrix as a result of diffusion from the flowing water into the fractures during the contamination process. Figure 6 presents a graphical history of contaminant levels in the rock fracture and in the rock matrix during the course

of the cleanup. Initially (i.e. at the end of the 20-year period of contamination) a substantial mass of contaminant has moved into the rock's matrix porosity as a result of diffusion. Actually, some 90 percent of the contaminant mass is held within the relatively immobile pore water, compared to only 10 percent in the flowing fracture water. The contaminant concentration at the midpoint of the block of porous matrix at this time is about 100 units. It is also evident that even as clean water begins to recharge the rock after the initial 20-year contamination period, diffusion continues to carry contamination farther into the rock matrix. This occurs even as contaminants closer to the fracture begin to diffuse back outward to the fracture. Contaminant continues to diffuse farther into the rock matrix for a period of approximately 50 years after the contaminant source has been cut off, ultimately reaching at that time a maximum concentration of approximately 1100 units at the block midpoint.

As seen in this case, diffusive movement of contaminant in rock often goes through three phases: an initial, or contamination phase, an intermediate phase, and a final phase. The latter two occur during aquifer restoration. In the contamination phase, contaminants are diffusing from the high concentrations in the mobile fracture water into the uncontaminated pore water in the rock matrix.

The intermediate phase begins once the contaminant source is removed and clean groundwater begins to enter the contaminated zone. The intermediate phase is characterized by simultaneous inward and outward diffusion. Contamination in the interior of the block continues to migrate inward toward the block's midpoint, while contaminant closer to the fractures begins to diffuse outward in response to the lower concentrations now occurring in the fracture water. In Figure 5 this phase is represented by the "initial" to 50 year (after source removal) curves.

The final phase occurs once the concentration at the midpoint of the block reaches a maximum (approximately 50 years in Figure 5) and the diffusive flux becomes universally outward to the fracture flow system. The final phase is characterized by concentrations in the fracture which decrease exponentially (linearly on a logarithmic scale) with time, as in Figure 5 after approximately 80 years. This means that in the final phase, each order of magnitude reduction in contaminant concentration requires the same length of time (approximately 260 years in this example).

If the matrix diffusivity is relatively high, the fracture spacing small, or the period of contamination long, contaminant can fully permeate the block, achieving a steady-state concentration equal to that in the mobile fracture water. In such cases, the intermediate phase does not occur; the contamination phase is directly followed by the final phase.

In order to assess the relative importance of the various parameters employed in the numerical modeling, a sensitivity analysis was performed using the parameters of Example 1 described above. This evaluated the effects of variations in matrix porosity, matrix diffusivity, fracture spacing, fracture porosity, longitudinal dispersivity, and the length of the antecedent period of contamination. The sensitivity analysis revealed that aquifer cleanup time is most sensitive to changes in matrix porosity, matrix diffusivity and fracture spacing. The sensitivity analysis is described in an earlier paper (Mutch, Scott, and Wilson, 1993).

EXAMPLE 2

Igneous and metamorphic rock aquifers often have low matrix diffusivities, low porosities, and wide fracture spacings. This combination of properties leads to hydrogeologic behavior which warrants special attention. Our second example therefore

addresses the cleanup of a representative rock aquifer of this type. A rock formation with the following properties was modeled:

fracture porosity	0.0005
matrix porosity	0.001
matrix diffusivity	1.0×10^{-13} m^2/sec

All other parameters are the same as in the previous example, with the exception of fracture spacing. Because the matrix diffusivity of igneous and metamorphic rock is so low (on the order of 1×10^{-13} m^2/sec), if fracture spacings are greater than approximately 0.4 m each fracture behaves essentially independently of the others over the time frames involved in this analysis. Therefore, in the simulation of igneous and metamorphic rock aquifers, the model was modified to divide the rock matrix of each volume element into 15 cells, each having a thickness of 0.01 m. The reasonableness of this approximation was tested by running the model for a simulated 1,000 year period and observing the buildup of contaminant in the innermost cell, representing the midpoint of the matrix block. In all cases the concentration developed in the innermost cell was negligibly small and insufficient to adversely affect the accuracy of the simulation.

The results of the igneous and metamorphic rock simulation are presented in Figure 7. As a result of the low matrix diffusivity and low porosity, improvement in water quality begins rapidly in igneous and metamorphic rock aquifers. In fact, a 99.99 percent improvement in water quality occurs in the first 35 years; this might be sufficient for many situations. However, higher degrees of aquifer quality restoration are more difficult to achieve because of the pronounced "tailing" effect evident in Figure 7. The very low matrix diffusivity of igneous and metamorphic rocks dictates that a correspondingly small diffusive flux out of the rock will occur for many centuries. Whether the resulting "tailing" effect is a problem will depend upon the nature of the contaminant and the cleanup objectives.

EFFECTIVENESS OF GROUNDWATER EXTRACTION SYSTEMS

A groundwater extraction and treatment system increases the rate of aquifer restoration by drawing groundwater through the contaminated zone more rapidly than would occur naturally, thus flushing contaminants more rapidly from the aquifer. We evaluated the effectiveness of groundwater extraction and treatment systems in restoration of water quality in the fracture system discussed above by means of our mathematical model. We used the parameters of our Example 1 (sedimentary rock) in simulating the effect of a groundwater extraction and treatment system; we increased the rate of groundwater flow through the 100 meter-long contaminated zone by a factor of five. This increase in flow is considered generally representative of what is achievable by a typical groundwater recovery system. The first simulation involved a 22-year period of groundwater extraction and treatment which, as indicated in Figure 8, improved groundwater quality during the active pumping period by 99 percent. However, upon cessation of pumping, contaminant concentration relatively quickly rebounded to levels nearly as high as would have occurred if no groundwater extraction had been undertaken. On comparing the cleanup curve for the 22-year period of remediation with the natural restoration curve, it becomes evident that the rebound effect negates most of the improvement in contaminant concentration attained during the active pumping period. In fact, after conclusion of the pumping, contaminant concentration is only 10 to 15 percent lower than would have been realized if no remedial action were taken.

A second simulation was performed to simulate a 100-year period of groundwater extraction; this is also shown in Figure 8. It is evident that in order to sustain a 99 percent improvement in water quality, given the rebound in contamination levels which occurs upon cessation of pumping, it would be necessary to pump the fracture for close to 100 years. The same degree of water quality improvement at this point in the fracture would be achievable by natural flushing in approximately 120 years.

The above analysis indicates that groundwater extraction and treatment programs in fractured rock aquifers are likely to meet with only limited success in restoring the quality of water in fractured bedrock aquifers in a reasonable period of time. In particular, overpumping to increase flow rates appreciably beyond those required to prevent further migration of the contaminant plume is not likely to result in significant benefits when one takes the rebound effect described above into account. In fractured rock aquifers, the rate of cleanup may well be controlled by the rate of contaminant diffusion from the rock matrix into the fractures--a process which cannot be very much enhanced by increasing groundwater velocities in the fractures, since increasing fracture flow velocity generally only marginally increases the concentration gradient between the rock matrix and the fracture flow system and has no effect on the low diffusivity of the contaminant in the porous medium. Thus, the rate of diffusion and the rate of cleanup are increased only marginally by pump and treat operations under these conditions.

CONCLUSIONS

1. Matrix diffusion can significantly retard the advance of a plume of contamination through a fractured rock, although the retardation is much less in low porosity igneous and metamorphic rock.

2. Cleanup of fractured rock aquifers, particularly more porous sedimentary rocks, can be exceedingly slow if the release of contaminants from the porous rock matrix is diffusion-controlled. This is especially true where an improvement in water quality of greater than 99 percent is necessary.

3. Igneous and metamorphic rocks, because of their typically low matrix porosity and matrix diffusivity, are capable of a more rapid initial restoration in water quality as compared to most sedimentary rocks. As much as a 99.99 percent improvement in water quality is achievable in relatively short periods of time. However, further improvements in water quality (above this level) may be quite time consuming, as the lower matrix diffusivity results in smaller but more persistent diffusion of contaminant out of the rock matrix into the mobile fracture water.

4. The analysis indicates that conventional groundwater extraction and treatment programs, while effective in preventing the further spread of a contaminant plume in an aquifer, are not likely to result in significantly more rapid rates of cleanup even if the wells are pumped at rates much faster than the minimum necessary to prevent further spread of the contaminant. Such overpumping improves aquifer water quality as long as it continues, but contaminant concentrations rebound relatively rapidly to nearly the no action levels upon cessation of pumping.

The persistence of contamination in fractures rock aquifers and the relative ineffectiveness of conventional extraction and treatment remedial programs which our

results indicate lead us to urge that greater emphasis should be placed upon the prevention of contamination in fractured rock aquifers.

1.0 INTRODUCTION

1.1 BACKGROUND

The Southwest Florida Water Management District (SWFWMD) is responsible for managing sensitive water resources within 16 counties in west-central Florida (Figure 1.1). Within this area, the SWFWMD is responsible for water supply, water quality, and the protection of natural systems related to water resources. The Floridan aquifer system is the primary source of potable groundwater within the southern portion of the SWFWMD. In this area, approximately 85% of groundwater supplies are derived from the Floridan aquifer system. Saltwater intrusion into the Floridan Aquifer along the coast of southern Hillsborough, Manatee, and Sarasota Counties is a principal constraint on the development of additional groundwater resources in the southern portion of the SWFWMD. Monitoring data collected by the SWFWMD indicates that saline water is slowly advancing further inland due to lowered water levels within the southern portion of the SWFWMD.

In response to this problem, the SWFWMD Governing Board designated the southern portion of the SWFWMD as the Southern Water Use Caution Area (SWUCA) (Figure 1.1). This area included all of the Eastern Tampa Bay and Lake Wales Ridge Water Use Caution Areas (WUCAs) and the areas within the SWFWMD that are south of Interstate 4. In total the SWUCA encompasses 5,100 square mile area including all of Manatee, Sarasota, Hardee, and DeSoto Counties and portions of Hillsborough, Charlotte, Polk, and Highlands Counties. In 1994, SWFWMD staff developed a resource management plan and a set of rules for water resources permitting aimed at limiting saltwater intrusion with the SWUCA. A principal objective of these rules was to protect freshwater resources within the Floridan aquifer system. For the past several years, the SWFWMD has revisited its options for managing groundwater within the SWUCA in an effort to develop additional sources of water for the growing population of the region while continuing to protect existing supplies. Physically based, numerical groundwater flow models of the region have provided an important component to the decision making process.

1.2 PROJECT OBJECTIVES

In October 2001, HydroGeoLogic, Inc. was retained by the SWFWMD to develop a density-dependent groundwater flow and solute transport numerical model to simulate the position and movement of saline water in the Upper Floridan aquifer along the coastal area of the SWUCA (Figure 1.2). The primary objective of this effort was to predict the long-term impact of proposed water use options on saltwater intrusion within the Upper Floridan aquifer. The saltwater intrusion model may be further used to establish minimum water levels or maximum pumping levels for groundwater extraction wells within the Upper Floridan aquifer or for developing a refined understanding of the stress response of chlorides to various regional management scenarios. The density-dependent model was constructed and calibrated to simulate conditions in the Upper Floridan aquifer that existed from the pre-development period (approximately 1900) to present conditions (through 2000). The model was then used to predict the long-term impacts associated with different usage rates for water within the area.

1.3 METHODOLOGY

The modeling investigation was completed in four phases including:

- Phase 1: Background literature review, conceptual model development, and model setup;
- Phase 2: Model calibration;
- Phase 3: Predictive scenarios; and
- Phase 4: Governing board meetings/presentations.

During Phase 1, historical reports and previous modeling investigations were reviewed to understand the hydrogeologic conceptual model, identify model calibration targets, and construct the framework for the saltwater intrusion model. Particular emphasis was placed on reviewing the Southern District Groundwater Flow model developed by the SWFWMD (2001) and an uncalibrated, saltwater intrusion model that was initiated by Waterstone Environmental Hydrology and Engineering, Inc. (Waterstone). These models will henceforth be referred to as the Southern District Model (SWFWMD, 2001) and the Waterstone Model (Waterstone 2001), respectively. Both of these models were provided to HydroGeoLogic in electronic form *via* Groundwater Vistas (Environmental Simulations, Inc.) project files. At the end of Phase 1, the framework for the saltwater intrusion model was established, and preliminary simulations were performed to ensure that all data was correctly entered into the density-dependent model, before proceeding to the Phase II calibration activities.

During Phase 2, the saltwater intrusion model was calibrated to simulate hydraulic heads and chloride concentrations in the Upper Floridan aquifer. The model was calibrated to steady-state pre-development (approximately 1900) conditions and transient conditions from approximately 1900 to 2000. A sensitivity analysis was also conducted, to identify the parameters that have the greatest impact on calibration and conclusions of the model.

Predictive simulations were completed as part of Phase 3 activities. The model was used to predict hydraulic heads and saltwater intrusion (i.e., saline water concentrations) for 20- to 50-year time periods. Four different water use scenarios proposed by the SWFWMD were evaluated. These comprise of withdrawing 400, 600, 800 and 1,000 million gallons per day (MGD) from the Southern District Model (SWFWMD, 2001) area. A predictive sensitivity analysis was also conducted to evaluate the uncertainty associated with the modeling results.

1.4 REPORT ORGANIZATION

This report documents the development of the conceptual and numerical model for saltwater intrusion in the SWUCA. Section 2 documents the hydrogeologic conceptual model, and Section 3 summarizes the previous modeling analyses that provide information and insights that will be utilized during the current modeling effort. Section 4 describes construction of the preliminary model, and Section 5 describes the model calibration effort and results. Section 6 details the sensitivity analysis that was conducted and Section 7 discusses the predictive analysis and predictive sensitivity studies. Finally, Section 8 provides a brief summary of the modeling activities and presents the major conclusions.

2.0 HYDROGEOLOGIC CONCEPTUAL MODEL

2.1 PHYSIOGRAPHY AND TOPOGRAPHY

The physiography of the Eastern Tampa Bay Water Use Caution Area (ETBWUCA) includes three provinces described by White (1970): Gulf Coastal Lowlands, the DeSoto Plain and the Polk Upland. These provinces reflect a series of marine sand terraces formed by the advance and retreat of shallow seas during ice age events. Elevations of these terraces correspond to changes in sea level. Additional physiographic features that lie within the SWUCA include a series of north-northwesterly trending sand ridges found along the eastern boundary of the SWFWMD. The elevation in the study area ranges from sea level along the coast to approximately 150 ft National Geodetic Vertical Datum (NGVD) along the ridges (SWFWMD 1993).

2.2 RAINFALL, EVAPOTRANSPIRATION AND RECHARGE

The climate in the southern SWFWMD is humid, subtropical and is characterized by warm, wet summers and mild, dry winters (SWFWMD, 1993). Based on records since 1911, the mean annual rainfall is about 54 inches per year at Bradenton in Manatee County. During the summer months of June through September, monthly rainfall averaging between 7 and 9 inches accounts for approximately 60 percent of the annual total. The mean evapotranspiration rate estimated for the ETBWUCA is 39 inches per year (Dohrenwend, 1977). According to SWFWMD (1993), nearly 60 percent of the annual evapotranspiration occurs between May and September with the greatest rates usually observed in May and June.

Recharge to the surficial aquifer occurs by infiltration of rainfall and irrigation water. Figure 2.1 depicts areas of recharge and discharge to the Upper Floridan aquifer for pre-development hydrologic conditions (Aucott, 1988).

2.3 HYDROGEOLOGY

Various geologic formations characterized by unconsolidated and consolidated sediments comprise the three principal aquifer systems that underlie the study area as shown in Table 2.1. These include: the surficial aquifer system; intermediate aquifer system; and the Floridan aquifer system. Undifferentiated near-surface deposits of sands, clayey sands and silts with some peat and shell comprise the surficial aquifer system. The intermediate aquifer system corresponds to the Hawthorn Group and generally consists of phosphatic clay and limestone. These near-surface materials in turn overlie the massive marine carbonates, limestones and dolomites of the Floridan aquifer system. Each of the three principal aquifer systems consists of higher permeability aquifer layers that are separated by lower permeability semi-confining layers, which restrict the vertical movement of groundwater between the aquifers.

Four major units comprise the Floridan aquifer system: the Upper Floridan aquifer, the middle confining unit, the Lower Floridan aquifer and the lower confining unit (Figure 2.2). Due to its large thickness and low permeability, the middle confining unit is generally considered as a barrier to flow. The Lower Floridan aquifer in the region is salty, and not a source of potable water.

Consequently, for the purposes of this study, the following discussion of the hydrogeology of the study area will focus on the surficial aquifer system, the intermediate aquifer system, the Upper Floridan aquifer and the middle confining units of the Floridan aquifer system.

2.3.1 Surficial Aquifer

The unconfined surficial aquifer system consists primarily of fine-to-medium grained quartz sands of the Holocene and Pleistocene epochs that range in thickness from 77 feet in south-central Hillsborough County to 19 feet in northern Sarasota County (Basso, 2001). The surficial aquifer generally produces only small quantities of water suitable for domestic purposes. The water table varies seasonally and has depths ranging from near land surface to depths of perhaps tens of feet beneath some sand ridges. Groundwater flow in the surficial aquifer system typically follows local topography and occurs in an east to west direction on a regional scale. Seasonal fluctuation of the water levels is generally less than 5 ft (SWFWMD, 1993). The base of the surficial aquifer system consists of Pliocene age clays and clayey sands that form the top of the intermediate aquifer system.

Basso (2001) cites various studies for the hydraulic properties of the surficial aquifer system. Two aquifer tests conducted in southeast Hillsborough County yielded hydraulic conductivity estimates of 6 and 18 ft/day. A hydraulic conductivity value of 9 ft/day was determined from a pumping test in Hardee County. An aquifer test in northeast Sarasota County resulted in an estimated hydraulic conductivity of 13 ft/day. The specific yield values from these tests ranged from 0.05 to 0.12.

2.3.2 Intermediate Aquifer System

The Peace River and Arcadia Formations of the Miocene age Hawthorn Group comprise the intermediate aquifer system. In general, the interbedded phosphatic clays, sands, gravels, dolomite and thin limestone beds of this system function as a confining unit that separates the surficial aquifer from the Upper Floridan aquifer; however, permeable units are found to exist within the clay matrix. In the ETBWUCA (Figure 1.1), the thickness of the intermediate aquifer system increases to the southwest (the direction of dip) from 230 to over 500 ft (Basso, 2001). While there is no clear pattern of decreasing vertical hydraulic conductivity southward, the increasing thickness acts to restrict vertical flow to the southwest (Waterstone, 2001a).

Three separate flow zones, identified as PZ1, PZ2 and PZ3 (in descending order), and three confining units, designated as UICU, MICU and LICU, occur within the intermediate aquifer system in Sarasota County (Barr, 1996). The lateral continuity of these zones is typically limited. The PZ1 zone is generally absent from the ETBWUCA. The PZ2 zone is more extensive than PZ1, but it is not very productive. The most productive aquifer unit is PZ3 which is mostly represented by the Tampa Member of the Hawthorn Group. In some areas, clays found at the base of the Tampa Member act as a confining unit between the intermediate aquifer system and the Upper Floridan aquifer; in others, the carbonate units of the Tampa Member appear to be in direct hydraulic communication with the Upper Floridan aquifer.

Basso (2001) presents a summary of hydraulic properties for the intermediate aquifer system. Based on the results of 10 falling-head tests conducted on core samples, the mean vertical hydraulic conductivity of the confining units in the system is $5x10^{-4}$ ft/day. The properties of the aquifer units in the system are available from pumping tests. For the PZ2 zone, the estimates of horizontal hydraulic conductivity from three tests showed large variability. Two of the tests yielded values of 0.01 ft/day while the other produced a value of 36 ft/day. Hydraulic conductivities determined from four tests conducted in the more productive PZ3 zone averaged 9 ft/day and varied from 0.3 to 19 ft/day. The groundwater flow direction is generally west to southwest. Seasonal fluctuations of the potentiometric surface may reach 30 ft (SWFWMD, 1993).

Figures 2.3, 2.4 and 2.5 show the leakance distributions of the various confining units of the intermediate aquifer system, as estimated during the calibration of the Southern District Model (SWFWMD, 2001). These leakance values are pertinent to development of the density-dependent, saltwater intrusion model (Section 4).

2.3.3 Upper Floridan Aquifer

Massive carbonates of the Suwannee Limestone, Ocala Limestone and part of the Avon Park Formation comprise the Upper Floridan aquifer in the study area. Each of these stratigraphic units corresponds to distinct hydrogeologic units. The Suwannee Limestone, a cream to tan, sandy, vuggy and fossiliferous limestone, functions as an aquifer unit designated as the upper permeable zone (UPZ). The Ocala Limestone is a white to tan, fine-grained calcavenitic limestone that behaves as a confining unit known as the semi-confining unit (SCU). The upper portion of the Avon Park Formation or lower permeable zone (LPZ) is a brown, sucrosic and fractured dolomite. The direction of groundwater flow in the Upper Floridan aquifer varies seasonally.

According to Basso (2001), the permeability of the UPZ is primarily intergranular. Secondary porosity such as fractures or solution conduits appear to be mostly absent from this unit. The top of the UPZ, which corresponds to the top of the Suwannee Limestone, ranges from about -250 to -450 ft NGVD in the Eastern Tampa Bay WUCA and exhibits a south to southwest dip direction. Figure 2.6 depicts the top of the Suwannee Limestone as assigned in the Waterstone Model (Waterstone, 2001b). The total thickness of this unit varies from 200 to 300 ft. Horizontal hydraulic conductivities estimated for this moderately permeable aquifer are generally uniform. Based on the results of 11 pumping tests, the mean horizontal hydraulic conductivity is 61 ft/day and ranges from 6 to 143 ft/day. Figure 2.7 provides the transmissivity distribution of the Suwannee Limestone over the study area, as assigned in the Southern District Model (SWFWMD, 2001). Transmissivities range from as high as 100,000 ft^2/d under Pinellas County to 16,250 ft^2/d in Sarasota County. Storativity values for this unit vary between $1.0x10^{-5}$ and $6.5x10^{-4}$.

The SCU of the Upper Floridan aquifer is characterized by a fine-grained calcarenitic limestone that typically corresponds to the Ocala Limestone (Basso, 2001). The base of this hydrogeologic unit is defined as the contact with highly permeable fractured dolomites that comprise the LPZ. Because the lower part of the Ocala Limestone may contain a sucrosic dolomitic limestone, the transition from the SCU to the LPZ may occur within the Ocala Limestone or the Avon Park

Formation. The top elevation of the SCU ranges from -500 to -800 ft NGVD in the Eastern Tampa Bay WUCA and dips to the southwest. Figure 2.8 depicts the top of the Semi-Confining Unit as provided by the Waterstone Model (Waterstone, 2001b). The total thickness of the unit is variable, ranging from 200 to 500 ft. The horizontal hydraulic conductivity of the SCU estimated from 16 packer tests ranges of 0.01 to 2.4 ft/day with a mean of 0.53 ft/day. Vertical hydraulic conductivities for this unit have been determined from field and laboratory tests. The vertical hydraulic conductivity estimated from aquifer performance test (APT) at the Region Observation and Monitor-Well (ROMP) TR9-2 site is 0.03 ft/day (Basso, 2001). Vertical hydraulic conductivities determined from 56 falling-head tests conducted on core samples obtained at different depths from 10 different sites within the Eastern Tampa Bay WUCA ranged from $1.0x10^{-7}$ to 2.5 ft/day with a mean of 0.19 ft/day and median of 0.023 ft/day. The APT value probably provides a more realistic estimate of the mean vertical hydraulic conductivity for the entire thickness of the SCU. The leakance distribution of the SCU is uniform with a value of 0.01 day^{-1} in the Southern District Model (SWFWMD, 2001).

The LPZ of the Upper Floridan aquifer is a regionally extensive, highly transmissive, sucrosic and fractured dolomite (Basso, 2001). Conceptually, the top of the LPZ corresponds to the top of the Avon Park Formation, but occasionally the lower portion of the Ocala Limestone also contributes to this unit. Within the Eastern Tampa Bay WUCA, the top of this unit occurs between -700 and -1400 ft NGVD. Figure 2.9 depicts the top of the LPZ as assigned in the Waterstone model (Waterstone, 2001b). The total thickness of this zone varies from 500 to 700 ft. According to Basso (2001), secondary porosity accounts for the permeability of the LPZ, the most productive unit in the Upper Floridan aquifer. Although multiple discrete flow zones are typical with perhaps 100 ft or more of relatively tight sections between individual flow zones, conceptual models of this unit tend to treat it as an equivalent porous medium. Based on eight APTs, the horizontal hydraulic conductivity of this unit varies from 96 to 475 ft/day with a mean of 308 ft/day. Figure 2.10 provides the transmissivity distribution of the Avon Park Formation over the study area, as used by the Southern District Model (SWFWMD, 2001). This transmissivity distribution is subsequently used for developing areal conductivity distributions for the Avon Park Formation in the density-dependent saltwater intrusion model.

2.3.4 Middle Confining Unit

The middle confining unit, composed of interbedded dolostones and evaporites, separates the Upper Floridan aquifer and Lower Floridan aquifer in the Floridan aquifer system (Basso, 2001). The top of this unit ranges from -1,200 to more than -1,700 ft NGVD in the Eastern Tampa Bay WUCA and forms the bottom of the model domain. Figure 2.11 depicts the top of the Middle Confining Unit as provided by the Waterstone Model (Waterstone, 2001). The horizontal hydraulic conductivity determined from five packer tests in the Middle Confining Unit ranges from 0.002 to 0.04 ft/day. No explicit vertical hydraulic conductivity measurements are available for this unit.

2.4 GROUNDWATER SOURCES AND SINKS

Over the past ten years (1989-1998), groundwater withdrawals from the SWUCA fluctuated between 562 MGD (1994) and 832 MGD (1989). Approximately 65 percent of this water is withdrawn for permitted agricultural use. The second largest demand is for public supply, approximately 21 percent. The surficial aquifer system produces only small quantities of water for lawn irrigation and domestic water supply. The intermediate aquifer system is primarily a source of domestic water supply, but occasionally supplements the Upper Floridan aquifer for both irrigation and public supply. Well yields in the intermediate aquifer system generally range from 20 to 200 gallons per minute (gpm). The Upper Floridan aquifer is the principal source of groundwater for water supply. Well yields in the UPZ range from 500 to 1,500 gpm. Wells completed in the highly transmissive LPZ can yield from 1,500 to 5,000 gpm (SWFWMD, 1993).

The Upper Floridan aquifer was once under artesian conditions along the coast, with at least 20 ft of pressure head at the coast. This implies that the Upper Floridan aquifer is well confined by the intermediate aquifer system, and that the intermediate aquifer system and Upper Floridan aquifer both extend a considerable distance offshore. The Upper Floridan aquifer likely subcrops about 120 miles offshore in the Gulf of Mexico where the sea bottom shelves abruptly. Offshore the Upper Floridan aquifer discharges into the Gulf of Mexico, probably mainly through diffuse leakage across the intermediate aquifer system. Potentiometric, water quality, and geologic data suggest that there is an enhanced discharge zone under Hillsborough Bay (Hutchinson, 1983).

In the coastal areas and southern portion of the basin, water levels in the Upper Floridan aquifer are usually higher than in the intermediate aquifer, creating areas of diffuse upward leakage. In these areas, groundwater discharge in the Floridan aquifer is on the order of zero to one inch per year (Barcelo and Basso, 1993).

2.5 GROUNDWATER FLOW DIRECTIONS

Pre-development groundwater flow patterns in the Upper Floridan aquifer are depicted in Figure 2.12 (Johnston, et. al, 1980). Regional groundwater flow is from the Green Swamp potentiometric high located near Polk City, Florida, toward the west/southwest. Major features of the potentiometric surface are the Green Swamp regional potentiometric high and the tendency for the potentiometric contours to wrap around the eastern portion of Tampa Bay, indicating discharge to the bay.

By the mid-1970s, pumping primarily for agricultural use, created a regionally extensive cone of depression at certain times of the year of over 40 feet in places in west-central Manatee County. Because all of the agricultural water use and a large portion of the public supply use are for supplemental irrigation, groundwater withdrawals are inversely correlated with rainfall. Consequently, maximum withdrawals occur near the end of the dry season, sometime in May or June. The potentiometric surface for May 2000 conditions is shown in Figure 2.13. The groundwater flow direction during this time is from the Gulf of Mexico inland. Since the transmissivity of the Upper Florida aquifer is high and the storativity low, most of the head recovery from pumping during the wet period occurs within a few months, resulting in groundwater flow resuming its coastward flow direction. However, recovery to pre-development

conditions does not occur. The potentiometric surface for September 2000 conditions is shown in Figure 2.14. The strong seasonal nature of demand causes considerable variability in the annual demand cycle and produces large fluctuations in groundwater levels during the year.

Barcelo and Basso (1993) provide a comparison of pre- and post-development potentiometric surface conditions. The major changes are that the 20- and 30-foot contours in Hillsborough and Manatee Counties have shifted significantly inland since pre-development, and the 50 to 100 foot potentiometric contours are closely spaced in the high-recharge region of northern Polk County.

2.6 GROUNDWATER QUALITY

2.6.1 General Water Quality Characteristics

The major threat to groundwater quality within the study area is considered to be the intrusion of saline waters, particularly seawater. Water quality in the area is generally good in all the aquifers above the middle confining unit ("evaporites") separating the Upper and Lower Floridan aquifers. In general, water quality degrades with depth and becomes more mineralized as the water flows from east to west along natural flow paths. The water quality also deteriorates from the north to the south as the thickness and depth of the Floridan and intermediate aquifer system increases (SWFWMD, 1993).

Water is generally considered fresh if it contains less than 1,000 mg/l (milligrams per liter) total dissolved solids (TDS), while brackish water ranges from 1,000 to 35,000 mg/l TDS (Clark and others, 1971). The SWFWMD defines saline water as water that is characterized by TDS concentration greater than 500 mg/l (SWFWMD, 1989). A concentration of 35,000 mg/l is considered equivalent to seawater. The State of Florida Drinking Water Standards requires that TDS concentrations for finished water be less than 500 mg/l (FDER, 1989).

There is considerable areal variation in the groundwater quality of the surficial aquifer system within the study area. Generally, the quality of the water in the surficial aquifer system is good except in the tidally influenced areas along the coast (Brown, 1983). Surficial aquifer system water along the coast and rivers is also influenced by lower quality water discharging from below (AGWQMP, 1991). AGWQMP (1991) also reports that chloride and sulfate concentrations in the study area are highest along the coastal reaches of the rivers.

The problem of assessing the water quality of the intermediate aquifer system is complicated by the hydrogeology of the aquifer. The existence of multiple, permeable zones, in poor hydraulic connection, complicates the analysis of water quality distributions (Ambient Ground-water Quality Monitoring Program [AGWQMP, 1990]). There is a lack of water quality data for this system, both spatially and temporally (SWFWMD, 1993). Overall water quality of the intermediate aquifer system is good (SWFWMD, 1993). Major ion concentrations in groundwater of the intermediate aquifer system are generally higher than ion concentrations observed in the surficial aquifer but lower than ion concentrations observed in the Floridan aquifer system (AGWQMP, 1990). The exception to this general observation is along the coast where chloride concentrations are frequently elevated (AGWQMP, 1990).

In the east and northeast areas of the study area, Upper Floridan aquifer water is principally of a calcium-magnesium-bicarbonate-sulfate type water of good quality (SWFWMD, 1993). Down gradient, to the west and southwest, the water changes to a sodium magnesium chloride type, similar to seawater. This down-gradient water of the Upper Floridan aquifer is of variable to poor quality (Steinkampf, 1982).

2.6.2 Saltwater Intrusion

In the coastal aquifers within the study area, lower density freshwater overlies denser seawater. The seawater and freshwater meet and blend in the aquifer to form a transition zone. The transition zone in the Upper Floridan aquifer ranges in thickness from about one hundred feet to several hundred feet (Beach and Kelley, 1998). The thickness depends on the conductivity of the subsurface matrix and the flow rate through the system. Chloride concentrations are the usual indicator of the transition zone existence. Chloride concentrations on the freshwater side (east) are often less the 50 mg/l and approach 19,000 mg/l on the seaward side (west) (Beach and Kelley, 1998). The ROMP wells located in Figure 2.15 provide the best quality information on chloride values at various depths within the study area. In general, the saltwater interface gets deeper from north to south. These depths generally coincide with a highly permeable zone within the Avon Park Formation. In addition, north of the Manatee River the transition zone is relatively sharp; while south of the river, the transition zone becomes more diffuse. This comparison is illustrated by the following discussion of water quality near Apollo Beach and Osprey, Florida (SWFWMD, 1993).

Near Apollo Beach an exploratory well (ROMP TR9-2) was cored to 819 feet and completed 1,254 feet below land surface (Figure 2.15). Based upon the observed relationship between chloride concentration and depth, the transition zone begins at a depth of 740 feet below land surface, and seawater is encountered at about 840 feet below land surface. The concentration of chloride is approximately 100 mg/l, or less, until the interface is contacted. This is slightly above the upper limit for ambient chlorides in Eastern Tampa Bay area from non-marine sources (Steinkampf, 1982). Above the interface, sulfate is the predominant anion. However, chloride replaces sulfate as the predominant anion below the transition zone.

Exploratory drilling near the city of Osprey began in 1991 (i.e., ROMP 20 site) (SWFWMD, 1993). Beginning at depths of 650 feet below land surface, the chloride concentrations began to increase above 100 mg/1. Chlorides increased gradually to a concentration of 2,230 mg/l at a depth of 1,439 feet below land surface where coring was discontinued. Subsequent thief sampling from the bottom of the well produced samples with chloride concentrations equivalent to seawater.

In 1991, AGWQMP conducted mapping exercises to delineate the chloride interface. More recently, Beach and Kelley (1998) projected the freshwater-seawater interface onto hydrogeologic cross sections at six locations along the coast (Figure 2.16). The cross section locations were selected where the SWFWMD has completed water quality explorations during drilling of ROMP wells (Figure 2.15). Detailed water quality data, often based on packer tests and thief samples, are available from these locations.

Based on exploratory drilling in the coastal regions of the SWUCA, the transition zone usually occurs in the upper portions of the Avon Park Formation within the Upper Florida aquifer. This represents the deepest production zone of the aquifer. In coastal Sarasota and Charlotte counties, the transition zone may occur within the Suwannee Limestone of the Upper Florida aquifer (Beach and Kelley, 1998). The transition zone may occur in the intermediate aquifer system when wells are drilled on the barrier islands or very near the coast. Exploratory wells completed in the surficial aquifer system (SAS) rarely encounter the transition zone although the transition zone may be present where such wells are adjacent to coastal surface water bodies (e.g., bays and estuaries) (Beach and Kelley, 1998).

The locations where multiple sites exist near the cross section were pivotal in this analysis. Multiple explorations along a transect permit estimates to be made as to the slope of the interface. Where a cross section had only one well to reference, the slope was interpolated from adjacent cross sections (Beach and Kelley, 1998). The interface line for each section was extended to the middle confining unit. The plane of the interface has a slight slope (0.5 to 3 degrees) downward as the interface dips landward (Beach and Kelley, 1998). The location where the interface intersects the bottom of an aquifer is known as the toe and defines the landward extent of seawater in the aquifer.

The distance along each cross section to the toe was superimposed onto a map. A smooth line through each toe was drawn delineating the 1,000 mg/l chloride concentration defining the areal extent of the interface between the freshwater and saltwater (Figure 2.16). This approach was later updated (Beach and Schultz, 2000) by delineating the top and bottom of the "highly permeable zone" within the Avon Park Formation from exploratory drilling data and adding this information to each cross section. Where exploratory drilling data was inadequate, the top of the "highly permeable zone" was derived from Miller (1986). The point on the cross sections where the interface exits the bottom of the "highly permeable" zone of the Avon Park was determined to be the toe of the interface.

Beach and Schultz (2000) determined that the current position of the interface toe in the Avon Park Formation is only two to three miles inland in south Hillsborough County. In Sarasota County, the interface toe in the Avon Park may be as much as ten miles inland. Beach and Schultz (2000) also provide estimates for future positions of the toe after 50 years of pumping at different levels (Figure 2.17). The estimates indicate that future movement will be greater in south Hillsborough County than in northern Sarasota County. Application of the Ghyben-Herzberg principal indicates that ultimately Sarasota County would be affected to a greater extent than Hillsborough or Manatee Counties (Beach and Schultz, 2000).

Appendix A shows the variation of chlorides with depth for various ROMP wells within the study area. Due to the high quality of spatial chloride distributions provided by this data, it is used for calibrating the density-dependent saltwater intrusion model.

2.6.3 Saltwater Intrusion Potential Risk

The risk of a well to saltwater intrusion is a function of at least four factors: (1) the completed depth of the well; (2) the proximity of the well to the coast; (3) the amount of water withdrawn

in the vicinity of the well; and (4) the local and regional properties of the aquifers and confining units (Beach and Kelley, 1998). Typically, deeper wells are closer to the transition zone and saline water. The closer a well is located to the coast, the thinner the freshwater zone. The greater the withdrawal quantity, the more likely wells are to induce local saltwater upconing from the transition zone. The distribution of hydraulic conductivity is the most important local and regional property of the aquifers and confining units, which affects the potential for saltwater intrusion. Sediments characterized by higher hydraulic conductivity values allow the interface to move more quickly under a given change in potential. Hydraulic conductivity heterogeneity is the variation in hydraulic conductivity that occurs from place to place in the aquifer and confining units. Frequently, hydraulic conductivity heterogeneity is caused by spatial or vertical variations in fracture density and/or distribution; lithologic properties; or distribution and magnitude of secondary dissolution features (i.e., karst conduits). Heterogeneity is the principal factor that accounts for multiple wells being affected to different extents by saltwater intrusion when all the wells are completed to the same depth, are located the same distance from the coast, and are located in similar withdrawal environments (Beach and Kelley, 1998).

Based on the four risk factors above, wells completed in the Avon Park Formation are generally at the greatest risk of experiencing saltwater intrusion. The Avon Park Formation of the Upper Floridan aquifer is a highly prolific water-producing unit due to its very high hydraulic conductivity. The high hydraulic conductivity results from a horizontal interval, about 100 to 400 feet thick, characterized by considerable fracturing and secondary porosity. This interval is frequently referred to as the "highly permeable" or "fractured" zone of the Avon Park Formation. Although this highly permeable zone comprises only 10 to 25 percent of the Avon Park thickness, as much as 95 percent of the Avon Park water production may be derived from this zone (Beach and Schultz, 2000). The remainder of the formation is characterized by relatively low permeability and limited groundwater production. For this reason, the Avon Park Formation wells are usually completed in the highly permeable zone.

Most exploratory drilling in coastal areas of Hillsborough, Manatee and Sarasota counties have located the seawater transition zone in the upper portions of the Avon Park. Increasing temporal trends in chloride concentration data from dedicated monitoring wells occur most frequently in wells completed in the Avon Park Formation. Based on that data, Beach and Kelley (1998) conclude that wells in Hillsborough and Manatee counties, completed in the Avon Park Formation and located within four to five miles to the coast, are most likely to experience saltwater intrusion in the near future. For the purposes of their discussion, the "near future" is considered to be within the next five or ten years (from 1998). On the other hand, wells completed above the toe of the interface would probably not experience saltwater intrusion within present long-term planning periods, generally out to 2025 (Beach and Kelley, 1998). These estimates assume no change in current withdrawal rates and patterns.

Avon Park Formation wells in Charlotte and DeSoto Counties already withdraw very poor quality water. The transition zone is more diffuse in these counties than in Hillsborough and Manatee Counties (Beach and Kelley, 1998). Data from exploratory wells in the area show the influence of seawater well into the Suwannee Limestone although chloride concentrations are somewhat less than 1,000 mg/l.

Based on the four risk factors, coastal Suwannee Limestone wells are at much less risk of saltwater intrusion than similarly located wells completed in the Avon Park Formation (Beach and Kelley, 1998). Generally, the lower hydraulic conductivity of the Suwannee Limestone is less susceptible to saltwater intrusion. Wells that appear to be a greatest risk are those located within several miles of the coast in Charlotte and southern Sarasota Counties (Beach and Kelley, 1998). Relatively high chloride concentrations, 570 to 1,800 mg/l were encountered in the Suwannee Limestone during exploratory drilling in those counties (i.e., ROMP 5, ROMP 9, and ROMP TR 4-1). In Hillsborough and Manatee Counties, there are a large number of Suwannee Limestone production wells located within several miles from the coast (Beach and Kelley, 1998). Based on water quality data from dedicated monitoring wells in the area, chloride concentrations range from 200 to 500 mg/l (ROMP TR 9-2, ROMP TR 9-3). However, there are no increasing trends in these data, unlike similar data from the Avon Park Formation dedicated monitoring wells at the same locations (Beach and Kelley, 1998). It has been demonstrated that such concentrated pumping from the Suwannee Limestone, as occurs in the area, could cause the interface to be pulled up into the Suwannee Limestone from the Avon Park Formation over the next 50 years (HydroGeoLogic, Inc, 1994a).

Regionally, the intermediate aquifer system and surficial aquifer system wells are at little risk of saltwater intrusion. However, there are local problems for intermediate aquifer system and surficial aquifer system wells in Manatee, Sarasota and Charlotte Counties that are located less than a mile from the coast or barrier islands (Beach and Kelley, 1998). The transition zone on the barrier islands is usually located in the intermediate aquifer system. The Water Use Permit (WUP) wells located on the barrier islands of northern Sarasota County are known to have experienced considerable degradation from saltwater intrusion for many years (Beach and Kelley, 1998). This is also true for many of the shallow intermediate and surficial aquifer system wells along the southwest coast of the area.

2.7 IMPLICATIONS OF CONCEPTUAL MODEL COMPONENTS AND UNCERTAINTY ON THE NUMERICAL MODEL

One primary goal of mathematical modeling is to synthesize the conceptual model into numerical terms from which flow and transport processes may be investigated under specified conditions. This process entails several discrete steps: (1) partitioning the conceptual model into units of time and space; (2) assignment of boundary conditions; and (3) specification of the parameter values. There are always uncertainties in predictions derived from modeling. These uncertainties are frequently divided into two main categories: 1) conceptual model uncertainty; and 2) parameter uncertainty. This section briefly describes these uncertainties and the approach that will be applied to address these uncertainties in the model calibration process.

The conceptual model is based on the modeler's experience and technical judgment and represents the modeler's understanding of the system framework and behavior, from all available data and information of a site. The conceptual model will naturally become more complex as more processes are identified and interrelationships of important components within the systems are considered. The transformation of the conceptual model into a mathematical model, is a further extrapolation of the basic understanding of the system, resulting in intrinsic simplifications of the system. For example, the mathematical model assumes that there is a direct scaling between the

model simulations and the scale at which the data are collected. The lack of knowledge about the system resulting from limited information also contributes to inevitable simplifications in the conceptual and mathematical models. Based upon the data and model review a number of conceptual model uncertainties have been identified and are presented in Table 2.2. This table also describes the methods that will be applied to address the primary uncertainties during the model calibration.

In addition to the conceptual model uncertainties, there are always uncertainties in the parameter values that are assigned in the model. As specified in the Work Order agreement between the SWFWMD and HydroGeoLogic, sensitivity analyses will be conducted to address parameter uncertainties during the model calibration. Sensitivity analyses will be conducted for key parameters (which may be performed on the pre-development or post-development model depending upon significance). Parameter sensitivities will be determined by varying a specific parameter and evaluating the change in hydraulic heads and/or chloride concentrations thus simulated. Depending upon the results of this initial sensitivity analyses, multiple parameters may be simultaneously perturbed during subsequent sensitivity analyses. Based on the results of the sensitivity analysis, the parameters will be categorized following the protocol developed by the American Society of Civil Engineers (ASCE) to determine the parameters of greatest concern. This approach will serve to provide recommendations for future data collection, as well as to design sensitivity simulations that will be conducted during the next phase of the project to evaluate prediction uncertainties.

3.0 SUMMARY OF PREVIOUS MODELING STUDIES

Over the last 15 years, a number of models have been constructed in the SWFWMD to address the problem of deteriorating groundwater quality due to lateral intrusion of seawater or the upconing of highly mineralized water from deeper stratigraphic units. One of the first documented studies is by Hutchinson (1983) in which a two-dimensional areal freshwater model was used to study the effects of the channelization in Tampa Bay and the effects of pumping in the vicinity. Wilson (1982) also used an areal freshwater model to predict the effect of pumping on the potentiometric surface in the west-central Florida area. Both investigators estimated the current location of the seawater-freshwater interface and estimated the rate of advancement using the freshwater flow velocity at the interface.

Mahon (1988) performed a cross-sectional analysis to evaluate the potential for saltwater intrusion in Hernando and Manatee Counties. Mahon conceptualized the Upper Floridan aquifer as having an upper permeable zone, semiconfining unit, and a lower permeable zone. Each hydrostratigraphic layer was divided into several computational layers for solute transport. The top of the middle confining unit was assumed to be impermeable, the intermediate aquifer system was explicitly simulated, and the surficial aquifer system was set as a constant pressure to provide a source for downward leakage to the intermediate aquifer system. The lateral freshwater flux on the landward model edge had to be lowered relative to the initial estimates in order to bring the approximate location of the interface to a reasonable location from its initial location somewhere in Tampa Bay.

HydroGeoLogic (1991a, b, and c) performed variable density flow and transport cross-sectional analyses (Figure 3.1) for three representative cross-sections in the Manatee-South Hillsborough Water Resources Assessment area where a large, groundwater depression was observed (Figure 2.9). The numerical code DSTRAM (Density-dependent Solute TRansport Analysis finite-element Model) was applied. For each cross-section, the model was first calibrated against steady-state pre-development conditions. Flow boundaries for the cross-sectional models were defined as a combination of flux and prescribed head boundaries based on the pre-development potentiometric surface map of the Upper Floridan aquifer. The middle confining unit at the bottom of the Avon Park were considered a no-flow boundary. Both Sinclair (1979) and Guyton and Associates 1976 report that highly mineralized water was found in this evaporites zone. Thus, along the bottom boundary, chloride concentrations were normalized to seawater (i.e., set equal to 1, which is representative of a chloride concentration of 18,000 mg/l). Hutchinson (1983) found that the water samples taken at Hillsborough Bay are slightly less saline than seawater (approximately, 14,400 mg/l). Therefore, the seaward boundary of the B-W cross-sectional model (HydroGeoLogic, 1991a) was assigned a concentration of 14,000 mg/l. Sensitivity analyses were subsequently performed to determine relative influences of changes in key parameters on system responses. Two post-development scenarios were simulated in a transient manner and are representative of the most pessimistic and optimistic conditions over a 100-year simulation period.

Model predicted chloride concentrations associated with pre-development conditions are shown on Figure 3.1 for the intermediate aquifer system. Modeling results along cross section B-W indicate that the length of the transition zone at the top of the Avon Park Formation is about 4

miles while at the bottom it is about 1 mile. The model predicted that chloride concentrations in wells constructed at the shoreline would range from 900 ppm to 17,000 mg/l over a depth of 250 feet in the Avon Park Formation. The vertical transition zone predicted by the model is more gradual than suggested by earlier field investigations. The authors note that the simulated transition zone can be made thinner by reducing the dispersivities and the element size further.

The second cross section, section M-S, passes through the city of Sarasota in Sarasota County, and terminates in the Gulf of Mexico (Figure 3.1). As shown in the figure, the pre-development 1,000 mg/l chloride isochlor in the Tampa/Suwannee layer is located somewhat west of the city of Sarasota. In the Avon Park, however, the 1,000 mg/l chloride is located approximately 6 miles east of Sarasota.

The third cross section, section H-M, is located along the Hillsborough-Manatee County border and lies in the middle of a large potentiometric depression during the dry season (Figure 2.9). Chloride concentration isochlors indicate that the chloride transition zone is very narrow which is consistent with field data indicating that wells located further inland and tapping the Tampa/ Suwannee and Avon Park Formations depict very small chloride concentrations values, as reported by Brown (1983).

During post-development simulations, the transition zones advanced landward in all three cross sections, however, with varying degrees. In the worst case scenarios the maximum advancement of 3 to 5 miles was observed in the southernmost section (S-M) while at most 2 miles of advancement was observed in the northernmost section (B-W).

In all three cross sections, the response of the saltwater-freshwater transition zone to the imposed conditions was more significant in the lower producing zone (the Avon Park Formation) of the Upper Floridan than in the upper producing zone (the Tampa/Suwannee Formation). Sensitivity analyses indicated that the results are very sensitive to vertical hydraulic conductivities of the confining units, particularly the Intermediate aquifer system.

Barcelo and Basso (1993) implemented a quasi-three dimensional MODFLOW modeling effort to assess regional groundwater flow in the eastern Tampa Bay WUCA. The flow model consisted of three layers to simulate groundwater flow within the Intermediate and Upper Floridan Aquifers and the vertical exchange of water between the surficial, intermediate and Upper Floridan Aquifers.

Although the Upper Floridan Aquifer has two major production zones (i.e., Suwannee Limestone, Avon Park Formation), the aquifer is conceptualized as a single hydrologic unit. Referring to the Upper Floridan Aquifer, Ryder (1982) noted that "despite the large permeability contrasts, aquifer-test results indicate that there is enough vertical interconnection between each formation to consider the Floridan Aquifer a single hydrologic unit." Menke (1961) noted that in Hillsborough County, the connection between the upper and lower production zones is such that "...when the time of interchange of water is great and the amount of water interchanged is small..." the system behaves as a single aquifer. The concept of treating the Upper Florida aquifer as a single hydrologic unit was further investigated by Guyton and Associates (1976). During an aquifer test of the Avon Park Formation that was performed in Manatee County, measured water

levels in two wells that were open to the different production zones were nearly identical. This conceptualization will be revisited for the saltwater intrusion model because it may not be adequate to investigate chloride intrusion.

Barcelo and Basso (1993) calibrated their model to steady-state, annual-average hydrologic conditions for calendar year 1989. Following the steady-state calibration, a transient calibration/ verification was performed to evaluate the response of the model to changes in hydrologic stress. The transient calibration was conducted for the period from October 1988 through September 1989.

As a means of evaluating the steady-state calibration effort during the calibration phase, the investigators periodically removed pumping from the model and the model was used to simulate pre-development hydrologic conditions. Because the original parameter estimates were based in part on a groundwater flow model that had been calibrated to pre-development conditions (Ryder, 1985), it was decided that emphasis should be placed on calibrating the model to more recent stressed conditions rather than calibrating to pre-development conditions. Calibration to pre-development conditions enables a determination of the areal distribution of the aquifer parameters without incurring the error associated with estimating water use; however, the authors believed that the pre-development target heads are not sufficiently well known. Although there is some degree of confidence in the pre-development potentiometric surface of the Upper Floridan aquifer (Johnston and others, 1980) there is no published map on the pre-development head distribution of the Intermediate Aquifer (Barcelo, and Basso, 1993).

In 1992, HydroGeoLogic developed a computer code called SIMLAS for the SWFWMD to simulate saltwater intrusion using a sharp-interface technique. The sharp interface technique assumes that the freshwater and the saltwater are immiscible and that the transition between the two liquids is abrupt. This assumption along with the Dupuit-Forchheimer approximation replaces the density-dependent flow and transport equations with a pair of flow equations for freshwater and saltwater. The two flow equations are still coupled, but are less prone to numerical difficulties than the variable density flow and transport equations for large scale simulations.

Two sharp-interface models were subsequently developed using SIMLAS (HydroGeoLogic, 1993; 1994b) to extend the work of Barcelo and Basso (1993) to include the dynamics of saltwater. One of HydroGeoLogic's objectives was to compare the sharp interface formulation in SIMLAS to the fully coupled density-dependent approach in DSTRAM. In order to make this comparison, the southernmost cross section (M-S) from HydroGeoLogic's 1991 study was selected. This southern cross-section was chosen, primarily because a well defined narrow transition zone exists in both lower and upper aquifer layers. Results indicated that the two numerical solutions are in good agreement when the effects of dispersion in the DSTRAM model are negligible. For zero dispersion, the only major difference between the two modeling approaches is the Dupuit-Forchheimer assumption employed in the sharp-interface formulation.

The saltwater-freshwater interface in the Upper Floridan aquifer was predicted by the SIMLAS model to occur over a large area. As shown in Figure 3.1, the predicted toe location is considerably further inland than in the Intermediate Aquifer System. The modeling results also indicted that when the leakance of the lower confining bed of the Intermediate System is reduced

(by a factor of 3), both the tip and the toe positions are pushed toward the coastline (west). However, the shift is much more pronounced for the tip than for the toe. Similar behavior was observed between the cross-sectional and areal simulations; the toe moved toward the coastline roughly five miles whereas the tip moved all the way to the offshore boundary.

Post-development simulations were also performed which concluded that after 500 years of pumping under post-development conditions, little change was observed on the position of the interface in the intermediate aquifer system. The toe of the interface in the Upper Floridan Aquifer, however, moved inland up to six miles in the northern half of the model domain. The tip of the interface hardly moved revealing the tightness of the overlying confining layer. The interface in the southern half of the model domain showed little change to the applied stress.

Major conclusions of these studies were that the Upper Floridan aquifer may need to be divided into major producing and confining zones, and that the leakance of the intermediate aquifer system should be adjusted to move the tip inland. In particular, the 1994 study showed that the MODFLOW-derived leakances offshore needed to be increased by a factor of 10 in order to avoid simulating the interface too far offshore.

In another variable density flow and transport analysis, HydroGeoLogic (1994c) performed two extensive cross sectional investigations of long-term pumping effects on chloride levels in the northern and southern regions of the ETBWUCA. The location of the toe of the pre-development interface at both cross sections is shown in Figure 3.1. With respect to the boundary conditions, Hillsborough Bay seawater was assigned a slightly lower (14,400 mg/l) chloride concentration than seawater (18,000 mg/l). The bottom of the model was placed at the top of the middle confining unit and assigned a concentration of seawater. However, no fluid flow was allowed along this bottom boundary. The system was found to be most sensitive to the vertical hydraulic conductivity of the evaporite zone and the horizontal hydraulic conductivity of the Avon Park formation. Recharge to the top of the Upper Floridan aquifer mainly affected heads with minor effects on chloride distributions, but both heads and chlorides were sensitive to the middle confining unit hydraulic conductivity.

All of the above models assumed that the fractured LPZ may be represented as an equivalent porous medium. Waterstone (Waterstone, 2001a), however, provides a discussion on alternative conceptualizations involving dual porosity, discrete fracture and dual permeability conceptualizations and their potential affects on groundwater flow and chloride migration. Waterstone concludes that an equivalent porous medium approach will adequately describe flow and transport through the LPZ.

4.0 NUMERICAL MODEL CONSTRUCTION

4.1 MODELING APPROACH

The following section describes the approach used to construct a density-dependent groundwater flow and solute transport model to simulate saltwater intrusion in coastal portions of the SWUCA. The framework for the saltwater intrusion model has been developed based on the conceptual model presented in Section 2.0. In addition, information derived from other modeling investigations has provided valuable information for the development of the current model. In particular, the regional groundwater flow model developed by the SWFWMD (2001) and an uncalibrated, local-scale, saltwater intrusion model developed by Waterstone (2001a, 2001b) have provided significant data that have been used for the preliminary construction of the current model.

As discussed in Section 3.3, the computer code MODFLOW (MacDonald and Harbaugh, 1988) has been applied by several models in the SWFWMD for simulating groundwater flow within the SWUCA. These models have culminated into the Southern District Groundwater Flow Model (SWFWMD, 2001), a regional MODFLOW model that integrates and updates previous models. This regional groundwater flow model, transmitted electronically (via Groundwater Vistas project files) to HydroGeoLogic, Inc. by the SWFWMD (SWFWMD, 2001), forms the basis for the current study. The primary objective of the Southern District Model was to provide a groundwater management tool to the SWFWMD. Currently, the SWFWMD is further updating the calibration of the regional groundwater flow model, but large changes to the model are not anticipated (Beach, pers. comm., 2001). Therefore, the Southern District Model of June 11, 2001 provided by the SWFWMD has been used to construct the current saltwater intrusion model. Since a report documenting the regional modeling effort is not completed, critical information related to the Southern District Model and its uncertainties have been acquired through numerous conversations with the SWFWMD and a thorough review of model input and output files.

Groundwater Vistas project files associated with an uncalibrated saltwater intrusion model developed by Waterstone (Waterstone, 2001b) have also been used to a certain extent in the current modeling effort. Specifically, the grid employed for their study, including hydrostratigraphic elevations and layering geometry, was also adopted for the current modeling investigation.

As will be discussed in greater detail in the sections that follow, both the Waterstone Model (Waterstone, 2001b) and the Southern District Model (SWFWMD, 2001) electronic data files were used to construct and initialize the density-dependent saltwater intrusion model. The regional MODFLOW model files were used primarily to assign hydraulic properties and boundary conditions, since the density-dependent model is conceptually based on the regional study. Alternatively, the Waterstone (Waterstone, 2001b) model files provided by the SWFWMD were used to assign the model domain, grid spacings and layer thicknesses to the density-dependent model, since these were acceptable to the SWFWMD for the previous study, and were reasonable for the goals and scale of the current study.

When the density-dependent model was constructed, it was first used to simulate groundwater flow only, to establish that the translation from regional to local grids was appropriate and that the simulated pre-development conditions for both models are the same. Once these "basecase" conditions were established (Section 5.1), the saltwater effects were incorporated into the density-dependent model. Parameter values (e.g., hydraulic conductivities) were, to a certain extent, adjusted from the basecase conditions during calibration of the density-dependent, saltwater intrusion model (Section 5.0), because the regional flow model does not include the affects of chloride concentration which affect groundwater flow.

4.2 COMPUTER CODE SELECTION AND OVERVIEW

The computer code MODHMS was selected for construction of the flow and solute transport model (HydroGeoLogic, 2000). MODHMS is a MODFLOW-based code developed by HydroGeoLogic for evaluating complex hydrologic and hydrogeologic settings. The density-dependent transport capabilities of MODHMS have been incorporated from DSTRAM, which is a well established and applied saltwater intrusion model developed by Huyakorn and Panday (1991). The MODFLOW structure of MODHMS provides several features that are attractive for use in this study. First, it makes the code fully compatible (in terms of numerical approximations, grid structure as well as input/output data structures) with the other MODFLOW- based models (regional as well as local) developed by the SWFWMD. Further, the MODFLOW framework of MODHMS allows for use of any of the pre- and post-processing tools developed for use with MODFLOW. Specifically, Groundwater Vistas (Environmental Simulations, Inc.) provides support to the additional modules of MODHMS used for density-dependent modeling. This is advantageous because the SWFWMD has developed the Southern District Model in Groundwater Vistas, and that model can be directly translated to MODHMS framework. In addition, all the MODFLOW features are available for use within MODHMS including a wide range of boundary conditions such as drains, streams, general-head conditions, and those involving water table conditions, infiltration, aquitard leakages, and pumping and injection wells. For contaminant transport simulation, MODHMS accounts for advection, anisotropic hydrodynamic dispersion (with separate areal and vertical components for the longitudinal and transverse dispersivities essential in such groundwater systems as encountered by the SWFWMD), linear equilibrium sorption, and first-order degradation.

The MODHMS code was selected for this study because of the following reasons:

- The code is fully documented and has been successfully applied to problems of similar complexity. For instance, the DSTRAM models for the Seminole County and East Orange County saltwater intrusion studies (Panday et al., 1994, HydroGeoLogic, 1998) were translated to MODHMS and transient as well as steady-state results were demonstrated to be accurate. MODHMS has also been verified against problems with known solutions.

- MODHMS employs the most advanced solution and matrix computation techniques available. The transport equation uses advanced flux-limiting Total Variation Diminishing (TVD) schemes to control unphysical oscillations and minimize numerical diffusion. The code has robust (Preconditioned Conjugate Gradient and Orthomin) matrix solvers unavailable in other standard codes which make it more efficient and versatile.

- MODHMS can quickly extend the Southern District Model developed by the SWFWMD under Groundwater Vistas, to include the density-dependent saltwater transport regime. Conversely, changes made within the calibrated saltwater intrusion model may be quickly and easily incorporated into the Southern District Model. Compatibility among all SWFWMD models allows for consistency and defensibility of results across models.

MODHMS is an extension to the USGS three-dimensional finite difference groundwater flow code, MODFLOW (McDonnald and Harbaugh, 1988), and is capable of simulating density-dependent, single-phase fluid flow and solute transport in saturated porous media. The code is applicable for complex situations where the flow of fluid (groundwater) is influenced significantly by variations in solute concentration. MODHMS can perform steady-state and transient simulations, and a wide range of boundary conditions can be accommodated. For contaminant transport simulation, MODHMS accounts for advection, hydrodynamic dispersion, linear equilibrium sorption, and first-order degradation. When MODHMS is used to simulate the combined processes of density-dependent groundwater flow and solute transport, the code solves two coupled partial differential equations: one for density-dependent fluid flow and one for the transport of dissolved solutes (e.g. chloride).

The governing equation for three-dimensional flow of a mixture fluid (i.e., water and salt) of a variable density in an aquifer system can be written in the form

$$\frac{\partial}{\partial x_i}\left[\rho\frac{k_{ij}}{\mu}\left(\frac{\partial p}{\partial x_i} + \rho g e_j\right)\right] = \frac{\partial}{\partial t}(\phi\rho), \qquad (4.1)$$

$$i,j = 1,2,3$$

where p is fluid pressure, k_{ij} is the intrinsic permeability tensor, ρ and μ are the fluid density and dynamic viscosity, respectively, g is the gravitational acceleration, e_j is the unit vector in the upward vertical direction, and Φ is the porosity of the porous medium. In working with the above flow equation, it is convenient to replace pressure by a reference hydraulic head defined as

$$h = \frac{p}{\rho_0 g} + z \qquad (4.2)$$

where ρ_0 is a reference (freshwater) density and z is the elevation above a reference datum plane. The reference hydraulic head is often referred to as the equivalent freshwater head. The reference hydraulic head is directly related to the true hydraulic head, H, by the relationship

$$H = \frac{h + z\eta c}{1 + \eta c} \qquad (4.3)$$

where H is defined as

$$H = \frac{p}{\rho g} + z \tag{4.4}$$

and

$$\eta = \frac{\rho_s - \rho_o}{\rho_o c_s} \tag{4.5}$$

where c_s is the solute concentration that corresponds to the maximum density, ρ_s. In practice, the term ηc is usually much less than 1 and thus equation (4.3) can be approximated by

$$H = h + \eta c z \tag{4.6}$$

In MODHMS, therefore, two types of boundary conditions must be entered: those that describe the reference (equivalent freshwater) head or fluid fluxes, and those that pertain to solute concentration or solute mass fluxes.

There is a third type of hydraulic head, referred to as environmental head (or potential head), which is defined as

$$\psi = h - \int_{z_1}^{z_2} \eta c \, dz \tag{4.7}$$

where z_1 is the elevation above datum at which the environmental head (ψ) is to be determined, and z_2 is the elevation above datum of the top of the model domain. The environmental head may be conceptualized as the head value that would be measured in a well that had open hole construction from the top of the aquifer system where solute concentrations are small or negligible (z_2) to a total depth of z_1.

The groundwater flow equation can be coupled with the solute transport equation, which may be written in the form

$$\frac{\partial}{\partial x_i}\left(D_{ij}\frac{\partial c}{\partial x_j}\right) - V_i\frac{\partial c}{\partial x_i} = \phi R\left(\frac{\partial c}{\partial t}\right) + \lambda\phi Rc, \qquad (4.8)$$

$$i,j = 1,2,3$$

where D_{ij} is the apparent hydrodynamic dispersion tensor, V_i is the Darcy velocity of fluid, R is the retardation coefficient, and λ is the decay or degradation constant of the solute. For a conservative solute species, such as chloride, there is no adsorption R = 1) and no decay (λ = 0). Equations (4.1) and (4.8) are coupled through the concentration variable and the Darcy velocity.

The hydrodynamic dispersion for three-dimensional anisotropic systems maybe computed from relations provided by Guvanasen (2002), as

$$D_{xx} = \alpha_{Lh}\frac{v_x^2}{|v|} + \alpha_{Th}\frac{v_y^2}{|v|} + \alpha_{Tv}\frac{v_z^2}{|v|} + \beta D_o \qquad (4.9a)$$

$$D_{yy} = \alpha_{Th}\frac{v_x^2}{|v|} + \alpha_{Lh}\frac{v_y^2}{|v|} + \alpha_{Tv}\frac{v_z^2}{|v|} + \beta D_o \qquad (4.9b)$$

$$D_{xz} = D_{zx} = \left(\frac{\alpha_{Lh} + \alpha_{Lv}}{2} - \alpha_{Tv}\right)\frac{v_x v_z}{|v|} \qquad (4.9c)$$

$$D_{zz} = \alpha_{Tv}\frac{v_x^2}{|v|} + \alpha_{Tv}\frac{v_y^2}{|v|} + \alpha_{Lv}\frac{v_z^2}{|v|} + \beta D_o \qquad (4.9d)$$

$$D_{xy} = D_{yx} = (\alpha_L - \alpha_T)\frac{v_x v_y}{|v|} \qquad (4.9e)$$

$$D_{yz} = D_{zy} = \left(\frac{\alpha_{Lh} + \alpha_{Lv}}{2} - \alpha_{Tv}\right)\frac{v_y v_z}{|v|} \qquad (4.9f)$$

where $|v|$ is the magnitude of the velocity vector, $|v| = (v_1^2 + v_2^2 + v_3^2)^{1/2}$, α_L and α_T are longitudinal and transverse dispersivities, respectively, δ_{ij} is the Kronecker delta, D^o is the free-water molecular diffusion coefficient, and β is the tortuosity given by the Millington-Quirk (1961) equation as $\beta = S_w^{10/3}\phi^{4/3}$. The subscripts *Lh*, *Th*, *Lv*, and *Tv* are indices for horizontal longitudinal, horizontal transverse, vertical longitudinal and vertical transverse directions respectively. Note that equations above collapse to equations for isotropic media when *Lv*=*Lh* and *Tv*=*Th*. The set of equations (4.9) is typically used to calculate dispersivities in a three dimensional system where vertical flow components are significant. In such cases, the vertical and horizontal components of dispersion can be an order of magnitude apart for their respective longitudinal and transverse components. For three-dimensional systems with mainly horizontal flows, the longitudinal dispersivities in vertical and horizontal directions may be treated as equal, to produce a 3-component dispersivity tensor. In such cases, the vertical transverse dispersivity is typically an order of magnitude less than the horizontal transverse dispersivity for areally extensive systems. Finally, for isotropic systems or two-dimensional analyses, the vertical and horizontal components of the transverse dispersivity may also be treated as equal, to produce the Scheidegger (1961) dispersivity equation.

The major assumptions and limitations incorporated into MODHMS that are relevant to this project are as follows:

- Fluid flow and salt transport occurs in a fully saturated porous medium. Flow and transport within individual fractures and solution cavities is not simulated explicitly.

- Flow of the fluid considered is isothermal and is governed by Darcy's Law.

- The fluid considered is slightly compressible and homogeneous.

- Dispersive transport in the porous medium system is governed by Fick's Law. The hydrodynamic dispersion is defined as the sum of the coefficients of mechanical dispersion and molecular diffusion. The medium dispersivity corresponds to that of an anisotropic porous medium and may be related to four constants, α_L and α_T, in the areal and vertical directions, which are the longitudinal and transverse dispersivities, respectively. This four component dispersivity tensor reduces to the two-component isotropic dispersivity tensor when the areal and vertical components for the dispersivities are equal.

One final comment is appropriate concerning the MODHMS code, and that is that it solves a mathematical problem that is "nonlinear". In the case of variable density flow, the nonlinearity of the system arises because the density of groundwater at some point depends upon the concentration of solute at that point, but the solute concentration is dependent upon the groundwater flow, which in turn depends upon the density, and so on. Nonlinear systems may be solved mathematically using iterative procedures. Iterative procedures require that some tolerance be specified for the dependent variables being solved for (in our case reference heads and concentrations at nodal points). When the differences between the dependent variable values calculated between successive iterations is less than the tolerance, the nonlinear solution is said to "converge" to within that tolerance. If the differences between the values calculated during successive iterates never become smaller than the tolerance, the solution is said to be

non-convergent. In many practical cases, one-step steady-state solutions may not converge, and transient time-marching or parameter stepping may be required to achieve a steady-state system.

The parameter stepping scheme uses a series of steady analysis starting from a mildly nonlinear problem that can be solved readily (see for example Herbert et al., 1988). Each successive problem, presumably more nonlinear, can be solved using the latest solution as the initial guess. The time-march approach starts from an initial condition, and the problem is solved by marching through a long period of time until a quasi-steady state is reached. The time-marching method is preferable, since the storage term provides greater stability to the linear matrix solver, which is not achieved by the parameter stepping scheme. To examine how close the final solution was to the true steady-state solution, the final solution was compared with earlier time solutions to detect movement. The mass-balance components were also examined and steady-state was assumed when the storage terms of the mass-balance for flow and transport are small in comparison to the other flux terms.

4.3 MODEL DOMAIN AND DISCRETIZATION

The domain of the Southern District Model (SWFWMD, 2001) includes all of the SWUCA as shown in Figure 4.1. The density-dependent saltwater intrusion model domain is identical to that of Waterstone Model (Waterstone, 2001b), and is also shown superimposed over the Southern District Model domain in Figure 4.1. The regional grid is uniform with nodal spacings of 5,000 by 5,000 feet (Figure 4.2). Such spacings are rather coarse when used to predict the transient movement of chlorides. In view of this, the density-dependent model grid was finer and consists of 103 columns and 123 rows with spacings that range from 2,500 to 5,000 feet (Figure 4.3). The 2,500 foot spacing within the density-dependent model is over the primary area of interest. The grid is deformed in the vertical direction to conform with formation geometries and topography.

As previously discussed in Section 2.0, groundwater flow occurs in three principal aquifers; the unconfined surficial aquifer, the intermediate aquifer, and the Upper Floridan aquifer. The Upper Floridan aquifer contains two productive zones, the upper productive zone (corresponding to the Suwannee Limestone) and the lower productive zone (corresponding to the Avon Park Formation), separated by the confining units of the Ocala Limestone. Two intermediate confining beds restrict vertical movement of groundwater between the overlying surficial and underlying Floridan Aquifers. The upper intermediate confining bed limits flow between the surficial and Intermediate Aquifers. The lower intermediate confining bed restricts flow between the Intermediate and Upper Floridan aquifers. The intermediate aquifer itself is divided vertically into two water producing zones separated by confining beds. The Southern District Model (2001), divides this hydrogeologic system into 5 model layers as shown in Figure 4.4, to represent the surficial, the two intermediate aquifer productive units, and the upper and lower productive zones of the Upper Floridan aquifer respectively.

To accurately simulate the migration of saltwater using MODHMS, the thickness of aquifers and aquitards must be explicitly assigned in the model, and hydraulic conductivity values must be assigned to each hydrostratigraphic unit. Because transmissivities (i.e., hydraulic conductivity multiplied by thickness), rather than hydraulic conductivities and thicknesses are assigned in the Southern District Model, the thicknesses of the aquifers and confining units could not be obtained

from the Southern District Model data files for input into the density-dependent model. The Waterstone Model (Waterstone, 2001b) includes generalized thicknesses and top/bottom elevations of the various hydrogeologic units. A comparison was made between the thicknesses provided in the Waterstone Model (Waterstone, 2001b) and several geologic cross sections constructed through the local model area. Barcelo and Basso (1993) present a series of cross sections and SWFWMD (1993) show similar cross sections. Basso (2001) also presents cross sections and isopach maps of the aquifers and confining units within the ETBWUCA. The hydrostratigraphy assigned in the Waterstone Model (Waterstone, 2001b) are consistent with the information provided in the cross sections and were used to construct the density-dependent model.

Vertical discretization of the density-dependent model is identical to that of the Waterstone Model (Waterstone, 2001b) and consists of 10 layers as shown in Figure 4.5. These layers conceptualize the Upper Floridan Aquifer system with explicit representation of the Suwannee Limestone, Ocala Limestone and Avon Park Formation, which are subdivided into 2, 3 and 5 finite-difference layers, respectively. The two upper units (i.e., Suwannee and Ocala) are equally divided and the Avon Park Formation has greater resolution in the uppermost layers (model layers 6 and 7) relative to the bottom model layers (8-10). The surficial aquifer system and intermediate confining units are incorporated into the density-dependent model via boundary conditions (Section 4.4).

The geometry of the hydrostratigraphic units assigned in the current model (i.e., top and bottom elevations) was adopted from the Waterstone Model (Waterstone, 2001b). During their modeling investigation, Waterstone estimated the top and bottom elevations for all of the hydrostratigraphic units based on lithologic data provided by the SWFWMD and information presented by Basso (2001). The uppermost formation in the current density-dependent model is the Suwannee Limestone. The Suwannee Limestone varies in thickness from less than 200 feet in central Hillsborough County to about 300 feet in northern Sarasota County (SWFWMD, 1993). The isopach map for the Suwannee Limestone as extracted from the Waterstone Model (Waterstone, 2001b) is shown in Figure 4.6. Figure 4.6 is essentially the difference between Figures 2.6 and 2.8. As shown in the figure, the Suwannee Limestone is thinnest in the east and thickens to approximately 465 feet along the western model boundary. Underlying the Suwannee Limestone are the Ocala Limestone and Avon Park Formation. Over the modeled area the Ocala thickens from approximately 200 feet in the northeast to approximately 800 feet thick in the southwest as shown in Figure 4.7. Figure 4.7 was created from the Waterstone Model (Waterstone, 2001b) files as a difference between Figures 2.8 and 2.9. Underlying the Ocala Formation is the soft to hard, chalky, cream to brown fossiliferous Avon Park Formation. The total thickness of the Avon Park Formation in the model area varies from approximately 400 to 710 feet as shown in Figure 4.8 which is the difference between the elevations of Figures 2.9 and 2.11. The evaporite zone within the Avon Park Formation is considered to be the bottom of the Upper Floridan aquifer, and the bottom of the model domain.

4.4 BOUNDARY CONDITIONS

4.4.1 Upper Boundary

As shown in Figure 4.4, the Southern District Model (SWFWMD, 2001) includes the unconfined surficial aquifer system (Layer 1) as well as two water-bearing zones in the intermediate aquifer

system (Layers 2 and 3). Instead of assigning precipitation recharge rates throughout the Southern District Model (SWFWMD, 2001) a constant head boundary condition, representing the water table was assigned in the uppermost layer (i.e., corresponding to the surficial aquifer system) of the model. Rather than explicitly incorporating the surficial and intermediate aquifers system into the density-dependent model, vertical flow through these aquifers is simulated by specifying a general head boundary (GHB) condition at the top of the UPZ (Layer 1 of the density-dependent local model). This approach is justified because the hydraulic conductivities of these intermediate aquifer system units are much smaller than those of the underlying Floridan aquifer system. Therefore, the hydraulic heads for the surficial aquifer system in the Southern District Model (SWFWMD, 2001) were used in conjunction with the leakance values assigned in the Southern District Model to represent the intermediate aquifer system (including confining units within the surficial aquifer system and two intermediate confining beds) to specify the general head boundaries. Figure 4.9 shows the head and conductance values of the general head boundary. The head values represent surficial aquifer system heads (extracted from the Southern District Model (SWFWMD, 2001), while the conductances were computed on a cell-by-cell basis as follows:

$$GHB_{cond} = 1/(1/L_1 + 1/L_2 + 1/L_3) * A_{Cell}$$

where

GHB_{cond} (ft^2/d)	=	The GHB conductance term between the Surficial Aquifer and Suwannee Limestone.
L_1 (1/d)	=	Leakance for Layer 1 (surficial aquifer) in the Southern District Model (Figure 2.3).
L_2 (1/d)	=	Leakance for Layer 2 (intermediate aquifer and confining unit) in the Southern District Model (Figure 2.4).
L_3 (1/d)	=	Leakance for Layer 3 (intermediate aquifer and confining unit) in the Southern District Model (Figure 2.5).
A_{Cell} (ft^2)	=	corresponding cell area in density-dependent model (Figure 4.3).

The exclusion of the surficial and intermediate aquifer systems facilitate the calibration of the density-dependent model (Section 5.0) by increasing the computational efficiency of the model. The justification for this approach is based upon the insensitivity of the water table to stresses within the lower artesian aquifers as evidenced by the fact that long-term and annual variations in water levels in the surficial aquifer are small compared to water level fluctuations in the Upper Floridan aquifer (Barcelo and Basso, 1993).

4.4.2 Lateral Boundaries

The pre-development heads simulated by the Southern District Model (SWFWMD, 2001) were used to provide prescribed head boundaries along the northern, southern and eastern faces of the density-dependent model. Prescribed heads along these boundaries were assigned to the Suwannee Limestone (Southern District Model Layer 2), and to the model layers that comprise the Avon Park Formation (Southern District Model Layers 6 though 10). The Ocala Limestone acts as a semi-confining unit within the modeled area and flow is predominantly vertical through this unit.

Therefore, prescribed head boundaries along the northern, southern and eastern faces of the Ocala Limestone were deemed unnecessary.

The western boundary conditions are also specified as constant heads (prescribed heads) and are in hydrostatic equilibrium with the Gulf of Mexico. These heads were adjusted during the model calibration process (Section 5.0). Theoretically, either hydraulic heads or water fluxes could have been applied along the lateral boundaries. The appropriateness of the constant head boundaries, particularly for the transient post-development simulations, was further evaluated during the model calibration process.

4.4.3 Lower Boundary

The lower boundary was chosen as the top of the middle confining unit of the Floridan Aquifer system. This is generally associated with the first occurrence of intergranular evaporites near the base of the Avon Park Formation (Barcelo and Basso, 1993). Because of the very low permeability in this part of the flow system, the bottom boundary was simulated as a no-flow boundary. This is consistent with all other modeling studies that have been conducted within the SWUCA.

4.5 PRELIMINARY MODEL PARAMETERIZATION

Hydraulic Conductivity

As discussed above, the modeling approach which was used by SWFWMD to perform the regional groundwater flow simulations requires transmissivity values as input for each of the aquifers and confining units. To accurately predict chloride transport through the aquifer, however, the two components of transmissivity (i.e., aquifer or confining unit thickness and hydraulic conductivity) must be explicitly defined using the following equation:

$$K_h = T/b$$

Where

K_h = aquifer layer horizontal hydraulic conductivity (ft/day)
T = aquifer layer transmissivity derived from the Southern District Model (ft^2/day)
b = aquifer layer thickness

Initial values for hydraulic conductivity of the aquifer layers and confining units were derived from calibrated transmissivity and leakance values that were assigned to the Southern District Model. These values may be slightly altered, however, during the future model calibration (Section 5.0), to honor the chloride transport physics and chloride data as well as the head data which alone were used to calibrate the regional groundwater flow model.

It was assumed that horizontal hydraulic conductivity is isotropic in all model layers. That is, horizontal hydraulic conductivity was assumed to be equal in the row and column directions. No regional-scale data on horizontal anisotropy exists within the model area, and the assumption of

isotropic conditions is consistent with previous models. A horizontal to vertical anisotropy of 100:1 is assumed for the aquifer units (i.e., the Suwannee Limestone and the Avon Park Formation). The vertical hydraulic conductivity of the Ocala Limestone was initially computed from the appropriate leakance of the Southern District Model, and Ocala Limestone thickness. However, since the leakance of the Southern District Model was a uniform value, its manipulation with non-uniform thickness provided spatially varying vertical hydraulic conductivities. This was deemed difficult to justify from sparse available measurements, therefore, a uniform vertical conductance of 0.2 ft/d was adopted early in the calibration process. It was noted that this conversion did not significantly affect simulated heads, flows or chlorides. A value of 2 ft/d was provided for the horizontal hydraulic conductivity of the Ocala Limestone. The horizontal conductance of the Ocala Limestone is much smaller than for the Avon Park Formation and the Suwannee Limestone with smaller total thickness, therefore the consequences of a uniform 2 ft/d horizontal hydraulic conductivity for the Ocala Limestone on horizontal flow through the system is minimal.

Suwannee Limestone

The transmissivity of the Suwannee Limestone assigned in the Southern District Model is shown in Figure 2.7. This transmissivity was divided by the thickness of the Suwannee Limestone (Figure 4.6) and input into the density-dependent model as horizontal hydraulic conductivity (Figure 4.10).

Ocala Limestone

In the Southern District Model the Ocala Limestone is treated in a quasi-three-dimensional manner, with leakance supplied across its thickness. A uniform leakance value of 10^{-2} ft/day was used throughout the domain. A uniform leakance value with varying thickness would produce a varying vertical conductivity for the Ocala Limestone, which would be difficult to justify based on available data. Therefore, a uniform value of hydraulic conductivity was used for the Ocala Limestone with horizontal conductivity of 2 ft/d and a vertical conductivity value of 0.2 ft/d. The vertical conductivity value is an average of available data. The horizontal conductivity value is not significant to the model because it is much smaller than the horizontal conductivity of the adjacent aquifer units of the Upper Floridan aquifer.

Avon Park Formation

The horizontal hydraulic conductivity of the Avon Park Formation (Figure 4.11) was derived by dividing the transmissivity of the Ocala Limestone/Avon Park Formation in the Southern District Model (Model Layer 5) (Figure 2.10) by the aquifer thickness of the Avon Park Formation in the Waterstone Model (Waterstone, 2001b) (Figure 4.8). This approach assumes that the Ocala Limestone does not contribute significantly to the transmissivity assigned to the Ocala Limestone/ Avon Park Limestone in the Southern District Model. Based upon the low hydraulic conductivity of the Ocala Limestone, this assumption is reasonable.

4.6 SOUTHERN DISTRICT MODEL TRANSLATION

The density-dependent saltwater intrusion study was initiated by first translating the regional model parameters and local model boundary conditions from the Southern District Model (SWFWMD,2001). A pre-development, steady-state groundwater flow simulation was then performed using MODHMS to evaluate the resultant hydraulic heads. This simulation was conducted in order to compare the hydraulic head distribution simulated using the local-scale MODHMS model to the hydraulic head distribution simulated using the regional MODFLOW model. The primary goals of this initial simulation were threefold: (1) to ensure that the input parameters and boundary conditions assigned in the local-scale model were consistent with the Southern District Model; (2) to detect errors in the model input files; and (3) develop the framework of the coupled flow and transport model, which will be calibrated to transient hydraulic heads and chloride distributions. For this simulation, pre-development steady-state conditions were evaluated by turning off all pumping and injection wells and the aquifer system was assumed to be free of saltwater. Parameter values and boundary conditions were derived from the regional groundwater flow model, of pre-development conditions. The pre-development modeling results (without saltwater) are shown for the Avon Park Formation (i.e., model layer 8) in Figure 4.12. The pre-development potentiometric surface for the Ocala Limestone/Avon Park Formation as predicted by the Southern District Model (SWFWMD, 2001) (i.e., model layer 5) is also presented in Figure 5.1. A comparison of the hydraulic heads simulated using both the regional and local-scale models indicates that the simulation results are in excellent overall agreement. The hydraulic head distributions calculated for the other model layers within the Upper Floridan aquifer also compare well with the Southern District Model.

4.7 SALTWATER TRANSPORT PROPERTIES

Since MODHMS simulates both freshwater and saltwater, additional data not contained in the Southern District Model files were required to complete simulations. The additional fluid and aquifer parameters required for this study are summarized in Table 4.1.

A key component in reliably evaluating density-dependent saltwater intrusion is the dispersivity of the various materials in the system. Due to large anisotropies between the horizontal and vertical directions, the dispersivities used in this system should reflect these anisotropies. The 4-component anisotropic dispersivity tensor of Guvanasen (2002) provides adequate control for such systems. The longitudinal and transverse dispersivities in the horizontal direction control dispersion due to horizontal flow in the longitudinal and horizontal transverse directions. The longitudinal and transverse dispersivities in the vertical direction control dispersion due to the vertical flow component, and vertical transverse dispersion due to horizontal flow, respectively. Typically, the vertical components of dispersivity are an order of magnitude lower than the corresponding horizontal components for three-dimensional anisotropic systems, since the mixing effects in the vertical direction are smaller than those of the horizontal direction. Using a 2- or 3-component dispersivity tensor for such systems tends to smear the transport species over the entire thickness of the modeled unit, and thus misrepresents the saltwater intrusion, causing further errors in the density-dependent flow term. Initial estimates of dispersivity coefficients for this study were taken from the Waterstone Model (Waterstone, 2001b) as shown in Table 4.2.

5.0 MODEL CALIBRATION

Model calibration is the process where model parameters and/or boundary conditions are adjusted to obtain a satisfactory match between observed and simulated conditions. Typically, the objective of model calibration is to develop a model that is capable of accurately predicting past, current, and/or future conditions. A model is calibrated by determining a set of parameters, boundary conditions, and hydraulic stresses that generate simulated potentiometric surfaces, fluxes and concentrations that match field-measured values to within an acceptable range of error. The end result of the process of model calibration is an optimal set of parameter values and boundary conditions that minimize the discrepancy between modeling results and the observed data.

The following sections detail the model calibration process that was completed as part of the current saltwater intrusion modeling investigation.

5.1 MODEL CALIBRATION STRATEGY

5.1.1 General Calibration Approach

At the beginning of the calibration process, model calibration goals were formulated in order to produce a model that accomplishes the project objectives outlined in Section 1.2, while recognizing the inherent uncertainties and limitations of the saltwater intrusion model. The primary limitations associated with the saltwater intrusion model are mainly caused by data uncertainties, resulting from the use of discrete borehole data to characterize subsurface conditions on a regional basis. Due to the size of the model domain and the spatial distribution of field data, hydraulic properties and boundary conditions are estimated over relatively large areas in the model, and small-scale heterogeneities cannot be represented. Therefore, the model is best suited to simulate groundwater flow patterns and chloride concentrations on a regional basis. This supports the primary objective of the model, which is to predict the large-scale impact of groundwater management options on saltwater intrusion.

The calibration strategy was designed to produce a model that is capable of simulating the general groundwater flow patterns and regional trends in chloride concentration. Consistent with this goal, model parameter values and boundary conditions were not adjusted beyond the limits of field measurements solely for the purpose of improving the calibration results. In addition, the principle of parameter parsimony was applied as a fundamental philosophy during the calibration. This rule dictates that the model should be calibrated with the fewest number of model parameters that are supported by field data or other supporting evidence. The use of excessive model parameters or parameter zones during model calibration creates a situation in which many combinations of model parameter values will produce equivalent calibration results. By following the principle of parameter parsimony, the goal is to reduce the degree of nonuniqueness and obtain a result which yields more reliable calibrated parameter values. The information gathered for the conceptual model guides any decision to add model parameters (e.g., zones of hydraulic conductivity) or change parameter values during the calibration process. Therefore, in the absence of hydrogeologic evidence that supports the inclusion of additional zones, the simpler model is preferred even at the expense of matching the calibration targets more closely. Although this approach may not result in the model that produces the best fit to the available data (i.e.,

calibration targets), it does, however, allow areas of greatest data uncertainty to be identified and targeted for future field work.

An iterative, two-phased approach was used to calibrate the local-scale, saltwater intrusion model. This involved the following:

- Pre-development Calibration (Phase 1): Calibration of the model to match hydraulic heads and chloride concentrations associated with pre-development conditions (i.e., year 1900); and

- Post-development Calibration (Phase 2): Transient calibration of the model to match hydraulic heads and chloride concentrations associated with post-development conditions (i.e., 1900 through 2000).

The first phase of the calibration process involved using MODHMS to simulate density-dependent groundwater flow and saltwater transport to reproduce pre-development conditions. During the calibration process, hydraulic parameters, transport parameters, and boundary conditions were adjusted, and the model results were compared to: (1) a map illustrating the development potentiometric surface in the Upper Floridan aquifer (Johnson et al., 1980); and (2) pre-development chloride concentrations simulated during previous saltwater intrusion modeling investigations (HydroGeoLogic, 1994a, 1994b, 1994c, 1993a, 1991a). Hydraulic head and chloride concentration data are not available for the pre-development period (i.e., approximately 1900); consequently, a rigorous, quantitative calibration was not performed during this phase of the calibration. However, estimates of the pre-development potentiometric surface was constructed by Johnston et al., (1980) and provided a qualitative means to check the pre-development calibration.

During the second phase of the calibration process, MODHMS was used to simulate transient, coupled groundwater flow and saltwater transport. These transient simulations were performed to simulate hydraulic heads and chloride concentrations from year 1900 (i.e., pre-development conditions) through December 2000. During the transient calibration, simulated hydraulic heads and chloride concentrations were compared to field data measured between 1993 and 2000. During the second phase, parameter values, model layering and boundary conditions were adjusted to allow the model to fit the calibration criterion discussed in detail in Section 5.1.2. The following sections describe the calibration process in greater detail.

5.1.2 Pre-Development Calibration

Prior to initiating the pre-development calibration, the local-scale model was revised to simulate coupled groundwater flow and saltwater transport. This involved the following:

- Assignment of constant chloride concentration boundary conditions along the lateral boundaries of the model:

- Specification of initial chloride concentrations throughout the model domain; and

- Assignment of transport properties within the model domain (e.g., porosity, dispersivities, fluid density, etc.).

The initial chloride concentrations that were assigned in the model were estimated based on observed chloride concentrations. Likewise, the preliminary chloride concentrations assigned to the constant concentration boundary conditions were also based on field data. These boundary conditions were adjusted along with transport properties, groundwater flow parameters, and constant head boundary conditions during the model calibration process described in Section 5.2.

Due to convergence problems that were encountered during preliminary simulations, the time-marching method described in Section 4.2 was applied during the pre-development simulations. To examine how close the final solution was to the true steady-state solution, chloride concentrations calculated for the last time step were compared to chloride concentrations calculated for earlier time steps. The solution was deemed to represent steady-state conditions when there were insignificant changes in chloride concentrations and when the storage terms of the mass-balance for flow and transport were small in comparison to the other flux terms.

The objective of the pre-development calibration was to simulate steady-state groundwater flow conditions and chloride concentrations for the period prior to the development of groundwater resources (i.e., approximately 1900). Because conditions that existed during this time are not known with certainty, a rigorous, quantitative calibration could not be completed. Instead, a qualitative calibration was completed, which involved the adjustment of model parameters and boundary conditions to match the following: 1) potentiometric surface contours estimated by Johnson et al., 1980; and 2) the lateral and vertical extent of chloride predicted for pre-development conditions during earlier investigations.

As discussed in Section 3.0, the distribution of chloride for pre-development conditions was estimated during several modeling investigations (HydroGeoLogic, 1994a,1993a,1991a). During the pre-development calibration, the chloride concentrations predicted by the current saltwater intrusion model were compared to the distribution of chloride presented in Figures 2.16 and 3.1. Because direct observations are not available for pre-development conditions, there is significant uncertainty in the distribution of chloride shown on these figures. Consequently, the goal of the pre-development calibration was to match the general pattern shown on the figures. A similar approach was adopted for calibrating the model to the inferred pre-development potentiometric surface contours developed by Johnson et al. (1980). The goal was simply to match the general shape of the contours.

5.1.3 Post-Development Calibration

During the second phase of the calibration process, the model was calibrated to post-development conditions (i.e., post-1900). To investigate the impact of groundwater withdrawals on the flow system, hydraulic heads and chloride concentrations were simulated for a period extending from approximately 1900 (i.e., pre-development conditions) to 2000. During these simulations, the hydraulic stresses associated with pumping were simulated by making two modifications to boundary conditions assigned in the model. First, the lateral boundaries of the model were modified to reflect the post-development hydraulic heads resulting from regional groundwater

production. The post-development hydraulic heads that were assigned as lateral boundary conditions in the density-dependent model were derived from hydraulic heads simulated using the Southern District Model (SWFWMD, 2001). Secondly, groundwater extraction rates associated with production wells were assigned throughout the model. The groundwater extraction rates assigned in the model were based on the estimated water use for the area, and derived from the pumping/ injection well data compiled by the SWFWMD and represented in the Southern District Model (SWFWMD, 2001).

To complete the simulations, landward lateral boundary heads and well pumping rates were varied every 5 years for the first 60 years, with yearly variations for the next 15 years, followed by variations every 4 months up to December 2000. Boundary heads were obtained using the hydraulic head fields developed by performing parallel transient simulations using the Southern District Model (SWFWMD, 2001) constructed by the SWFWMD. The location and model layer of the groundwater extraction/injection wells within the density-dependent model domain are shown in Figure 5.1. These wells were represented in the local-scale saltwater intrusion model using an analytic element boundary condition. This type of boundary condition allows the water, entering the well from multiple model layers, to be proportioned based upon the hydraulic properties of the respective model layers.

Both quantitative and qualitative methods were employed to calibrate the local-scale saltwater intrusion model to post-development conditions. As part of this effort, the following data were used as the primary calibration targets:

- Chloride data collected as part of the Regional Observation Monitoring Well Program (ROMP);
- Chloride data collected as part of the Water Quality Monitor-Well Program (WQMP); and
- Potentiometric surface maps prepared by the USGS (2001) for the Upper Floridan aquifer.

Chloride data collected as part of the Regional Observation Monitoring Well Program (ROMP) provided the primary data set that was used to calibrate the saltwater intrusion model to post-development conditions. The ROMP data differs from other sources of chloride data in that it characterizes both the spatial and vertical distribution of chloride through a large number of exploratory wells (Figure 2.15). This data generally characterizes the distribution of water quality with depth at a single location during a single sampling event. The ROMP data is collected using a variety of sampling methods including bailers, thief samplers, and packer tests. The locations of the ROMP wells that were used for determining model calibration statistics are shown in Figure 5.2. These wells lie in the central portion of the model domain within the primary areas of interest. Since the data quality at a number of the ROMP wells is questionable, only the ROMP data identified by the SWFWMD as being of high quality were used for this investigation. Chloride concentrations with depth for each of these ROMP wells are presented in the Appendix B.

Chloride data collected as part of the WQMP were used to augment the ROMP data during the model calibration. Under the WQMP, the SWFWMD routinely samples and analyzes

groundwater to monitor potential saltwater migration. This data is collected by the SWFWMD primarily from dedicated monitoring wells. The WQMP data is the best source of temporal chloride data within the coastal region of the SWUCA.

In addition to chloride data, the model was calibrated to hydraulic head data compiled by the USGS, which develops potentiometric surface maps for the Floridan Aquifer for September and May of each year. Typically, these represent the annual water-level low and high periods, respectively. During the post-development calibration, simulated hydraulic head distributions were compared to potentiometric surface maps developed for May and September 2000. This time period was selected, because it is the most recent time period in which hydraulic head data were available during this investigation.

Using the data described above, several measures were used to calibrate the saltwater intrusion model to post-development conditions including the following:

- Visual comparison of vertical profiles illustrating simulated chloride concentrations and chloride concentrations (using data from WQMP and ROMP wells);
- Statistical comparison of simulated chloride concentrations and chloride concentrations observed at the ROMP wells (using data from WQMP and ROMP wells);
- Plots illustrating the relationship between simulated chloride concentrations and chloride concentrations obtained from ROMP wells;
- Visual comparison of the predicted chloride distribution to maps illustrating the current extent of saltwater;
- Visual comparison of observed and temporal changes in chloride concentrations (using WQMP data); and
- Visual comparison of potentiometric surface maps developed using observed and simulated hydraulic head data (i.e., using potentiometric surface maps developed by the USGS for year 2000).

The vertical chloride profiles provided the most useful calibration measure to evaluate the model's ability to reproduce post-development conditions. The profiles that were used during the calibration are presented in Appendix A. The vertical profiles provided a mechanism to evaluate the slope, thickness, width, and depth of the saltwater interface. The ROMP wells provided the majority of the data that were used to develop the vertical profiles. However, the vertical profiles also included limited data that were collected as part of the WQMP.

A more quantitative assessment of the calibration was completed using statistical measures describing the relationship between simulated chloride concentrations and chloride concentrations observed at selected ROMP wells. The primary criterion for evaluating the calibration of a groundwater transport model is the difference between simulated and observed chloride concentrations at a set of calibration targets (typically monitoring wells). A residual or model

error, e_i, is defined as the difference between the observed and simulated chloride concentrations measured at a target location:

$$e_i = c_i - \hat{c}_i$$

where c_i is the measured value of chloride concentration and $\hat{c}_i$ is the simulated value at the ith target location (i.e., at an individual ROMP wells). A residual with a negative sign indicates over-prediction by the model (i.e., the simulated chloride concentration is higher than the measured value). Conversely, a positive residual indicates under-prediction.

Several statistical measures were used to gauge the success of the model calibration. During the calibration process, an objective was to minimize the residual sum of squares (RSS) while still honoring the field data:

$$RSS = \sum_{i=1}^{n} (e_i)^2$$

where n is the total number of calibration targets. The RSS is a primary measure of model fit. The root mean squared (RMS) error, which normalizes the RSS by the number of calibration targets, is defined as follows:

$$RMS = \sqrt{\frac{RSS}{n-1}}$$

Another calibration measure that was used to evaluate the calibration is the residual mean:

$$\bar{e} = \frac{1}{n} \sum_{i=1}^{n} e_i$$

A mean residual significantly different from zero indicates that the model produces biased results (i.e., over-predicts or under-predicts chloride concentrations).

The chloride concentrations observed at the ROMP wells represent a small, discrete vertical interval within a given hydrostratigraphic unit. The groundwater samples taken from the ROMP wells represent a much smaller interval than the thickness of the finite-difference cells in which chloride concentrations are calculated using the saltwater intrusion model. In fact, for each finite-difference cell containing a ROMP well, there are typically multiple observed chloride concentrations associated with different depth intervals. In order to compare the observed and calculated chloride concentrations, average observed chloride concentrations were calculated for each model layer associated with a ROMP well location, and the residuals were calculated by subtracting the simulated chloride concentration at each finite-difference cell from the average chloride concentrations obtained from the ROMP wells. This averaging, however, produced inherent errors within the statistical analysis which are accentuated due to the sharp increases in chloride concentrations over short intervals. A vertical refinement of the numerical grid would

probably result in better calibration statistics, although it would probably have little impact on the overall characteristics of the chloride distribution.

After a review of the existing data, and conversations with the SWFWMD regarding the quality of the well data, sixteen ROMP wells were selected for the statistical analysis. As shown in Figure 5.2, the majority of the wells are located over the primary area of interest, within the west central portion of the model domain within the chloride interface zone. Several of these wells are closely spaced, and aligned in an east-west orientation (e.g., TR AB-1, TR 9-2, TR AB-3). The data from these wells provided a means to evaluate the slope of the chloride interface during the model calibration.

In addition to the statistical evaluation of model residuals and the visual comparison of model results to vertical chloride profiles, maps were developed to evaluate the reliability of the calibration. A comparison between contour maps of measured and simulated values (i.e, hydraulic heads and chloride concentration) were prepared to provide a visual, qualitative measure of the similarity between patterns, thereby giving some idea of the spatial distribution of calibration errors. In addition, vertical and horizontal hydraulic heads and the fluid flux moving across the model boundaries were used as qualitative calibration criteria.

5.2 MODEL CALIBRATION IMPLEMENTATION

Section 4 describes in detail the approach used to construct the preliminary density-dependent groundwater flow and solute transport model to simulate saltwater intrusion in coastal portions of the SWUCA. The sections that follow primarily describe the changes and refinements that were made during the calibration process.

5.2.1 Evaluation of Alternative Conceptualizations and Uncertainty

One primary goal of mathematical modeling is to synthesize the conceptual model into numerical terms from which flow and transport processes may be investigated under specified conditions. This process entails several discrete steps: (1) partitioning the conceptual model into units of time and space; (2) assignment of boundary conditions; and (3) specification of the parameter values. There are always uncertainties in predictions derived from modeling. These uncertainties are frequently divided into two main categories: (1) conceptual model uncertainty; and (2) parameter uncertainty. This section briefly describes these uncertainties and the approach that was applied to address these uncertainties in the model calibration process.

The conceptual model is based on the modeler's knowledge, experience and technical judgment and represents the modeler's understanding of the system framework and behavior, from all available data and information at the site. The conceptual model will naturally become more complex as more processes are identified and interrelationships of important components within the system are considered. The transformation of the conceptual model into a mathematical model is a further extrapolation of the basic understanding of the system into a discretized numerical framework resulting in intrinsic simplifications of the system. The lack of knowledge about the system resulting from limited information also contributes to inevitable simplifications in the

conceptual and mathematical models, in the sense that spatial correlations or zoning of material properties may not represent existing conditions.

As part of the model calibration process, a series of hypotheses were developed and numerical experiments were performed to address aspects of the conceptualization or parameterization that could improve model performance during the model calibration. Table 5.1 provides several significant results of these analyses.

5.2.2 Calibrated Model Domain and Discretization

As described in Section 4.0, the initial local-scale model consisted of 10 layers of finite-difference cells. During the model calibration process, an additional model layer was added to the base of the model to allow chloride transport through the Middle Confining Unit (i.e., evaporites) to be explicitly simulated. The vertical discretization of the calibrated density-dependent model consists of 11 layers as shown in Figure 5.3. This additional layer provides the necessary mechanism to more adequately simulate chlorides entering the Avon Park Formation from the evaporites below.

5.2.3 Calibrated Boundary Conditions

Upper Boundary

As presented in Section 4.4, rather than explicitly incorporating the surficial and intermediate aquifer system into the density-dependent model, vertical flow through these aquifers is simulated by specifying a general head boundary condition at the top of the Suwannee Limestone (model layer 1). This conceptualization was maintained throughout the model calibration and the upper boundary and its values were unchanged from those presented in Figure 4.9. The exclusion of the surficial and intermediate aquifer system facilitated the density-dependent model calibration by increasing the computational efficiency of the model, and is justified based upon the insensitivity of the water table to stresses within the lower artesian aquifers as evidenced by the fact that long-term and annual variations in water levels in the surficial aquifer are small compared to water level fluctuations in the Upper Floridan aquifer (Barcelo and Basso, 1993).

Lateral Boundaries

The pre-development and post-development heads simulated using the Southern District Model (SWFWMD, 2001) were used to develop prescribed head boundaries along the northern, southern and eastern faces of the density-dependent model (Section 4.4). Prescribed heads were assigned along these boundaries in model layers representing the Suwannee Limestone (model layers 1&2) and Avon Park Formation (model layers 8,9 and 10). The Ocala Limestone acts as a confining unit within the modeled area and flow is predominantly vertical through this unit. Therefore, prescribed head boundaries along the northern, southern and eastern faces of the Ocala Limestone were deemed unnecessary. The northern, southern, and eastern lateral boundary heads presented in Section 4.4 were unchanged for the final calibration simulation. Figure 5.4 shows the boundary conditions that were applied to the lateral boundaries of the density-dependent model.

The western boundary conditions are also specified as constant heads (prescribed heads) and were originally derived from the heads calculated in the Southern District Model (SWFWMD, 2001). These heads are based on assumptions pertaining to the relationship between the pressure head within the aquifers and the hydrostatic head within the ocean. Therefore, in the calibrated model the heads along the western boundary are set to zero in the uppermost layer and increase with depth to account for chloride density.

During the post-development calibration, the hydraulic stresses associated with pumping were simulated by making two modifications to boundary conditions assigned in the predevelopment model. First, the landward lateral boundaries of the model were modified to reflect the post-development, transient hydraulic heads resulting from regional groundwater production. These boundaries were modified based on the results of transient simulations performed using the Southern District Model (SWFWMD, 2001). These transient effects on the head boundaries are obtained from parallel transient simulations made with the Southern District Model (SWFWMD, 2001) by the SWFWMD and representative variations in the north and southeast corners of the model domain as illustrated in Figure 5.5. Second, transient groundwater extraction rates associated with production wells were assigned throughout the model.

A relative chloride concentration of one was applied along the western lateral boundary and along seaward portions of the northern and southern lateral boundaries. These boundaries for concentrations are prescribed for all inflow nodes. The option in enabled in MODHMS to provide flux boundaries at outflow nodes along this boundary.

Lower Boundary

The lower boundary for the calibrated model is located between 200 and 400 feet below the top of the middle confining unit of the Floridan Aquifer system. A general head boundary (GHB) condition was applied along this boundary. A uniform environmental head of 40 feet and a vertical conductance of 0.001 ft/day was assigned to all general head boundary conditions. Concentrations assigned to the general head boundary conditions are variable and range from 5,700 mg/l along the eastern boundary to 19,000 mg/l at the ocean (Figure 5.6). This concentration distribution does not significantly affect results as compared with applying a uniform 19,000 mg/L concentration, however, the distributed concentration boundary was adopted in the calibrated model to honor available data.

5.2.4 Calibrated Model Parameters

Groundwater Flow Parameters

As discussed in Section 4, initial values for hydraulic conductivity of the aquifer layers and confining units were derived from calibrated transmissivity and leakance values that were assigned to the Southern District Model (SWFWMD, 2001). This approach was adhered to during the model calibration process.

A uniform vertical conductivity of 0.02 ft/d was applied to the Ocala Limestone to conform with average measurements. It is assumed that horizontal hydraulic conductivity is isotropic in all

model layers. That is, horizontal hydraulic conductivity was assumed to be equal in the row and column directions. Regional-scale data related to horizontal anisotropy was not available for the modeled area, and the assumption of isotropic conditions is consistent with previous models. A vertical to horizontal anisotropy ratio of 1:100 was applied to all units as discussed in Section 4.

Although the transmissivity assigned to the Avon Park Formation is the same in both the calibrated saltwater intrusion model and the Southern District Model (SWFWMD, 2001), the distribution of hydraulic conductivities among model layers within the Avon Park Formation was altered during model calibration. The Avon Park Formation is now conceptualized as having a highly permeable zone (in model layers 6 and 7) overlying the rest of the formation (model layers 8, 9 and 10). The hydraulic conductivities of these zones are presented in Figure 5.7 (for model layers 6 and 7) and Figure 5.8 (for model layers 8, 9, and 10). This hydraulic conductivity distribution provides an effective transmissivity for the Avon Park Formation that is identical to that used for the Southern District Model (SWFWMD, 2001), except for under Hillsborough Bay and Tampa Bay where the areal zones of transmissivity have been slightly modified by assigning a more gradational trend.

Saltwater Transport Properties

The values for effective porosity, dispersivity and storativity were adjusted during the model calibration in order to better match the measured field data. In general, lower effective porosities resulted in greater saltwater intrusion due to the increased velocities. Dispersivity values had a dominant effect on the spread and concentrations of the chlorides, with larger dispersivities causing a larger transition zone. The distribution of the post- development hydraulic heads are sensitive to the assigned storativity values. The transport properties that were assigned in the calibrated model are presented in Table 5.2.

5.3 MODEL CALIBRATION RESULTS

5.3.1 Pre-Development Calibration Analysis

As previously presented in Section 5.1.2, the calibration criteria for pre-development conditions are based primarily on the results of earlier modeling work that predicted the location of the saltwater interface shown in Figure 3.1. A comparison of the current modeling work with those earlier results is presented in Figure 5.9. As shown in that figure, the tip of the interface crisscrosses the tip location predicted by the HydroGeoLogic (1994) model. In the southwestern portion of the model the tip makes a sharp turn inland, due most likely to localized boundary effects. The toe of the plume follows the same general shape as that of the previous modeling investigations conducted by HydroGeoLogic, in 1993 and 1994. The most recent modeling, however, predicts greater saltwater intrusion in the northern part of the model domain than the other models and less intrusion from the center of the model southward. The toe location, in the cental portion of the model coincides reasonably well with the location predicted by the cross sectional model of HydroGeoLogic (1991).

Figure 5.10 presents calibrated pre-development potentiometric surface for the Suwannee Limestone (model layer 2) superimposed over the pre-development potentiometric surface

prepared by Johnston et. al. (1980). The model is in very good agreement with the estimated hydraulic heads and typically differ by less than 5 feet except in the northeastern region of the model. In a similar comparison, the potentiometric surface prepared by Johnston et. al. (1980) was superimposed over the surface predicted by the model for Avon Park Formation (model layer 7) (Figure 5.11). Again the heads compare favorably and generally there is less than a 5-foot head difference.

5.3.2 Post-Development Calibration Results

After satisfactory pre-development, steady-state chloride concentrations were simulated using the local-scale model, the model was calibrated to conditions observed between 1993 and 2000 by performing transient simulations. The local-scale model was used to simulate conditions from 1900 (i.e., pre-development conditions) through 2000.

Chloride Interface Characteristics

Chloride concentrations with depth have been measured for each of these ROMP wells and are presented in the Appendix B. As discussed in Section 5.1.2, the chloride concentrations predicted by the model were superimposed over the actual field data to visually inspect the ability of the model to simulate the observed vertical and spatial distribution of chloride. A more quantitative assessment of the calibration was performed by computing an average error and a root mean square error for chloride concentrations observed at selected ROMP wells. Since the data quality at a number of the ROMP wells is questionable only the ROMP wells where the data is known to be of high quality were used for this analysis and are shown in Figure 5.12 along with the areal distribution of calibration errors (i.e., residuals). These errors are depicted in three distinct model layers to present the distribution of errors within different aquifer units. It is noted that the model errors are generally unbiased in space. However, the model overestimates chloride concentrations in the deeper layers in the southern coastal regions of the domain and underestimates chloride concentrations in the deeper layers in coastal Hillsborough County.

The calibration statistics are also summarized in Table 5.3 and a scatterplot of measured vs. simulated chlorides is shown in Figure 5.13. The scatterplot presented in Figure 5.13 illustrates that there is not a systematic bias (i.e., underestimation or overestimation) of chloride concentrations within the model domain. This observation is supported by the part that the residual mean (-0.00439) is close to zero. It may be noted from the chloride profiles (Appendix B) that concentrations change over several orders of magnitude within a few hundred feet. As shown in the scatter plot and Table 5.3, the residuals are generally unbiased and tend to be over- and under-estimated with approximately the same degree of frequency. Other observations with respect to the model comparison with the ROMP well data includes the following:

1. A good fit was obtained to the low chloride concentrations inland at ROMP 61, 49, 39, 33, and 22.

2. The model predicted chloride concentrations satisfactorily match observed chloride concentrations in the Ocala Limestone in the north for coastal wells TR AB-1, TR 9-2, TR 9-1, TR AB-3, TR 8-1.

3. Model predictions are low for chloride in the Avon Park Formation in the north at TR AB-1, TR 9-2.

4. The model provides a good fit to chloride concentrations in the Avon Park Formation at coastal well TR 8-1 (northern well south of TR 9-2).

5. A good fit for chloride was obtained in the Ocala Limestone and Avon Park Formation at coastal wells TR 7-2 and TR 7-4 (south of TR 8-1).

6. Model predictions are high in the Ocala Limestone and low in the Avon Park Formation at coastal wells TR SA-1, TR SA-3 (south of TR 7-2).

7. Model predictions for chloride are high in the Ocala Limestone at coastal wells 20, TR 4-1 (south of TR SA-3).

8. The model provides a good fit to chloride concentrations in the Ocala Limestone at inland well 9 near the southern model boundary.

The slope of the chloride interface, that can be calculated from the exploratory data at TR-SA-1 and TR-SA-3 was also used as a calibration measure which was evaluated against ROMP wells TR AB-1, TR 9-2 and TR AB-3 in coastal Hillsborough County. These wells are aligned perpendicular to the coastline and provide a good cross-sectional representation of the interface slope since the interface lies within the sampled interval in all three wells. As shown in Appendix B, the model provides a good depiction of the chloride profiles for these wells, and, hence, of the interface slope.

Another metric applied to the calibration effort was the thickness of the transition zone. It is noted from available data (see Appendix A for chloride data in ROMP wells) that the transition zone is fairly thin with rapid degradation of water quality from fresh to saltwater across the interface. This feature was duplicated by the model in addition to providing a good fit on average chloride data and depth to interface.

As previously discussed in Section 2, Beach and Kelley (1998) projected the freshwater-seawater interface onto hydrogeologic cross sections at six locations along the coast (Figure 2.16). The distance along each cross section to the toe was superimposed onto a map. A smooth line through each toe was drawn delineating the 1,000 mg/l chloride concentration defining the areal extent of the interface between the freshwater and saltwater. This approach was later updated (Beach and Schultz, 2000) by delineating the top and bottom of the highly permeable zone from exploratory drilling data and adding this information to each cross section. Beach and Schultz (2000) determined that the current position of the interface toe in the Avon Park Formation is only two to three miles inland in south Hillsborough County. In Sarasota County, the interface toe in the Avon Park Formation may be as much as ten miles inland. These estimates have been superimposed on the calibrated model results and presented in Figure 5.14. This figure indicates that the model predicts a similar overall shape to the saltwater interface but predicts that the saltwater interface is less inland in the northern and southern portions of the model domain.

The chloride interface in the Suwannee Limestone is shown on Figure 5.15. The calibrated model indicates that there has been almost no saltwater intrusion within the Suwannee Limestone except in the southern portion of the model domain south of Sarasota. Chloride interface for the Avon Park Formation layers 6, 8, and 10 are shown in Figures 5.16 through 5.18, respectively. These figures indicate that chloride intrusion roughly follows the coastal profile and increases with depth in the Avon Park Formation.

To illustrate the changes of chloride concentrations with time, a series of plots have been constructed comparing the model predictions to the actual field data. Figures 5.19 through 24, show the model predicted chloride concentrations versus time, superimposed on field data measured at selected ROMP wells.

The trend of the chloride data in TR-9-3 is relatively stable in the Suwannee Limestone, and sharply increases in the Avon Park (Figure 5.19). The model underpredicts the chloride concentrations in both layers. The trend of the data in the Avon Park illustrates the difficulty in matching the sharp increases in concentrations over short time periods. Although the trend in the model is upward it is not nearly as steep as that observed in the measured data. Some of this difference can be attributed to the fact that the model averages chloride concentrations over grid blocks and cannot simulate the sharp fluctuations in the chloride concentrations, which occur over short intervals. Again, a similar effect is observed in ROMP TR 9-2 (Figure 5.20). TR 8-1 provides a very good match to the data in both chloride concentrations as well as temporal trends (Figure 5.21). Observed chloride concentrations in ROMP 50, however, are significantly overestimated by the model (Figure 5.21), although the tends are similar. ROMP 22 provides a reasonable match to the data, but the increasing trend predicted by the model is not replicated by the field data. The model overestimates the chloride data collected from ROMP 20 (Figure 5.22) and predicts an slightly increasing trend which the data suggests that the chloride concentrations may be decreasing. The model underestimates the observed concentrations in both in ROMP 33 and 39 (Figure 5.23), although at the low chloride concentrations in these wells the differences could represent only minor differences. Figure 5.24 indicates that indicates that the model is slightly over predicts the data from TR SA-1, and significantly over-predicts the data from ROMP TR SA-3.

Although the model did not fit the transient chloride data particularly well, in general, the model provided a much better fit to the static ROMP well data. The greatest source of error aside from the unknown heterogeneities within the aquifer property values, is probably associated with the vertical discretization of the model not being at the same scale as the collected data. Chloride concentrations in the model are averaged over several hundred feet as compared with tens of feet in the field. This inconsistency in scale makes it difficult to precisely match the field data, particularly at high chloride concentrations, without introducing too much chloride to the model. This problem is aggravated because the interface transition zone is relatively thin and concentrations change dramatically over short vertical distances. The model does, however, provides a very good representation of the chloride intrusion characteristics and should provide an adequate means to meet the project objectives of the SWFWMD.

Post-Development Hydraulic Heads

To evaluate the hydraulic response of the calibrated model, a comparison of the calibrated model hydraulic heads was made against the potentiometric surfaces from September 2000 and May 2000 prepared by the U.S. Geological Survey (USGS). Typically, these represent the annual high water level period and the annual low water period, respectively. A comparison between the USGS potentiometric surface for May 2000 and the corresponding model predicted head distribution for the Suwannee Limestone is shown in Figure 5.25. The potentiometric surface constructed by the USGS indicates that the measured head values are lower than the predicted head values by approximately 35 feet in the northeastern portion of the model to about zero feet within the southeastern portion of the model. The measured heads are approximately 5 to 20 feet lower than predicted values in the central portion of the model. The general shape of both contour sets, however, is very similar throughout the model domain.

A similar comparison of May 2000 heads for the Avon Park Formation is presented in Figure 5.26. Again the heads predicted by the model are higher than measured values. The greatest discrepancies between the measured and predicted heads are located in the central and northeast portions of the model domain. The general shape of the potentiometric surface contours for the model versus field data is very similar over the entire model domain, with contours closing around a depression in the potentiometric surface in the central portion of the region.

A comparison between the measured and predicted head values for September 2000 for the Suwannee Limestone and Avon Park Formation are shown in Figures 5.27 and 5.28, respectively. Of particular relevance is that the measured values for May and September vary by about 30 feet over much of the model domain. The predicted heads for the Suwannee Limestone are in reasonably good agreement with measured head contours over most of the model area. As shown in Figure 5.28, the predicted heads in the Avon Park Formation are not as close to the field data but still capture the general shape of the measured potentiometric surface.

The most probable reason for the differences between measured and predicted head values is that there are significant transient hydraulic stresses within the hydrogeologic system which are not captured by the flow model, which uses applying 4-month averaged pumping and boundary conditions. It should be noted that the head responses of the saltwater intrusion model are very similar to that of the transient Southern District Model (SWFWMD, 2001) run with similarly time-averaged pumping conditions.

Another calibration criterion is the head difference between the Suwannee Limestone and the Avon Park Formation for which there is not expected to be an appreciable difference. This assumption is based upon an aquifer test conducted in Manatee County within the Avon Park Formation. During the pumping test, measured water levels in two wells that were open to the different production zones (i.e., Suwannee Limestone and Avon Park Formation) were nearly identical (Guyton and Associates,1976). Figure 5.29 shows the difference between the heads predicted in the Suwannee Limestone verses those in the Avon Park Formation. Over most of the model domain the difference in heads is less than 5 feet. The exceptions to this are along the northeastern and southern boundaries which are local boundary effects.

Mass Balance

The reliability of the model was also assessed during the calibration process by evaluating the computed water balance. The water balance calculated for pre-development conditions using the calibrated model is shown in Figure 5.30 and Table 5.4. The locations of the eastern, southern and northern freshwater boundaries are shown in Figure 5.4 as a series of blue dots. These boundaries were set to prescribed heads as determined from the Southern District Model (SWFWMD, 2001). The lateral saltwater boundaries are designated in Figure 5.4 as green dashes along the northern and southern boundaries and as a solid red line along the western boundary. Information for the drains (i.e., location, depth, conductivity, heads) was derived directly from the Southern District Model (SWFWMD, 2001). The bottom boundary represents the amount of fluid exchange between the Avon Park Formation and the middle confining unit (i.e., evaporites) (Figure 5.3). The top boundary represents the interface between the Tampa and Suwannee Limestone members of the Upper Floridan aquifer (Figure 4.4).

The water balance indicates that during pre-development conditions large volumes of water enter from the eastern freshwater and lateral saltwater boundaries. Appreciable amounts of water also leave the model domain from the lateral, saltwater and top boundaries. Although considerable volumes of water enter the model through the top and bottom boundaries, a significant amount of water leaves the model through the top boundary due to upward gradients over much of the model, particularly in the western portions of the model domain. The total volume of water entering the model domain is essentially equal to that leaving the model.

The computed water balance for post-development conditions (i.e., December 2000) is shown in Figure 5.31 and Table 5.5. The greatest differences between the pre- and post- development water balances are the large volume of water removed by wells during the post development (current) period, although a small amount of water is introduced to the model via injection wells. The stress imposed on the system by the pumping wells considerably alters the head gradients which induces water to flow downward through the upper boundary and laterally from the eastern and saltwater boundaries. Greater amounts of water also enter the domain from the lower boundary during the post development simulations. Water entering the model from the top and bottom boundaries are almost equal. Furthermore, almost no water exits the bottom boundary. The total inflow and outflow for post-development conditions are also in excellent agreement.

6.0 SENSITIVITY ANALYSES

6.1 GENERAL SENSITIVITY APPROACH

The purpose of sensitivity analyses are to quantify the uncertainty in the calibrated model caused by uncertainty in the estimates of aquifer parameters, stresses, and boundary conditions (Anderson and Woosner, 1992). Their significance and use is aptly summarized by ASTM (1994) as:

1. To identify which model inputs have the most impact on the degree of calibration and on the conclusions of the modeling analysis.

2. To categorize the parameter sensitivities in a manner that identifies the predictive capability of the calibrated model for its intended conclusions.

The ASTM (1994) procedures were applied to perform the sensitivity analysis for this study. Where applicable, this process was enhanced to provide a further understanding of system behavior in the presence of uncertainties (ASTM, 1994).

The sensitivity analysis was performed in two parts. The first part was a parameter sensitivity performed by systematically changing the values of the calibrated model parameters or boundary conditions within pre-established reasonable limits. The second part investigated the effects of alternative conceptualizations on the calibrated model. The first step in both parts was to identify the parameters or model inputs that need to be varied during the sensitivity analysis. Then for each parameter, the specified range of variation was determined based on the expected range of observed values (i.e., field data) or conceptual validity. Simulations were subsequently performed over this range for each parameter or conceptualization, for steady-state pre-development and transient post-development conditions. For the current study, the 'most probable high and low' values associated with each parameter or boundary condition were used to perform the sensitivity analyses.

For the parameter sensitivities, the calibration residuals and the results of model predictions of chloride intrusion were graphed as a function of parameter input value for each of the parameters investigated. In this study, the model conclusions were defined as the percentage of pumping wells impacted by chlorides at concentrations exceeding 500 ppm, and the total chloride mass that is contained within the model domain. The first conclusion was selected as a specific model outcome of interest to the SWFWMD, the second being a general conclusion on the state of chlorides within the entire simulation domain. From this set of graphs, the model input parameters that have the most impact on the degree of calibration and on the conclusions, were identified. This set of graphs is also used to categorize parameter sensitivities into four types, which are described below.

Type I sensitive parameters are those which cause insignificant changes in calibration residuals as well as model predictions. Type I sensitivity on a parameter is of no concern, because regardless of the parameter input value (within the predetermined range), the model predictions remain the same. Type II sensitive parameters cause significant changes in the calibration residuals but insignificant changes in the model predictions. Type II sensitivity on a parameter

is of no concern because regardless of the value of the input, the model predictions remain the same. Type III sensitive parameters cause significant changes to both calibration residuals as well as the model predictions. Type III sensitivity on a parameter is of no concern because even though the model predictions change as a result of variation in input, the parameters used in those simulations cause the model to become uncalibrated with residuals increasing from the calibrated model that best represents the field conditions. Type IV sensitive parameters cause insignificant changes in calibration residuals but cause significant changes in the model predictions. Type IV sensitivities can have greater uncertainties because over the range of that parameter in which the model can be considered calibrated, the model predictions can change substantially. A Type IV sensitivity generally requires additional data collection to decrease the range of possible values of the parameter (ASTM, 1994).

For the conceptual sensitivities, the calibration residuals and model conclusions are noted along with a general description of notable or significant effects of the conceptual change, compared to the base case calibration simulation (Section 5.2.1). These conceptual changes from the base case correspond to uncertainties in the hydrogeologic system.

6.2 PARAMETER SENSITIVITY ANALYSIS AND RESULTS

A parameter sensitivity analysis was first conducted for the calibrated saltwater intrusion model to identify the model input groups that have the most impact on the model calibration and on the model predictions. The parameters and their range of variation were chosen in collaboration with SWFWMD staff, and are considered to be the important parameters that govern the behavior of saltwater intrusion in the domain. The parameter sensitivity study is summarized in Table 6.1. The first column of the table shows the parameters that were chosen for this sensitivity analysis followed by their selected variations in the second column. The remaining columns summarize calibration statistics and model predictions for the various parameters that were evaluated. The last column categorizes the various parameters into one of the four sensitivity analysis categories (i.e., Type I, II, III, or IV) as defined by ASTM (1994). The first row of Table 6.1 provides results for the calibrated model while subsequent rows discuss the various parameter sensitivities. Figure 6.1 provides significant calibration statistics and the results of model predictions of chloride intrusion for each of the parameter sensitivities. These calibration statistics include those that were evaluated during the model calibration process (i.e., residual mean error and root mean square error (RMS)).

Porosity (Parameter 1) is the most sensitive parameter in terms of the calibration statistics as well as on the conclusions of this study (Type III sensitivity). Since the effect of porosity is mainly to control the transient movement of chlorides, it is possible based on these statistics, to have an error in the pre-development location of chlorides with an associated error on porosity in the same region, to produce the same current conditions for chlorides. Therefore, the possibility of multiple solutions exists, to produce the same calibration, however, within the limits of the assumptions made in the model (uniform porosities of all materials), the calibrated model provides appropriate results for the noted transient behavior as discussed in Section 5.3.2. In fact, it may be noted that the multiplication factor of 2 (see Figure 6.1a) to the base-case porosity values provides a better "calibrated" model with a smaller average error and less spread in the results from observed chloride levels. However, these values are considered to be outside reasonable limits for

porosities in the region, and the transient behavior is inferior to that of the calibrated model in terms of depth to chlorides (also used as a calibration measure) and its movement. Finally, on Figure 6.1a, the mass of chlorides in the domain is an inappropriate surrogate measure for the general intrusion of chlorides into the domain, since the porosity value affects volume and hence mass of chlorides within the domain, for the same amount of intrusion.

The second most sensitive parameter is the landward lateral boundary head (Parameter 12) in terms of the calibration statistics and the model predictions (Type III sensitivity). Figure 6.11 shows that the model is well calibrated to this parameter, with an increase in the average error and RMS error for an increase or a decrease in the lateral landward boundary head value.

The bottom GHB head value (Parameter 9) is the next most sensitive parameter in terms of the calibration statistics and the conclusions of this study (Type III sensitivity). As may be noted from Figure 6.1i, a 10 ft drop in the heads assigned to the GHB boundaries gives a substantially smaller average error, with not much effect on the spread of the error (RMS). However, lowering the head assigned to the bottom GHBs by 10 feet, degrades the ability of the model to match vertical chloride profiles observed in many of the ROMP wells.

The other parameters with a high degree of sensitivity, in terms of the model calibration and predictions (Type III sensitivity), include:

- the hydraulic conductivity associated with the entire Avon Park Formation (model layers 6 through 10) (Parameter 2);

- the hydraulic conductivity associated with the "highly permeable zone" within the Avon Park Formation (model layers 6 and 7) (Parameter 3); and

- the head value applied to the GHB condition along the bottom model boundary (Parameter 8).

Parameter sensitivities 2 and 3 are similar (the former being on the entire Avon Park Formation, the other on the "high-flow-zone" only) with a multiplying factor of 2.0 providing significantly reduced average errors (Figure 6.1b) and only a slight increase in the error spread. In fact, as noted in Table 6.1, the average change in December 2000 heads from the base case is significantly positive indicating lower heads than the base case for December 2000 conditions. However, this was a less desirable option for the calibrated model because measured values are considered to be more reliable than a factor of 2, and because it produced less accurate depth to chlorides than shown in Appendix B. Similarly, the +10 ft sensitivity simulation of parameter sensitivity 8 has a smaller residual with less spread, however, 10 ft is added to all top GHB nodes including those in Tampa Bay and Gulf of Mexico, which would be conceptually questionable. This exhibited sensitivity suggests that the GHB heads could be refined if more data become available.

Parameter sensitivities 6, 10, and 11 (for top GHB conductance values, Bottom GHB conductance values and the coastal lateral boundary head respectively) show a Type II sensitivity whereby the parameters are sensitive to the residuals, but not to the conclusions or requested prediction. The calibration sensitivity is considerable for these parameters, with a large change in the average

chloride error for the range of parameters considered. Finally, parameter sensitivities 4, 5, 13, 14, and 15 (for vertical conductivity values of the modeled Ocala Limestone, hydraulic conductivity values of the modeled Suwannee Limestone, dispersion coefficients, diffusion coefficient, and Avon Park Formation's vertical anisotropy ratio, respectively) show Type I sensitivities whereby neither the residuals nor the conclusion are sensitive to changes in the parameter value. From Table 6.1, however, it may be noted that the Ocala Limestone's vertical conductivity value is most sensitive to the vertical head separation between the Suwannee Limestone and the Avon Park Formation. Conductivity values for the Avon Park Formation are the next most sensitive parameters for this head separation effect. Other parameters were not as sensitive.

Other model data that was evaluated during calibration included the overall bias of the model versus the data. It is noted in Table 6.1 that porosity, model layers 6 and 7 conductivity values, and bottom GHB head values can have the largest impact on chloride data fit among all the parameters. Fluxes through the top and bottom of the model were also evaluated during calibration and their sensitivity is also addressed. Flow in from the top GHB boundary was most sensitive (as much as 45% in volume) to top GHB conductance followed by top GHB heads (parameters 6 and 8 respectively). Flow out of the top GHB boundary was most sensitive (as much as 45% in volume) to top GHB conductance, top GHB heads and Coastal lateral boundary heads (6, 8, and 11 respectively) with a moderate sensitivity to the Avon Park conductivity values of sensitivities 2 and 3. Flow in and out of the bottom of the domain was most sensitive to bottom GHB head and bottom GHB conductance values. Aside from the porosity simulation, whereby chloride mass is not an indicator of intrusion into the domain as discussed earlier, the maximum chloride mass in the domain exists for the simulation with coastal lateral heads increased by +20 ft, and the minimum exists for the simulation with top GHB heads increased by +10 ft. In general, about two-thirds of the wells that are contaminated by chlorides greater than 500 ppm, also contain chlorides greater than 1,000 ppm. However, in general, the trends in parameter sensitivity of these conclusions are similar to those of the total chloride mass which may be used as an indicator here for the total chloride intrusion amount.

6.3 CONCEPTUAL SENSITIVITY ANALYSIS AND RESULTS

Conceptual uncertainties of the system, and their effect on saltwater intrusion have been investigated by the conceptual sensitivity analyses. Two primary conceptualizations are studied here, as an alternate to the calibrated model. First, it is unknown how the middle confining unit interacts with the overlying Upper Floridan aquifer, therefore, a sensitivity analysis was performed on this interaction. Second, the conceptualization of having a higher permeability zone within the Avon Park Formation was tested by performing a sensitivity simulation in which the higher permeable zone was removed from the model. Table 6.2 details these sensitivity analyses and provides calibration statistics and results.

For the first conceptual sensitivity simulation, the middle confining unit and its interaction with the Floridan Aquifer system under study exist only under the zone of high transmissivity in the Avon Park Formation under Pinellas County, Hillsborough Bay and Tampa Bay, to allow for saline water below the middle confining unit to interact with the Upper Floridan aquifer in this region only. The rest of the domain is unaffected by this interaction, as is the conceptualization

used throughout the Southern District Model (SWFWMD, 2001). Two simulations were performed for this sensitivity analysis, to understand the behavior of this boundary in a systematic manner. The first simulation is designed from the calibrated model by cutting off the bottom GHB condition from portions of the domain not underlying the highly permeable zone under Pinellas County, Hillsborough Bay, and Tampa Bay. The second simulation further increases the GHB conductance under the highly permeable zone by an order of magnitude to increase the interaction with the middle confining unit in this region (i.e., the intrusion of chlorides from the MCV can be larger due to its larger vertical conductivity). This conceptualization is motivated by the fact that modeled chlorides have the tendency to be excessive in the southern portions of the domain, while they are less in the north, specifically in the area of TR AB-1, TR 9-2 and TR AB-3.

The calibration statistics associated with these simulations show much improvement over those of the base-case calibrated model with lower average errors and a similar RMS error to the base-case. Final heads are higher than those of the base-case, which is also a desirable feature. Flow in and out of the top GHB boundary is similar to that of the base-case, however net flow in/out of the bottom GHB boundary changes. For the first simulation, net flow in the bottom is less because of the smaller area of interaction with the middle confining unit than the base-case. For the second simulation, the net flow in the bottom is higher because of the higher GHB conductances which increase the interaction. For this sensitivity, only around half the pumping wells extract greater than 500 mg/l chloride than for the base-case. This conceptualization therefore, has the possibility of improving calibration. Thus, if a data collection program can validate the possibility of this conceptualization, further tuning on the parameters may be performed with investigations of depth to chlorides, slope of the interface, and thickness of the transition zone - all features that were examined in calibrating the model. A general inspection of the results indicates that chlorides are not affected by this calibration in the southern regions of the domain, chlorides intrude less than the base case in the middle portion of the domain, and chloride intrusion can be greater in northern parts of the domain if the bottom GHB interaction there is increased.

For the second conceptual sensitivity simulation, the Avon Park Formation is treated as a single unit vertically. The hydraulic conductivity of this unit is applied in a manner that provides an equivalent transmissivity to the base-case simulation. This conceptualization is examined as an alternative, to investigate the results of this simplification (always made in flow models), on chloride transport behavior. The average error for this simulation shows an improved fit than for the base case, with a similar RMS error (Table 6.2). Other flow statistics and model conclusions are similar to that of the base case. The model is quite insensitive to this alternative conceptualization which may be used instead without significant loss of accuracy or predictive capability. However, the nature of the calibration of such a model should be first examined with respect to depth to chlorides, width of transition zone, and slope of interface to determine if it would be adequate. A general inspection of the results indicates that the chlorides moved seaward in the entire domain from the base-case, and the interface slant became more vertical (not desirable) for this simulation.

6.4 QUALITY ASSURANCE REVIEW RESULTS

After calibrating the density-dependent model, the SWFWMD reviewed the wells and well depths assigned in the Southern District Model (SWFWMD, 2001) and in the local-scale, density-dependent model. The review was undertaken to reconcile differences between previous assessments of wells at risk of saltwater intrusion prepared by the SWFWMD and the current, preliminary estimates made with the local scale density-dependent model.

The review examined the total depth and/or casing depth assigned to wells for which no value is reported in the SWFWMD Water Use Permit (WUP) data base. The review determined that procedures used to assign these values to model layers in the Southern District Model (SWFWMD, 2001), which does not use elevations or depths, had incorrectly assigned total depth and casing depth elevations to wells in the local scale density-dependent model. After assessing the situation, a revised process assigned corrected total depth and casing elevations to the wells of the transport model.

This resulted in 512 of the 2,681 wells being eliminated from the model when the total depth elevations were above the top of the UPZ as configured in the transport model. A review of these wells indicated that most of these wells were located along the southwest coast and are known to be completed in the IAS, which is not simulated by the transport model. Although the number of wells removed is nearly 20 percent of the total, the total withdrawal rate is only 5.7 percent of the original 223.38 mgal/day. The result of this change on the calibrated model is minor as illustrated by the relative chloride concentration contours for model Layers 2 and 6 (Figures 6.2 and 6.3). The results of the comparison of the environmental head potentiometric surfaces for Layers 2 and 6 also indicate minor changes (Figures 6.4 and 6.5).

The total withdrawal rate associated with each predictive scenario is unchanged. The reported number of wells at risk of saltwater intrusion under each scenario in Section 7.0 reflects the revised pumping data set.

7.0 PREDICTIVE SIMULATIONS

The calibrated density-dependent saltwater-intrusion model was used to predict potential changes to the groundwater flow system and associated chloride conditions, which would result from changes in groundwater withdrawals in the Upper Floridan aquifer. Projected pumping conditions include withdrawals of 400, 600, 800 and 1,000 MGD within the SWUCA. Based on these pumping projections, the saltwater intrusion model was used to predict the distribution of chloride after 20 years and 50 years of pumping. December 2000 conditions provided the initial conditions for the predictive simulations. Most boundary conditions for the predictive simulations were kept the same as those used for the pre-development to post-development simulation. The only differences in model input were groundwater withdrawals and the lateral landward freshwater boundary heads which were provided by the District for the saltwater intrusion model by performing parallel simulations with the Southern District Model (SWFWMD, 2001). Since the saltwater intrusion model includes only a portion of the SWUCA individual well pumping within the saltwater intrusion model was scaled according to the ratio of total pumping of the various scenarios (i.e., 400, 600, 800 or 1,000 MGD), to total pumping for December 2000 conditions. In addition, a predictive sensitivity analysis was conducted on each of the four scenarios. For these simulations, selected input parameters were changed in order to provide a range of potential impacts. The parameters included for the predictive sensitivity study were selected from those found to be most sensitive during the sensitive analysis discussed in Chapter 6.

For the predictive scenarios, an analysis was performed to determine the number of wells contaminated by chloride concentrations either exceeding 500 mg/l or 1,000 mg/l, at 20 and 50 years of simulation (i.e., year 2020 and 2050). For production wells that are completed across multiple hydrostratigraphic units, the chloride concentrations predicted by the model represent a homogeneous mixture of water that is contributed by each unit. This mixed concentration should approximate the actual concentration that is observed at the individual wells. The results of the predictive simulations are presented in Table 7.1. Also presented in the table is the 1995-1999 average annual usage from the contaminated wells and the associated 1999 permitted pumping from those wells. These columns of the table denote how much pumping (or permitted pumping) within the Upper Floridan aquifer would be at risk due to chloride intrusion, or moved to other locations. A total of 1,806 wells are included in the domain of the saltwater intrusion model. The saltwater intrusion model predicts that 154 of these wells (8.5%) are currently impacted by chloride at concentrations exceeding 500 mg/l. Furthermore, the model predicts that after 50 years of pumping, 224 of these wells (12.4%) will be impacted by chlorides at concentrations exceeding 500 mg/l. The model predicts that 63 wells (3.4%) are currently impacted by chlorides exceeding 1,000 mg/l, and chloride concentrations will exceed 1,000 mg/l in 147 wells (8.1%) after 50 years of continued pumping. Tables 7.2, 7.3 and 7.4 provide a detailed breakdown of this production well impact analysis for the Suwannee Limestone, the Ocala Limestone and the Avon Park Formation respectively. These tables illustrate that for the wells within the model domain, the wells completed in the Avon Park Formation are most likely to be impacted by saltwater.

Figure 7.1 shows the projected extraction well chloride concentration histogram for December 2000 of the post-development simulation. The histogram shows 1418 extraction wells with chloride concentration less than 100 mg/L and 1777 extraction wells with chloride concentration

less than 2000 mg/L. Notice that the 136 wells between 200 mg/L and 500 mg/L are decreasing from left to right and the 91 wells between 500 mg/L and 1,000 mg/L are approximately uniformly distributed. This suggests that for the predictive simulations, the number of wells above 500 mg/L will increase along a non-linear trend and number of wells above 1,000 mg/L will increase along a linear trend. Figure 7.1 also shows the average pumping rate for the wells in each histogram bar. Notice that the wells between 200 mg/L and 500 mg/L have a lower average pumping rate than the wells between 500 mg/L and 1,000 mg/L. All of the predictive simulations have more extraction wells passing the 1,000 mg/L threshold than pass the 500 mg/L threshold (Table 7.1). Column 7 of Table 7.1 shows that the number of wells above 500 mg/L increased along a non-linear trend and the number of wells above 1,000 mg/L increased along a linear trend. Columns 8 of Table 7.1 indicates that the extraction wells passing the 1,000 mg/L threshold have a higher average pumping rate than the wells passing the 500 mg/L threshold.

Figures 7.2, 7.3, 7.4 and 7.5 show the areal distribution of chlorides within the highly permeable zone of the Avon Park Formation after 50 years of pumping for each of the four scenarios respectively. The largest intrusion in the highly permeable zone of the Avon Park Formation was for model layer 7 for each of the four simulations, which is shown in these figures. Chlorides move inland by about 2.5 miles from the current position within 50 years of pumping 400 MGD, about 5 miles for a pumping of 600 MGD, about 7 miles for a pumping of 800 MGD and about 9 miles for a pumping of 1,000 MGD within the highly transmissive zone of the Avon Park Formation. Movement of chlorides is less in the northern portion of the domain where the aquifer is thinner.

Figure 7.5 shows the 1,000 mg/l chloride isochlor in the highly permeable zone of the Avon Park Formation, after 50 years of pumping for the various scenarios. A comparison of this figure with estimates of Beach and Schultz (2000) provided in Figure 2.17 shows a reasonable comparison of the modeled saltwater front with their estimates, for pumping of 400, 600, 800, and 1,000 MGD. The 50-year movement from current conditions is also similar for the various pumping cases. Chlorides are however, more landward in the southern regions of the model, and slightly more seaward in the northern portions of coastal Hillsborough County than the estimates of Beach and Schultz (2000).

7.1 PREDICTIVE SENSITIVITY ANALYSIS

The possible effects of projected pumping within the Floridan Aquifer System upon chloride intrusion to wells, is of particular concern within the SWUCA. Therefore, a sensitivity analysis was conducted to estimate the potential ranges of the predicted number of wells contaminated by greater than 500 mg/l and 1,000 mg/l of chlorides. This analysis is further broken up into estimating potential ranges for the predicted number of wells contaminated by greater than 500 mg/l and 1,000 mg/l of chlorides in each of the aquifer units (i.e., the Suwannee Limestone, the Ocala Limestone, and the Avon Park Formation).

Sensitivity parameters selected for this analysis include the porosity of the aquifer and aquitard materials, the landward lateral freshwater boundary head, and the GHB head value applied to the bottom of the model. In terms of the model predictions, these were determined to be the most sensitive parameters (Section 6). For each sensitivity simulation set, the parameter value was

raised and lowered by a predetermined amount that provides a reasonable range bounding that parameter value. This range of parameter sensitivity is identical to that used for the model sensitivity analysis in Chapter 6.

Table 7.5 shows the results of the predictive sensitivity study in the Floridan Aquifer system, and Tables 7.6, 7.7 and 7.8 provide a breakdown of these results for the Suwannee Limestone, the Ocala Limestone and the Avon Park Formation, respectively. The table presents the additional number of wells affected for each sensitivity study, from the respective base case scenario. It may be noted that multiplying the porosity value by 0.2 had greatest impact on the modeling results, in terms of increasing the number of wells that are affected by chlorides (both in the individual hydrostratigraphic units and within the entire Upper Floridan aquifer). The number of wells impacted by high chloride concentrations approximately double from the base case for this parameter perturbation, with wells completed in the Suwannee and Ocala Limestones being much more susceptible to contamination than wells completed in the Avon Park Formation. The decrease in the number of wells, affected by chlorides in the Suwannee Limestone and the Ocala Limestone, is most strongly influenced by the addition of 10 ft to the landward lateral boundary heads with the largest impact being in the Suwannee and Ocala Limestones. Alternatively, the most dominant factor for the decrease in the number of wells affected by chlorides in the Avon Park Formation is the lowering of the GHB boundary head value at the base of the model by 10 feet.

7.2 MODEL LIMITATIONS

The model described in this report is a numerical groundwater flow and solute transport model that uses the MODHMS computer code to approximate the groundwater flow and chloride transport system in the SWUCA. The model results are limited by the simplification of the conceptual model upon which the numerical model is based, by the grid scale, by the inaccuracies of measurement data and by incomplete knowledge of the spatial variability of input parameters.

The conceptual model used to construct the density-dependent saltwater intrusion model for the SWUCA is a simplified representation of the true groundwater flow and transport system. Due to its karstic nature, the Floridan aquifer system can be characterized as an extremely complex, heterogeneous aquifer system. These features may cause zones of preferential pathways caused by secondary porosity features and solution conduits. However, the secondary porosity features are believed to be so ubiquitous that the system behaves as an equivalent to a porous-medium at the scale of the modeled system.

The density-dependent saltwater intrusion model is based upon the Southern District Model (SWFWMD, 2001) for groundwater flow developed by the SWFWMD using the popular USGS MODFLOW code. Further, the calibrated saltwater intrusion model has almost the same conceptualization and parameter distribution as that of the Southern District Model (SWFWMD, 2001). Differences in conceptualizations are associated with the specifics of saltwater intrusion modeling. For instance, use of a transmissivity value for each aquifer unit is sufficient for groundwater flow modeling, however, saltwater intrusion simulations require the additional vertical resolution to capture the gradients in concentration resulting from saltwater intrusion

within each aquifer unit. To address these issues, the density-dependent model was more finely discretized than the Southern District Model.

Averaging of boundary conditions and well pumping over 4-month intervals for the latter part of the transient simulations should not have much impact on chloride intrusion levels, since intrusion is an extremely slow process with time-scales that are orders of magnitude larger than four months. However, this averaging has a significant impact on the simulated head field within the aquifers, which do not exhibit the seasonal extremes noted in the field since the time-scales for head response to pumping can be much smaller than four months.

The model simulates conditions represented by the static chloride data from the ROMP wells better than the subsequent field data collected over some ten years as shown in Figures 5.19 through 5.24. The primary reason for this discrepancy in the model predictions is that greater reliance was placed on establishing the chloride interface position and vertical concentration gradients rather than attempting to match the transients in the chloride data. The justification for this approach is that chloride interface changes very slowly with time and the chloride profiles provide a better overall description of the chloride distribution within the modeled area. Local chloride vs. time data were obtained from relatively short monitoring intervals within respective monitoring wells. These local concentration data are governed by small-scale heterogeneity. The model's inability to mimic the magnitudes of local-scale time dependent chloride data may be attributable to the finite-difference grid size that is larger than the local heterogeneity scale. In addition, local changes in chloride concentrations with time could be affected by ephemeral processes (e.g. changes in recharge rates). These processes may be either too localized to be captured adequately by the model, or are of such short duration that the quarterly averaging by the model is insufficient to duplicate the temporal changes in the field data.

Horizontal and vertical discretization into model grid cells requires the assumption of average values of hydrologic properties and stresses for each grid block. The larger the range of the true values of a property or stress within a grid cell area, the greater the difference between the average value and the true value at any particular location within a cell. This difference is probably greatest for confining unit leakances which can vary greatly due to local changes in thicknesses and vertical hydraulic conductivity not represented in the model. The location of stresses is also somewhat distorted by the grid scale since all pumping in the model is accumulated at a grid-block center. This error should be small for the current simulations due to the distributed nature of pumping throughout the model domain which is applied to a reasonably fine grid. Another error source is that the resolution of results cannot be made finer than that of the grid. This is significant for representing chloride values within the model, since chloride data from ROMP wells is at a much finer vertical scale than the model's vertical resolution. This problem is compounded by the fact that chlorides can change dramatically within the domain with an extremely narrow transition zone between freshwater and seawater.

Model results are limited by incomplete knowledge of the true spatial variability of input parameters. However, sensitivity analysis conducted on the input arrays of parameters and stresses used for this model have indicated that the model's calibration and predictive results are sensitive to certain input parameters and stresses and insensitive to others. Model calibration and predictions are most sensitive to the value of porosity used for the aquifer units, followed by value

of the lateral landward freshwater boundary head and the value of the bottom GHB head. Uncertainty of model results is therefore related primarily to the uncertainty in these input parameters. However, since the calibration is also sensitive to these parameters, a perturbation on the parameter value causes the model to be uncalibrated thereby restricting their values to those that provide a calibrated model. It may be noted that the model did not show a Type IV sensitivity to any parameter examined (A Type IV parameter is one which exhibits sensitivity to results but not to the calibration). Therefore, the reliability of the model is not compromised in this respect.

Results of the predictive sensitivity analyses indicate a range for the number of wells contaminated by 500 and 1,000 mg/l of chlorides after 50 years for the various scenarios examined. This range is greatest for the Avon Park Formation for all the cases examined, thereby providing a larger uncertainty of results for the Avon Park Formation than for the other units analyzed.

The density-dependent saltwater intrusion model was designed with grid-block scales of one-half mile. Material property zones were designed at a scale that is an order of magnitude larger. Temporal scales for varying pumping and boundary conditions for pre- to post-development simulations were initially large, reducing to an order of four months near the end of the simulation. Therefore, model results should be viewed at these space and time scales, and the model may be used to examine the general chloride intrusion trends for long-term average stress conditions.

8.0 SUMMARY AND CONCLUSIONS

HydroGeoLogic has completed the development of a numerical, coupled groundwater flow and density-dependent transport model for the coastal portions of the SWUCA. The primary objective of this effort was to predict the long-term impact of proposed water use options on saltwater intrusion within the Upper Floridan aquifer. The saltwater intrusion model may be further used to establish minimum water levels or maximum pumping levels for groundwater extraction wells within the Upper Floridan aquifer or for developing a refined understanding of the stress response of chlorides to various regional management scenarios.

Historical reports and previous modeling investigations were reviewed to understand the hydrogeologic conceptual model, identify model calibration targets, and construct the framework for the saltwater intrusion model. Once the density-dependent model was constructed, it was calibrated to simulate conditions in the Upper Floridan aquifer that existed from the pre-development period (approximately 1900) to present conditions (through 2000). The pre-development simulations were calibrated to the results of earlier modeling work that predicted the position of the tip and toe of the saltwater interface, and a historical reconstruction of pre-development hydraulic heads. The density-dependent model predicts greater saltwater intrusion in the northern part of the model domain than the earlier models, and less intrusion from the center of the model southward. Differences in the modeling results would be expected, however, since different approaches (e.g., two-vs. three-dimensional) and assumptions (e.g., sharp interface vs. fully coupled flow and transport) were made in the various models. A favorable comparison between the pre-development potentiometric surfaces predicted by the model and historical estimates were also obtained.

Following the calibration of the model to pre-development conditions, the hydraulic stresses associated with pumping were integrated into the model and the model was calibrated to post-development conditions (i.e., post-1900). During the post-development calibration process, the results of the model calibration were evaluated both qualitatively and quantitatively. In some instances, a comparison between contour maps of measured and simulated values (i.e, hydraulic heads and chloride concentration) was prepared to provide a visual, qualitative measure of the similarity between patterns, thereby giving qualification of the spatial distribution of calibration errors. In addition, vertical and horizontal hydraulic heads and the fluid flux moving across the model boundaries was used as qualitative calibration criteria. Quantitative statistical assessments were also performed on the model residuals to assess the reliability of the calibration.

A general observation, with respect to the model calibration, is that the model does not always provide a good match to the chloride data on a well-by-well basis. From a more regional perspective, however, the model does provide a reasonably good fit to chloride distribution maps that show the extent of the chloride interface. There are several explanations for this apparent discrepancy between the model predictions at the local and regional scales. One of the most significant of which is that the chloride interface is relatively thin vertically, and narrow in the east-west direction. This limited extent of the interface causes the chloride distribution to be controlled by heterogeneities at a scale that is considerably smaller than the horizontal discretization of the model elements (i.e., 2,500 feet). Similar issues arise with the vertical discretization of the model. Since the discretization is at a larger scale than the collected data,

chloride concentrations in the model are averaged over several hundred feet as compared with tens of feet in the field. In fact, for each finite-difference cell containing a ROMP well, there are typically multiple observed chloride concentrations associated with different depth intervals. This inconsistency in scale makes it difficult to precisely match the field data, particularly at high chloride concentrations. This problem is aggravated by the fact that the interface transition zone is relatively thin and concentrations change dramatically over short vertical distances. Furthermore, since all of the calibration wells are located within the chloride interface, the models inability to capture the effects of the localized heterogeneities on the chloride distribution give the impression that the model predictions are unreliable. As noted above, however, the model does perform well when compared to the regional chloride maps. Although the model could be more finely discretized in both the horizontal and vertical dimensions to improve the localized calibration, the simulations times (which currently are on the order of 16-18 hrs at a 2.0 Ghz processing speed) would become excessively long. Furthermore, as described in greater detail in Section 5, the principle of parameter parsimony was applied as a fundamental philosophy during the calibration. This principle favors the use of uniform parameter zones unless there is hydrogeologic evidence indicating the presence of localized heterogeneous properties. Therefore, rather than attempting to precisely match the localized borehole data, by increasing the discretization and/or heterogeneities, the model was calibrated to provide a very good representation of the chloride intrusion characteristics on a more regional scale and should provide an adequate means to meet the objectives of the SWFWMD.

A comparison of simulated potentiometric surfaces to potentiometric surface maps developed by the USGS indicates that the model predicted head distributions for the Suwannee Limestone and Avon Park Formation tend to be lower than actual field data. The general shape of the potentiometric contour developed for simulated heads is very similar to the potentiometric surface developed using field data. The most probable reason for the differences between measured and predicted head values is that the model does not exactly simulate the transients within the flow system, in which hydraulic heads vary by about 30 feet from May to September.

A sensitivity analysis was also conducted, to identify the model input parameters and boundary conditions that have the most impact on the model calibration and on the model predictions. Porosity was found to be the most sensitive parameter, followed by the landward lateral boundary heads and the bottom GHB heads. The hydraulic conductivity associated with the entire Avon Park Formation (model layers 6 through 10), and with the "high-flow-zone" within the Avon Park Formation (model layers 6 and 7) also exhibited a high degree of sensitivity, in terms of the model calibration and predictions.

Predictive simulations were completed to estimate hydraulic heads and saltwater intrusion (i.e., saline water concentrations) for 20- to 50-year time periods. The possible effects of projected Floridan aquifer system pumping upon chloride intrusion to wells is of particular concern within the SWUCA. Therefore, four different water use scenarios proposed by the SWFWMD were evaluated. These comprise of withdrawing 400, 600, 800 and 1,000 MGD within the SWUCA. For the predictive scenarios, an analysis was performed on the number of wells contaminated by average chloride concentrations either exceeding 500 mg/l or greater than 1,000 mg/l, at 20 and 50 years of simulation (years 2020 and 2050, respectively). A total of 1,806 wells are included in the domain of the saltwater intrusion model. The saltwater intrusion model predicts that 154

of these wells (8.5%) are currently impacted by chloride at concentrations exceeding 500 mg/l. Furthermore, the model predicts that after 50 years of pumping, 224 of these wells (12.4%) will be impacted by chlorides at concentrations exceeding 500 mg/l. The model predicts that 63 wells (3.4%) are currently impacted by chlorides exceeding 1,000 mg/l, and chloride concentrations will exceed 1,000 mg/l in 147 wells (8.1%) after 50 years of continued pumping.

A predictive sensitivity analysis was also conducted to provide confidence limits on the results. Sensitivity parameters selected for this analysis include the porosity of the aquifer and aquitard materials, the landward lateral freshwater boundary head, and the GHB head value applied to the bottom of the model. Results of the predictive sensitivity analyses indicate a range for the number of wells contaminated by 500 and 1,000 mg/l of chlorides after 50 years for the various scenarios examined. This range is greatest for the Avon Park Formation for all the cases examined, thereby providing a larger uncertainty of results for the Avon Park Formation than for the other units analyzed.

TABLES

Table 2.1
Geology and Hydrogeology of the Eastern Tampa Bay WUCA
(modified from Barr, 1996, Miller, 1986, and Basso, 2001)

Series	Stratigraphic Unit		Hydrogeologic Unit		Lithology
Holocene to Pliocene	Undifferentiated Surficial Deposits		Surficial Aquifer		Sand, silty sand, clayey sand, peat, and shell
Miocene	Hawthorn Group	Peace River Formation	UICU	Intermediate Aquifer System	Predominantly phosphatic clay, gray to green to brown, plastic, ductile, minor sand, residual limestone, and dolostone
			PZ2		
			MICU		
		Arcadia Formation			
		Tampa Member	PZ 3		Limestone, gray to tan, sandy, soft, clayey, minor stone, phosphatic. Chert found locally
			LICU		
Oligocene	Suwannee Limestone		UPZ	Upper Floridan Aquifer	Limestone, cream to tan, sandy, vuggy, fossiliferous
Eocene	Ocala Limestone		SCU		Limestone, white to tan, friable to micritic, fine-grained, soft, abundant foraminifera
	Avon Park Formation		LPZ		Limestone and dolomite. Limestone is tan, recrystallized. Dolomite is brown, fractured, sucrosic, hard. Peat found locally at top. Interstitial gypsum in lower part.
			Middle Confining Unit		

Table 2.2
Conceptual Model Components and Related Uncertainties

Conceptual Model Component	Integration into the Numerical Model	Conceptual Model Uncertainties and Possible Resolution
Physical Framework		
The Middle Confining Unit, because of the presence of evaporites, has a very low hydraulic conductivity.	The top of this unit may be assumed to be the base of the Upper Floridan Aquifer System (bottom of the model domain) and will be assigned no flow boundaries.	Hickey (1989) performed an assessment to evaluate the potential for groundwater from below the Middle Confining Unit to flow vertically upward into the permeable zone of the Avon Park. Hickey concluded that flow is upward and velocities vary by approximately 1 order of magnitude between pre and post-development conditions. Waterstone (2001) present calculations that show that the amount of vertical flow derived from below the Middle Confining Unit would have negligible impact on the water quality in the permeable portion of the Avon Park. This aspect of the conceptual model will probably not be tested during the model calibration. However, a sensitivity analysis could be performed in which the sensitivity of the effects of upward flow into the Avon Park on the water quality would be evaluated. This would also involve varying the chloride concentration derived from the anhydrites (see conceptual model components pertaining to lower boundary transport conditions).
The lower permeable zone (i.e., Avon Park Formation) of the Upper Floridan Aquifer may have discrete zones of high permeability.	The Avon Park will be discretized into multiple layers.	Aquifer tests of the Avon Park generally test the entire interval and are not at a resolution sufficient to differentiate individual zones in the Avon Park that may be laterally extensive. The implications of these zones are that they could create "fast paths" for chloride intrusion. The best means to investigate the potential existence of these high permeability zones is to calibrate the model to the high resolution chloride profiles available from the ROMP wells (Figure 2.10). This alternative conceptualization will also be evaluated during the sensitivity analysis if it is found to produce a reasonable calibration.

Table 2.2 (continued)
Conceptual Model Components and Related Uncertainties

Conceptual Model Component	Integration into the Numerical Model	Conceptual Model Uncertainties and Possible Resolution
The Ocala Formation behaves as a semi-confining unit.	The Ocala will be discretized separately from the Avon Park Formation.	Similar hydraulic responses were observed in the Suwannee and Avon Park during aquifer stress tests. This observation suggests that the Ocala is not fully confining and will not prevent water from moving upward. Therefore, upward coning from the Avon Park through the Ocala and into the Suwannee is a possibility. HydroGeoLogic (1994) evaluated a scenario in which the confining properties of the Ocala were decreased and found that the 1,000 mg/l isochlor rose over 200 feet in 50 years. Until more information becomes available from field tests of the Ocala vertical hydraulic conductivity, reliance will have to be placed on the model calibration and on the Southern District Model parameterization for estimating the actual conductivity of the Ocala.
Productive zones in the Intermediate Aquifer System are hydraulically isolated from the Upper Floridan Aquifer by clay units in the Hawthorn Group.	Units above the Suwannee Limestone do not have to be explicitly simulated, but can be treated as a general head boundary that considers the vertical conductance and overlying hydraulic heads, since these units are not of consequence to saltwater intrusion.	This aspect of the conceptual model could be tested by turning the wells on in the Suwannee and Ocala/Avon Park of the Southern District Model and observing head changes within the intermediate aquifer system in the Southern District Model.
All of the aquifer units behave as an equivalent porous media for both flow and transport.	The localized effects of fractures and molecular diffusion into matrix blocks is negligible.	There is evidence that suggest that flow and transport through the Avon Park may be controlled by dual porosity and/or dual permeability conceptualizations. The dual porosity conceptualization collapses to the equivalent porous medium representation for two extreme cases. When the fracture-matrix interaction is large, the equivalent porous medium representation allocates all pore spaces in the domain (fracture plus matrix) to transport. When this interaction is small, the equivalent porous medium representation allocates only the pore spaces within the fractures to transport approximate. Porosity values used in simulations will be adjusted to note the more appropriate representation.
Hydraulic conductivity does not show anisotropy in the horizontal direction within each respective confining unit and aquifer.	Horizontal hydraulic conductivities will be assumed to be isotropic within each respective unit.	Previous aquifer testing has not suggested that there are strong anisotropic components to flow. The validity of this assumption can be evaluated during sensitivity analyses to the regional model.

Table 2.2 (continued)
Conceptual Model Components and Related Uncertainties

Conceptual Model Component	Integration into the Numerical Model	Conceptual Model Uncertainties and Possible Resolution
Hydrologic Framework		
The majority of the water entering the study area from the north, east and south is of good quality.	The boundary conditions on these borders will all assume freshwater.	This component of the conceptual model is currently well supported by the existing field data, and will not be tested further.
Lateral encroachment of seawater and subsequent upconing in areas where wells are completed above the wedge is the primary source of high salinity water.	The boundary conditions on the western border (i.e., ocean) will be set at chloride concentrations measured in the bay.	This component of the conceptual model may be tested during model calibration by adjusting the chloride source concentrations.
Upconing of high salinity water derived from beneath the anhydrites in the Avon Park is not a significant source of chloride.	The lower boundary will be assumed to be impermeable to both water and chloride.	The effect of upconing of high salinity waters from the Middle Confining unit could be tested during the model calibration by placing a diffusion controlled chloride source at the base of the model (i.e., evaporites at the top of the Middle Confining Unit). As mentioned above, however, it is unlikely that the volume of chlorides derived from below the Middle Confining Unit would significantly affect the water quality.
The hydraulic heads along the ocean are probably not in hydrostatic equilibrium with the Gulf of Mexico, since the upper confining unit isolates the aquifer from the Gulf along this boundary, and the Upper Floridan aquifer outcrops into the Gulf probably more than a 100 miles offshore.	Prescribed equivalent freshwater heads will be used for the saltwater flow regime along the western lateral boundaries.	There is very little available data with respect to the equivalent freshwater heads along the western boundary. Consequently, these values will be adjusted during the model calibration.
The chloride concentrations in the Gulf of Mexico are approximately 14,500 mg/l.	The chloride concentrations along the western boundary will be assumed to be that of seawater (relative concentration equal to one). For inflow nodes, this chloride concentration is applied along the boundary. For outflow nodes, the concentration is not prescribed, and chloride levels will depend on the concentration of the outflowing water.	The information regarding chloride data for the post-development time period is relatively good. However, the chloride concentrations assumed for the pre-development time period, which are used to initialize the model, are relatively uncertain. This uncertainty will probably not be addressed during model calibration.

Table 2.2 (continued)
Conceptual Model Components and Related Uncertainties

Conceptual Model Component	Integration into the Numerical Model	Conceptual Model Uncertainties and Possible Resolution
Chloride Transport Characteristics		
The effects of elevated sulfate and constituents other than chloride can be neglected.	Fluid densities will be dependent solely upon chloride concentration values.	Different geochemical facies within the model area may impact the fluid densities. The effects, however, are expected to be small and will not be explicitly addressed during the model calibration.
The interface is relatively sharp and dispersion values are small.	As presented in Section 4.6, a four component dispersivity approach may be appropriate	Field tests typically do not provide reasonable estimates of dispersivity. Therefore, the dispersivity values will be based on calibration results. Based on earlier modeling activities it is expected that small dispersivity values will result in a better calibration.

Table 4.1
Transport Properties

Parameter	Value

Ocala Limestone	10	5	5
Avon Park Formation	80	15	10

Table 5.1
Representative Calibration Simulations for the Saltwater Intrusion Model

Statement of the Problem	Hypotheses for the Cause	Experiments Designed to test the Hypotheses	Predicted Results	Observed Results	Conclusions from Results
1) Chloride intrusion from the Tampa Bay area to the east (landward) is too limited, particularly in the Avon Park Formation.	Resistance caused to landward movement of chlorides by the zone of high hydraulic conductivity extending under Tampa Bay abutting lower conductivity regions to the east.	The zone of high hydraulic conductivity under Pinellas county and Tampa Bay is extended to the Hillsborough County shoreline.	Chloride intrusion will accordingly move landward until the shoreline.	Chlorides move shoreward but not proportionately. More shoreward movement in upper layers of Avon Park Formation causes interface slant to become more vertical.	Experiment successful to a certain degree. However, this conceptualization was undesirable since the hydraulic conductivities are no longer representative of the District's conceptualization. A more vertical interface is also less desirable.
	Freshwater is not flowing out of the top of the model (i.e., Suwannee) at a sufficient rate to allow saltwater to intrude.	The general head boundary (GHB) conductance term of Layer 1 is increased by a factor of four.	Chloride intrusion will be greater.	In Tampa Bay area, chlorides intrude about 3 miles in layer 6 and about half a mile in layer 10 making the interface more vertical.	Desirable intrusion effects but undesirable effect on the slope of the interface.
	Saltwater is moving vertically up through the Ocala, rather than intruding further laterally.	The vertical hydraulic conductivity of the Ocala is lowered by an order of magnitude.	Chlorides should intrude more inland with less saltwater moving upwards.	In northern part of the model domain, chlorides move seaward. In south, chlorides remain the same.	The lower vertical (Kv) hydraulic conductivity of the Ocala also reduces upward freshwater flow pushing chlorides seawards in the North. In the South, the Ocala is thick, so the confining effect is not altered by reducing Kv further.

Table 5.1 (continued)
Representative Calibration Simulations for the Saltwater Intrusion Model

Statement of the Problem	Hypotheses for the Cause	Experiments Designed to test the Hypotheses	Predicted Results	Observed Results	Conclusions from Results
1) Chloride intrusion from the Tampa Bay area to the east (landward) is too limited, particularly in the Avon Park Formation. (continued)	From previous experiment described above, it was determined that freshwater needs to exit the Avon Park Formation faster than saltwater for further intrusion top layer of the model (i.e., Suwannee) to allow saltwater intrusion.	The vertical hydraulic conductivity of the Ocala is made four times higher throughout the model domain.	Chlorides should push more inland with more freshwater escaping upwards.	Chlorides move landward throughout domain. More movement is observed in layer 6 than in layer 8. Thus, the slope on the interface becomes more vertical.	Helps with front location but not with interface slope. Higher Kv reduces confining effect of thick Ocala in south. Experiments 12 and 13 suggest non-uniform (from east to west) changes in Ocala Kv may be needed.
	Intruding seawater follows path of least resistence upwards to Tampa Bay.	Use a 1,000:1 (Kh/Kv) anisotropy ratio for Avon Park Formation to reduce its vertical conductance.	Chloride front will move more landward.	Almost no change in front location, or in simulated heads.	Uniform anisotropy reduction slows down upward movement of both salt and freshwater. A non-uniform reduction in vertical hydraulic conductivity over Tampa Bay may be needed.
	Possible chloride intrusion from bottom of model (i.e., evaporites) is ignored.	Allow chloride intrusion from bottom using a GHB condition	More chlorides in domain due to intrusion from bottom.	Chloride landward intrusion is too far especially in southern portions of the model domain.	Chloride intrusion from the bottom could help solve the problem of chlorides being to far seaward.

Table 5.1 (continued)
Representative Calibration Simulations for the Saltwater Intrusion Model

Statement of the Problem	Hypotheses for the Cause	Experiments Designed to test the Hypotheses	Predicted Results	Observed Results	Conclusions from Results
1) Chloride intrusion from the Tampa Bay area to the east (landward) is too limited, particularly in the Avon Park Formation. (continued)	Too much freshwater is coming into the model domain from upstream (i.e., northen, southern and eastern) boundaries.	Reduce transmissivity of Avon Park Formation by 30% to allow less water to enter/flow through the domain	Less freshwater entering domain allows for the saltwater to intrude more.	Chlorides move landward in Avon Park Formation.	Reduced flows help saltwater intrusion, however smaller transmissivities are not justifiable based on the field data.
2) Chloride upconing from the base of model (i.e., evaporites) is too large, once this conceptualization is included.	Conductivity of GHB on the base of the model is too high allowing excessive brine to intrude from the bottom.	Reduce GHB conductance value at bottom.	Less saltwater entering the domain from bottom will push chlorides seaward.	Chlorides are more seawards in the south, but too far seawards in Tampa Bay area in the north.	Bottom boundary GHB of constant value either underpredicts chlorides in north or overpredicts them in south. It may be necessary to assign variable GHB boundaries and/or chloride concentrations on the GHB.
	Bottom GHB instantly supplies chlorides which results in chloride concentrations being too high.	Add one more layer representing the middle confining unit (i.e., evaporites) at bottom, through which chlorides move before reaching the Avon Park Formation.	Chlorides residing within middle confining unit should now move towards Avon Park Formation thereby reducing the intrusion rates.	Chlorides do not instantly upcone into Avon Park Formation.	An extra layer for MSU is needed at the bottom to appropriately represent the transients in the chloride migration.

Table 5.1 (continued)
Representative Calibration Simulations for the Saltwater Intrusion Model

Statement of the Problem	Hypotheses for the Cause	Experiments Designed to test the Hypotheses	Predicted Results	Observed Results	Conclusions from Results
3) Chlorides are too dispersed vertically, thereby limiting lateral intrusion.	Vertical dispersivity is too large.	Apply a 4-component dispersivity formulation and reduce longitudinal vertical dispersivity.	Chloride front will be less vertically diffuse causing more intrusion in lower layers of the model.	Areal chloride contours became more closely spaced in Suwannee Limestone but are still too dispersed vertically.	Reduction in vertical dispersivities results in greater saltwater intrusion inland.
	Diffusion is spreading the chlorides.	Diffusion coefficient is set to zero.	Chloride spread should be less due to no diffusion.	Very slight effect, although helpful.	Reducing diffusion helps but only marginally.
	Dispersion is spreading the chlorides.	All dispersion coefficients are reduced.	Chloride spread should be less due to lower dispersion coefficients.	Reduced the chloride spread considerably. The slope of the interface is also improved although more improvement is needed.	Low dispersivities are needed to reduce spread of chlorides and provide a slope to the interface.
4) Boundary conditions may not be appropriate	Western boundary heads are not representative of field conditions. These heads were taken from the Southern District Model which already account for average density effects.	Heads along western boundary set to zero (previously ranged from 10 - 20 ft), increasing with depth to account for chloride density.	Conceptualization is consistent. Chlorides will move seaward due to reduction of seaward heads.	Chlorides move seaward by about 1 mile. Environmental heads drop but still high as compared to Southern District Model.	Head field is satisfactory but chlorides need to move landward especially in Tampa Bay area. Effect of this on chlorides exists, but is not very prominent.

Table 5.1 (continued)
Representative Calibration Simulations for the Saltwater Intrusion Model

Statement of the Problem	Hypotheses for the Cause	Experiments Designed to test the Hypotheses	Predicted Results	Observed Results	Conclusions from Results
4) Boundary conditions may not be appropriate (continued)	Need to test the effect of northern lateral boundary heads on the area of interest.	Variation of heads along this boundary from west to east changed.	Unknown.	No change in chloride concentrations throughout the domain, or in heads in areas of interest.	Northern lateral boundary heads insensitive to intrusion and can be used from the Southern District Model.
5) Chloride front not sloped like observed under Tampa Bay.	A vertically consistent high K region under Tampa Bay makes the chlorides sit vertically abutting it.	Remove the high K region with K of a similar order as those landward.	Deeper seawater will flow further inland as compared to shallower regions without being controlled by a "wall effect".	Chlorides move seaward due to lower conductivities in the seawater region, but the interface slant is not affected.	For the current state being simulated, the high K region under Tampa Bay is not a controlling mechanism.
6) Avon Park Formation conceptualization does not account for vertical zones of higher conductivity.	All Avon Park Formation model layers have same conductivity value as calculated from Southern District Model.	Model layers 6 and 7 conductivities increased with associated decrease in conductivity of layers 8, 9 and 10 to produce the same transmissivity values as for the Southern District Model.	Conceptualization is consistent with observations. Chloride intrusion behavior will change due to the further vertical zonation.	Chlorides at about the same location in lower layers, but moves westward in upper layers. Therefore, the interface slope is less vertical in layers 6, 7 and 8 (as needed), but becomes more vertical in the lower layers.	Chlorides need to be further landward. Also, interface slope needs to be less vertical specifically in model layers 9 and 10.

Table 5.1 (continued)
Representative Calibration Simulations for the Saltwater Intrusion Model

Statement of the Problem	Hypotheses for the Cause	Experiments Designed to test the Hypotheses	Predicted Results	Observed Results	Conclusions from Results
7) Vertical zones of higher conductivity in AP do not have the hydraulic conductivity characterized. Interface needs to be less vertical.	Southern District Model does not include this conceptualization.	Model layers 6 and 7 conductivities increased by factor of 3 from the above experiment, with reduction of conductivity of layers 8, 9 and 10 for same effective transmissivity as that of Southern District Model.	Problem 6 above made the interface less vertical, so furthering the conductivity contrast of layers 6 and 7 with layers 8, 9 and 10 should make it even less vertical.	No change in chlorides.	Conductivity contrast of high K flow zones within AP is not significant beyond what is provided in experiment 6 above.
8) Post-development heads are higher than for Southern District Model or observed cases.	Water entering from bottom GHB in addition to Southern District Model conceptualization causes higher heads.	Reduce bottom GHB conductance to allow less water in.	Less water inflow will allow for larger drawdowns during pumping.	Drawdowns are greater, but salt intrusion is not sufficient in Tampa Bay area.	Need more water inflow from bottom to maintain salts. Note that pre-development heads are also higher, than the Southern District Model, so drawdowns are not that different.
	Excess freshwater entering domain from north and east supplies wells.	Lower northern and eastern boundary heads by 10 ft.	Less freshwater entering domain will cause for larger drawdowns with pumping as well as greater intrusion of saltwater.	Drawdowns are greater, and, as desired, saltwater intrusion is more extensive in the Avon Park Formation in the Tampa Bay area, but also greater in the south which is undesirable.	Allowing less freshwater into the system from lateral boundaries helps calibrate heads and chlorides in the north but worsens chloride behavior in the south.

Water and Radioactive Tracer Flow in a Heterogeneous Field-Scale System

by Frank M. Dunnivant[a,b,c], Meredith E. Newman[a,b], Carolyn W. Bishop[a], Dave Burgess[a], John R. Giles[a], Brian D. Higgs[a], Joel M. Hubbell[a], Erick Neher[a] Greg T. Norrell[a], M. Cathy Pfiefer[a], Indrek Porro[a], Robert C. Starr[a], and Allan H. Wylie[a]

Abstract

A coupled field-scale aquifer pumping and water infiltration test was conducted at the Idaho National Engineering and Environmental Laboratory in order to evaluate subsurface water and contaminant transport processes in a heterogeneous flow system. The test included an aquifer pumping test to determine the storage properties of the aquifer and the state of confinement of the aquifer (~190 m below land surface), and a vadose zone infiltration test to determine vertical moisture and radioactive tracer migration rates. Pump test results indicated that the Snake River Plain Aquifer was locally unconfined with a transmissivity ranging from 5.57×10^5 to 9.29×10^4 m^2/day. Moisture monitoring with neutron probes indicated that infiltrating water was initially transported vertically through the upper basalt layer of the vadose zone, primarily through fractures and rubble zones, at an average rate of 5 m/day (based on vertical distance traveled and first arrival of water at the monitoring points). Analysis of breakthrough curves for a conservative tracer allowed estimation of the arrival of the peak concentration and yielded an average velocity of 1 m/day. The migration velocities from the neutron probe and tracer tests are in good agreement given the scale of the test and difference in analysis techniques. None of the data sets showed a correlation between migration velocity (arrival time) and distance from the point source, but they strongly indicate preferential flow through discrete fractures. Upon reaching the first continuous sedimentary interbed layer in the basalt formation, water flow was diverted laterally along the interbed surface where it spread outward in primarily three areas corresponding to topographic lows on the interbed surface, and slowly infiltrated into the interbed. The nonpredictable movement of water and tracer through specific fractures underlying the site suggests that a priori prediction of transmissive fractures in this media is not possible. Results do suggest that the continuous sedimentary interbed layers, in general, impede vertical water flow and contaminant migration.

Introduction

A difficult waste management problem facing developed countries today is the safe, long-term disposal and maintenance of nuclear waste. Considerable effort is currently being expended to locate one or more permanent storage facilities within the United States, as well as to understand the transport and fate of radioactive contaminants in existing burial sites. One of the largest subsurface disposal facilities of this type in the United States is located at the Idaho National Engineering and Environmental Laboratory (INEEL) and contains approximately one-third of the U.S. Department of Energy's (DOE) total inventory of plutonium-contaminated waste. Waste at the INEEL resides in the 144,100 m^2 (88-acre) Subsurface Disposal Area (SDA) within the Radioactive Waste Management Complex (RWMC) and was placed in unlined shallow pits, soil vaults, and trenches in surficial sediments. The waste, disposed during a 32-year period beginning in 1952, contains 31 radioactive contaminants (Arrenholz and Knight 1991; Loehr et al. 1994; EG&G Idaho Inc. 1994) as well as heavy metals, depleted uranium, asbestos, volatile and nonvolatile organics, and inorganic acids (Loehr et al. 1994). The SDA has been flooded on three separate occasions, in 1962, 1969, and 1982, by local snow melt water during Chinook-type conditions and infiltrating water may have contacted buried waste and promoted subsurface migration. Flood control and diking projects in the 1980s have, thus far, successfully avoided additional large-scale flooding events, although localized flooding may still occur during rapid snow melt and/or intense, short-term precipitation events. Thus, flow responsible for contaminant transport from the RWMC may be described as local intermittently saturated (during periods of high snow melt and flooding events), while the majority of the time the subsurface between land surface and the aquifer (at ~168 m) is unsaturated.

The INEEL burial site is unique in that it is underlain by undulating basaltic lava flows containing interbedded fluvial, lacustrine, and eolian deposits of clay, silt, sand, and gravel. The majority of the upper 168 m, the primary subject of this investigation, is unsaturated. One of the most important questions concerning the transport of radionuclide contaminants at the site is whether sedimentary interbeds in the vadose zone act as hydrologic barriers to water infiltrating to the eastern Snake River Plain Aquifer. The aquifer has been estimated to contain approximately 2.5×10^{11} m^3 of recoverable water (Hackett et al. 1986) and thus constitutes a major resource to the state of Idaho. Large-scale field investigations conducted in saturated, fractured media emphasize the complex

processes involved in the transport of contaminants in fractured media (Neretnieks 1987; Frick et al. 1992). The purpose of the Large-Scale Aquifer Pumping and Infiltration Test (LPIT) was to mimic the intermittent saturated flow events (flooding) potentially responsible for the migration of buried contaminants at the INEEL. The purpose of this article is to summarize and contrast the main elements of the test in one publication and inform the scientific community of the extensive data sets available through the cited Department of Energy publications. These diverse and complementary data sets will be useful to scientists studying flow through similar heterogeneous systems.

The LPIT consisted of several different, but complementary, experiments. Complementary methods were used to reduce data gaps and to provide moisture information in regions between monitoring wells. Results from four of these experiments are summarized in this paper and include: (1) the aquifer pumping test which determined characteristics of the aquifer such as transmissivity, specific yield, and state of confinement, and which also supplied water for the infiltration test; (2) the neutron probe monitoring of primarily vertical water movement in the vadose zone above a sedimentary interbed (located 55 m below land surface and ~113 m above the aquifer); (3) the surface direct-current resistivity monitoring of primarily lateral moisture movement, including spatial location and accumulation of perched water on the 55 m sedimentary interbed; and (4) the water sampling and analyses used to monitor the movement of radioactive tracers through the first 55 m of the vadose zone.

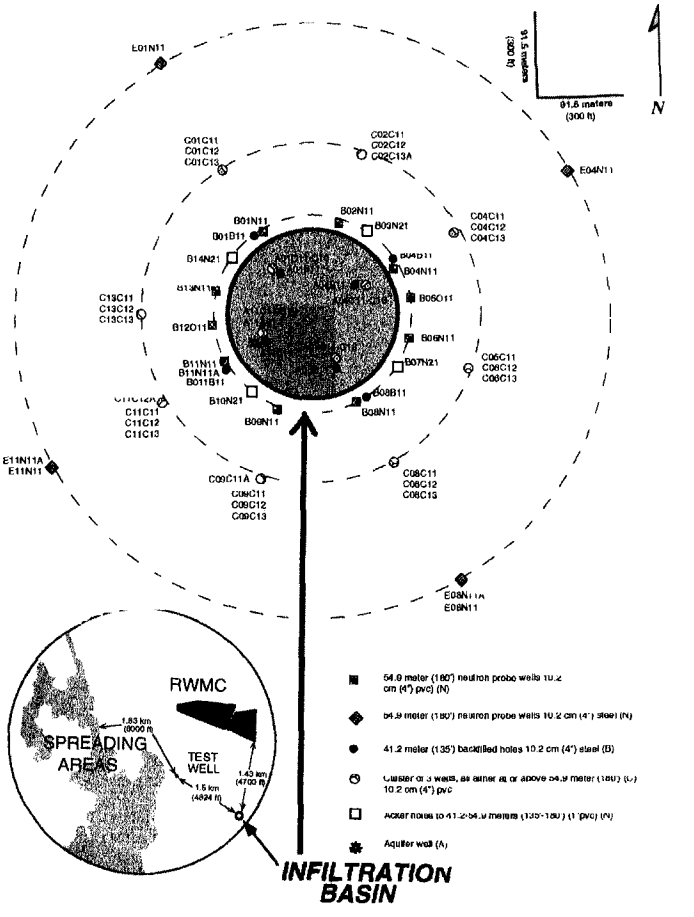

Figure 1. Map showing names and locations of wells, and general layout of the infiltration basin. Inset shows relative location of the RWMC, test well, spreading area for the diverted water, and the infiltration basin (shaded inner circle).

Methodology

General Test Design

Small- or intermediate-scale experiments are of limited value for hydrologic and geologic characterization in a highly heterogeneous environment such as the subsurface beneath the eastern Snake River Plain. In an effort to mimic the physical scale of the subsurface disposal area (144,100 m^2) while keeping the experiment to a manageable and economical size, a basin size of 26,300 m^2 (183 m diameter circular basin containing 32 million liters of water delivered from the test well) was selected. A subsurface monitoring network was set up that contained the basin and the area surrounding the basin, extending down to the 55 m interbed (contained a total monitoring volume of 17,660,000 m^3). Diagrams showing the locations of the RWMC, the test well, the infiltration basin (shaded inner circle), monitoring wells in and around the infiltration basin, and the spreading areas for water diverted from the test well are shown in Figure 1. The infiltration basin was located approximately 1400 m south of the RWMC. The circular basin (shaded area in Figure 1) was constructed by removing surface soil that was used to build an earthen berm (1.5 m high) around the area of interest. The floor of the basin was highly uneven. Approximately 80% of the basin floor consisted of a thin layer of soil overlying basalt while the remaining 20% consisted of exposed and elevated basalt. The water depth in the basin ranged from 0.3 to 2 m. The basin was approximately 1.5 km east of the test well, which was both the source of the water to the infiltration basin and the site for the aquifer pumping test (conducted simultaneously with the infiltration test). This distance of separation between the test well and the infiltration basin was based on the estimated region of influence of the test well and was selected to avoid interference between data collection for the aquifer pumping test and water reaching the aquifer from the infiltration test. Water was pumped from the test well at a rate of approximately 11,000 L/min. Because the infiltration basin could not accept the entire volume of water produced, a diversion pipe was installed to transport excess water to a spreading area approximately 1.8 km west of the test well (Figure 1; the lines and arrows indicate the location of the diversion pipe and the release point of water to the spreading area). The water level in the basin was maintained at a constant "pool-level" (32 million L) except during the addition of tracers to the subsurface. A complete summary of the water management system and water balance during the infiltration test is given in Starr and Rohe (1995).

A total of 70 wells were installed primarily along four axes extending radially from the infiltration basin with a few wells located between these axes (Figure 1). The primary monitoring area of interest was from land surface to the first continuous sedimentary interbed located at a depth of 55 m. Well depths ranged from 15 to 55 m (ground water beneath the basin was at approximately 190 m). Only well A11A31 penetrated the 55-m interbed and terminated in the aquifer at 207 m. Well A11A31 was screened from 165 to 207 m for collection of water samples. Wells in and around the infiltration basin were installed using an air rotary rig with a downhole percussion hammer, and were completed using PVC casing (five wells, for use in the DC resistivity system, were completed with carbon-steel casing). The annular space between the well casing and the borehole was completed using alternating layers of granular bentonite (10 to 20 mesh) and silica sand (6 to 10 mesh).

This type of well completion allowed water to pass freely through fractures or rubble zones, while impeding water movement along the annular space between the well casing and subsurface media in areas dominated by dense basalt. Fractures and dense basalt areas were located by reviewing caliper and video logs of the boreholes. Thus, sand was installed in the annular space when fractures or rubble zones were present, while bentonite was used to seal dense basalt areas between sand completion intervals. Wells were screened only at the bottom, which was usually located at the top of the interbed, to allow collection of water samples. The exact placement of the screen depended upon the presence of fractures, rubble zones, or voids in the area immediately above the interbed. In general, screened intervals ranged from 1 to 3 m immediately above the interbed down to the interbed (refer to Newman [1994] for completion diagrams and the location of all screened intervals). Nested lysimeters, for the collection of water samples, were installed in a similar manner using silica flour and silica sand filling materials immediately adjacent to the lysimeter and sealing between individual lysimeters, and between the lysimeters and land surface, using bentonite (refer to Newman [1994] for completion diagrams and the location of all lysimeters). Five wells and three lysimeter sets inside the basin were evaluated with respect to leakage of water (and ^{75}Se tracer) around the annular bentonite seals over the entire depth of the well. Results from this evaluation are reported in Dunnivant et al. (1997) and show that no leakage occurred; thus, the well installation methods used here appear to be adequate and allow the collection of water from individual fractures. This type of installation also allowed in situ moisture monitoring (with neutron probes) in discrete fractured intervals or rubble zones as well as in dense basalt formations over the entire depth of the wells, and collection of water samples from standing water at the bottom of the well as well as lysimeters located in fracture and rubble zones. Wells were clustered at the intersection of the four axes and four concentric circles moving outward from the basin (shaded area in Figure 1). The first ring of wells (A wells) were located within the basin at approximately 46 m from the basin center. The B, C, and E rings were located at 107, 183, and 320 m, respectively, from the basin center. All of these wells were used in moisture (neutron probe) monitoring and water sampling efforts. Piers were built from the berm out into the basin to provide access to the A-ring wells within the basin.

Water was first pumped into the basin July 25, 1994, at a rate of 11,000 L/min. The basin reached pool level, approximately 31.65×10^6 L (with water depth ranging from 0.3 to 2 m across the uneven surface of the basin), in two days. Tracers (selenium-75, ~2.0 Ci total; $t_{1/2}$ = 119.77 d, strontium-85, ~0.63 Ci total; $t_{1/2}$ = 64.84 d, and terbium-160, ~3.7 Ci total; $t_{1/2}$ = 70.3 d) were added July 31, 1994, as an 11-day finite-pulse input. Background tracer concentrations in the water from the test well were below the detection limit, which would be expected given the short half-lives of the tracers. Tracer addition was accomplished by adding the tracers as a spike to the full basin (approximately 31.65×10^6 L) and mixing the basin using three 7600 Lpm irrigation pumps. During this 11-day period, all water from the test well was diverted to the spreading areas. After the 11-day period, tracer-free water from the test well was again added to the basin and the basin was maintained at pool level through August 30, 1994. This last addition of tracer-free water provided approximately 86×10^6 L of water (or 2.72 times the volume of tracer-containing water) to move the tracers through the subsurface. The net result of this type of tracer addition was a potential broadening of the breakthrough curves and an increase in observed dispersion coefficients, but this was unavoidable given the scale of the experiment. Laboratory experiments confirmed the conservative (not reactive and adsorbed) nature of selenate for basalt and bentonite systems. Selenium-75 was selected because it should be present as the conservative (not reactive or adsorbed) selenate anion (SeO_4^{-2}) under the conditions of Snake River Plain Aquifer ground water (pH = 8.3, and E_H = + 0.24V). Analysis of basin and well water samples did not show a significant change in pH values, and since the water remained oxygenated during the infiltration experiment, ^{75}Se most likely remained present as the selenate anion. Strontium-85 was considered to be present as the free aquated cation and was selected because strontium is a fission product of concern at the RWMC. Terbium-160 was selected as a surrogate for lanthanides that have been disposed at the RWMC, and was expected to be strongly sorbed by INEEL subsurface materials. Laboratory studies indicated strontium had a K_d of 2.0 to 3.0 mL/g and was not expected to be observed at any of the monitoring sites under local equilibrium conditions. However, ^{85}Sr and ^{160}Tb were included to evaluate the presence of preferential flow and nonequilibrium transport in the system.

Aquifer Stress Test

The aquifer stress test was conducted by pumping the test well at an average rate of approximately 11,000 Lpm for 36 days. The test well was drilled to a total depth of 261 m with a cable tool rig and cased to 134 m. The remainder of the well was left as an open borehole with no casing or screen. Two observation wells were installed for this portion of the test; observation well 1 (OW1) was located 33.5 m N30E of the test well, and observation well 2 (OW2) was located 115 m S30E of the test well. The two observation wells were drilled to 304 m and cased to 183 m with a forward rotary drill equipped with a downhole hammer. The remainder of the boreholes were uncased. The water table was located at approximately 190 m below land surface and the presumed base of the aquifer is approximately 427 m below land surface. Drawdown of the aquifer during the pumping test was observed in three wells, OW1, OW2, and well 120 (229 m deep) located 36.6 m west of the test well (refer to the inset in Figure 2). Drawdown was measured in the observation wells using PTX-161D and PXD-260 transducers connected to a HERMIT 1000B and C data logger (In Situ Inc., Laramie, Wyoming). Observed drawdowns were corrected for fluctuations from barometric pressure changes, fluctuations associated with diurnal temperature/barometric pressure changes, and interruptions in pumping due to pump maintenance prior to data analysis. Data from the times when the pump was down for maintenance were deleted; these were short breaks in an otherwise long test.

Neutron Probe Measurements

Water movement and moisture changes in the vadose zone were monitored using 503DR HYDROPROBES (Boart Longyear CPN Co., Martinez, California). Several neutron probes of the same model were used during the test to provide increased coverage of the monitoring wells. Readings from the different probes were correlated to one another using calibration pits with different moisture conditions. This allowed readings made with one probe in a given well to be compared to readings made with other probes in the same well. All measurements during the experiment were made as 16-second counts at 0.30 m increments. All neutron probe wells at the test site were monitored at least once during the month just prior to the experiment to determine background moisture levels.

In most cases, wells were logged several times with several different probes. Sampling frequency of each well varied, and was intensive (approximately every four hours) during the initial portion of the test, but the frequency was reduced (approximately twice a day) as the changes in moisture decreased with time. Measurements made during the test were compared to the appropriate background log measurements to determine if moisture changes were occurring. Raw neutron probe counts were used in the analyses and no attempt was made to calibrate probe counts to water content. At each depth of measurement, a higher number of counts compared to the background level was taken as an increase in moisture. The positive difference between a given reading and the background was considered a real increase in moisture and not just the result of natural variation in readings if the difference continued to increase in subsequent logs. A more detailed description of the neutron probe monitoring can be found in Porro and Bishop (1995).

Direct Current Resistivity

The design for direct current (DC) resistivity monitoring of water infiltration was a bipole-bipole array using a fixed source bipole and a receiver array consisting of 2700 receiver bipoles (Pfeifer and Anderson 1995). The receiver bipole array consisted of a common remote electrode located near the center of the basin and a circular array of 2700 electrodes positioned in the areas between the monitoring wells outside the basin (Figure 1). The potential differences between each of the electrodes outside the basin and the common electrode within the basin were measured resulting in a maximum of 2700 potential difference measurements recorded during each monitoring session.

Water Sampling and Analyses

Water samples were collected on a regular basis from the infiltration basin, monitoring wells, and lysimeters in order to monitor the concentration of tracers in the basin and observe the breakthrough of tracers in the monitoring wells. A detailed account of the sampling methodology is given in Newman (1994) and Newman and Dunnivant (1995) and is only briefly summarized here. Eight locations within the infiltration basin were sampled using plastic containers. Well samples were collected using bottom-loading polyethylene bailers. Lysimeters were sampled by applying a vacuum of 65 to 70 kPa and allowing the lysimeter to collect water for 24 hours or until the tension in the lysimeter was approximately 35 kPa. The lysimeters were pressurized with bottled nitrogen or helium to evacuate the sample to land surface. Samples were analyzed on site in a mobile laboratory. Sample analyses included pH, specific conductivity, and radioactive tracers (^{75}Se, ^{85}Sr, and ^{160}Tb). Gamma spectroscopy for ^{75}Se, ^{85}Sr, and ^{160}Tb was performed using a high purity germanium system. Energy-line, full-width, half-maximum calibrations and background verifications were run each day prior to sample analysis. Specific conductivity and pH were analyzed using standard meters, cells, and electrodes. Instruments were calibrated once every two hours or prior to use.

Results and Discussion

Aquifer Stress Test

The aquifer pumping test was conducted to determine transmissivity, specific yield, and the state of confinement of the aquifer, as well as to supply water for the infiltration test. First, we will discuss the barometric "efficiency" of the well, which relates to the effectiveness of the pressure transmittal and is dependent upon the rigidity of the geologic media and the overall permeability of the rock. Typically the potentiometric surface of a confined aquifer is not affected directly by barometric pressure changes, so barometric pressure changes have a direct, measurable impact only on water levels in wells. However, the potentiometric surface of an unconfined aquifer is usually in direct contact with the atmosphere; hence, barometric pressure changes have a negligible impact on water levels in wells. Prior to the LPIT the barometric efficiency for well 120 in the Snake River Plain Aquifer was found to be approximately 90% for short-term fluctuations and 60% for long-term fluctuations, suggesting that the aquifer is confined (Wylie et al. 1995). However, data from the large-scale pumping test indicate that the aquifer is unconfined (Figure 2). One possible explanation for this observation is that those geologic units isolating the aquifer from barometric pressure fluctuations are above the potentiometric surface of the aquifer and do not act as aquitards. Our conceptual model is that aquifer permeability is largely controlled by the distribution of basalt flow contacts with some additional permeability contributed by fractures, vesicles, and intergranular pore spaces (Mundorff et al. 1964). Individual basalt flows within the Snake River Plain Aquifer consist of four elements: an upper vesicular element, a central nonvesicular element, a bottom vesicular element, and a substratum. The observed median thicknesses of the three upper elements are 1.8, 2.3, and 0.46 m, respectively (Knutson et al. 1989). On the scale of the aquifer test (hundreds of meters), dense basalt flow interiors act as "grains" while the "intergranular porosity" is reflected in the interflow zones between the dense interior (Whitehead 1992). These "grains" are formed as basalt flow sequences are deposited in an overlapping and coalescing manner, where younger flows build on the complex undulating topography of previous flows. Flow through the aquifer follows a tortuous path, around, through, and between these large particles in the general direction of the regional hydraulic gradient. If a well is open below the water table, or if the potentiometric surface is within a section of dense basalt, and the potentiometric surface is insulated

Table 1
Calculated Aquifer Coefficients

Observation Well	Transmissivity (m^2/day)	Storage	Kh/Kv Ratio	Analytical Method
OW1 upper	1.39×10^5	1.3×10^{-1}	1×10^2	Neuman
r = 33.5 m	5.48×10^5	5.3×10^{-2}		drawdown
				Theis recovery
OW1 lower	5.11×10^5	1.8×10^{-1}		Neuman
r = 33.5 m	3.25×10^5	2.3×10^{-2}		drawdown
				Theis recovery
Well 120	1.21×10^5	1.4×10^{-1}	6×10^1	Neuman
r = 60.96 m	1.11×10^5	5.0×10^{-2}		drawdown
				Theis recovery
OW2 upper	1.39×10^5	1.4×10^{-1}	3×10^1	Neuman
r = 115.2 m	7.25×10^5	4.2×10^{-2}		drawdown
				Theis recovery
All wells	1.30×10^5	9.0×10^{-2}		Distance drawdown

from barometric pressure changes, a barometric pressure change will result in a pressure difference between the well and aquifer, causing the water in the well to either rise or fall in response to the pressure difference.

The water level change is inverse to the barometric pressure change; if barometric pressure decreases, the water level will increase. Analytical results (Newman and Theis methods) for the pump test data presented in Figure 2 are summarized in Table 1. The Newman method was used to obtain estimates from the drawdown portion of the curve and the Theis method was used for the recovery portion of the curve. Estimates of transmissivity vary from 9.29×10^4 m^2/d to 5.57×10^5 m^2/d (1×10^6 ft^2/d to 6×10^6 ft^2/d) and the storage coefficient varies from 1×10^{-1} to 2×10^{-2}. The observed drawdown in the test well was 2.90 m, while the predicted drawdown using calculated aquifer coefficients from this test is 0.17 m. The well efficiency is 6%, yet the test well is completed as an open hole. An open hole is the most efficient well design possible. Perhaps the well efficiency is low because permeability is not evenly distributed throughout the length of the well. Aquifer permeability may be isolated in the basalt flow contacts, resulting in converging and turbulent flow within and adjacent to the well. Attempts to match the data with the Moench (1984) double porosity model yielded higher permeabilities within the matrix blocks than within the fractures. Perhaps the data are adequately described by the Neuman model because the matrix material is sufficiently low and the interflow zones are distributed evenly enough that fluid flow can be approximated with an equivalent porous granular media analytical model.

Neutron Probe Moisture Monitoring

Water movement in the fractured basalt vadose zone beneath and adjacent to the infiltration basin was monitored using neutron probes during the LPIT. Wetting fronts and wetted zones were readily distinguished using these probes. Moisture changes in the sand and bentonite used to fill the annular space between casing and basalt in the monitoring wells could also be detected during equilibration with antecedent vadose zone moisture. These changes occurred during the first few months after well completion and prior

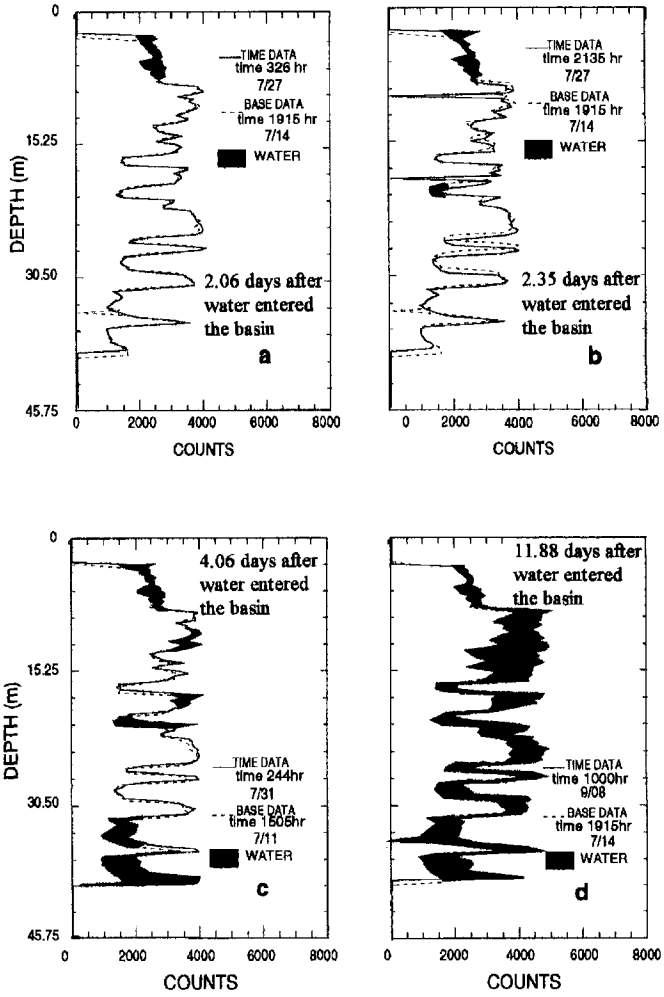

Figure 3. CPN (moisture monitoring) results from well A11C12 (inside the infiltration basin) illustrating the wetting progression from (a) 2.06 days after the addition of water to (b) 2.35 days after the addition of water to (c) 4.06 days after the addition of water to (d) 11.88 days after the addition of water to the basin. The dashed line in each plot represents the background neutron log while the solid line represents data collected on the specified day. Deviations between the two data sets are indicated by shaded areas.

to the LPIT so equilibrium was reached before infiltration was initiated. These observations indicate that vadose zone wells constructed in this manner and used in this type of subsurface environment should be installed and allowed to equilibrate sufficiently before they are used for moisture measurements.

In general terms, vertical water flow in the vadose zone during the infiltration test was confined within a cylinder directly beneath the infiltration basin. The rate of the wetting front advance averaged about 5.0 m/day (n = 38, ranging from 1.4 to 17.7 m/day, s.d. = 2.90). Although vertical water movement appeared to occur within a cylinder defined by the basin, wetting did not progress as a front uniformly distributed across this area. This is shown in neutron logs given in Figure 3. Figure 3 illustrates the general pattern of wetting observed in the infiltration basin monitoring wells. The shaded areas indicate where moisture levels have increased above background levels due to infiltration from the basin. Initial wetting was observed immediately underneath the infiltration basin to a depth of about 9 m (Figure 3a). Subsequently, a wetted zone appeared at the 19.8 to 21.4 m depths, while measurements between the 9 to 19.8 m depths remained unchanged from background levels (Figure 3b). Clearly, the water must have moved through preferential pathways to

reach the 19.8 to 21.4 m depths without wetting the zone from 9 to 19.8 m; it did not migrate downward uniformly through the geologic material surrounding the well. Figure 3c shows that water reached the 30.0 to 39.7 m depths while bypassing the 25.9 to 32.0 m depths, further illustrating preferential flow. A new wetted zone also appeared around the 12 m depth. Figures 3a to 3c illustrate water moving through the faster flowpaths. Figure 3d shows that 11 days after pumping entered the basin, wetting was evident throughout the entire length of the monitoring well. Water has obviously made its way more slowly through other pathways to wet those zones that were bypassed previously. While there was evidence of preferential and lateral flow within the cylinder beneath the basin, lateral flow did not extend to the B-ring wells just outside the basin, except in the region immediately above the 55 m sedimentary interbed. Moisture level changes were not observed at depths between land surface and the sedimentary interbed in any of the B-, C-, and E-ring wells, except in the media immediately above the interbed where water flowed along topographical lows.

Water movement through a few preferred pathways is suggested by the wetted porosity (0.02%). The wetted porosity was calculated by dividing the average infiltration rate (approximately 11 cm/day) by the wetting front travel rate (approximately 5 m/day). This compares to an average effective porosity of 0.23, which was averaged from 71, 5.6 cm long vesicular basalt cores taken from this area (Bishop 1991). This value was determined for a vesicular matrix without obvious fractures, and the presence of fractures and rubble zones in the field test should cause the porosity to increase. Thus, less than 10% of the total porosity actually conducted water. Bishop (1991) also found an average saturated hydraulic conductivity of 1.6 $\times$ 10^{-8} m/s for a 50 cm $\times$ 20 cm $\times$ 20 cm block of unfractured vesicular basalt. The much faster advance of the wetting front in the large-scale field test indicates that the basalt matrix played a minimal role in conveying water through the vadose zone and that fractures and rubble zones constituted the primary pathways.

Direct Current Resistivity

DC resistivity arrays are commonly used to map changes in the electrical properties of the subsurface due either to geological spatial changes or to changes in physical properties over time. The electrical properties measured are related to the moisture content of the medium so that changes in the DC resistivity measured over time can be used to monitor wetting or drying fronts (Pfeifer 1987; Ash and Morrison 1989; Truskowski 1994). Using this concept, a DC resistivity array was used to monitor the lateral movement of water outward from the infiltration basin. The array was designed to augment well data and to provide real-time coverage of the areas between the sampling wells. The areal extents needed to be covered in real time were large, and to expedite this process, only real-time lateral migration information could be obtained using the DC resistivity array configuration. However, well data were used to determine the depth of the lateral migration of water.

Real-time interpretation of the data was performed in the field and consisted of comparing the data collected during the test with background data collected prior to filling the basin with water. Interpretation consisted of two steps. The first step was to detect anomalous regions in the subsurface geology and the second step was to monitor changes in the potential electric field that could be related to the lateral spreading of water from the basin. First, a map of anomalous areas was generated using the data from each of the electrodes. The geology of the area was modeled using a layered

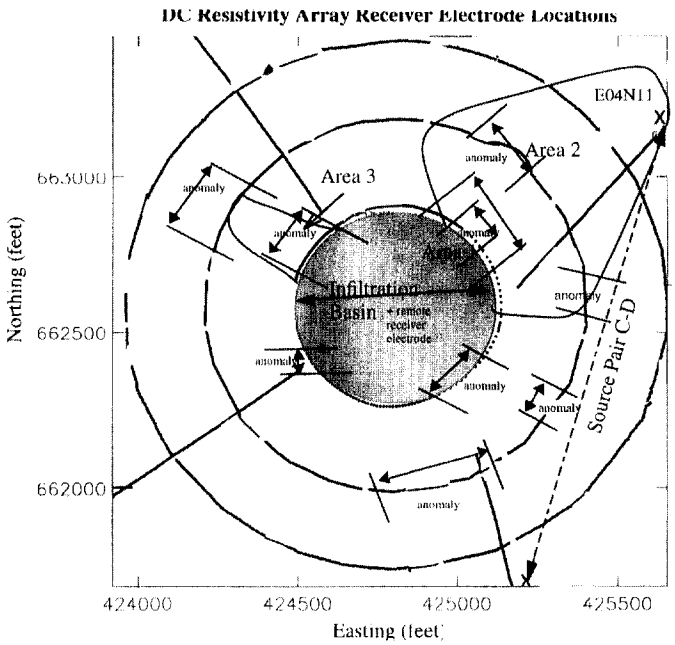

Figure 4. Map of anomalies detected by DC resistivity array superimposed on receiver array positions. Areas 1, 2, and 3 are areas corresponding to changes in the potential field due to lateral water migration. Note that the orientation of this figure is identical to Figure 1.

earth model; anomalous areas are those regions where the data diverged from the layered earth model indicating the presence of three-dimensional geologic structures such as rubble zones, depressions in the top of the interbed, and similar structures. Figure 4 is an areal summation of the geologic anomalies superimposed on the receiver array positions. The anomalous areas were postulated to be areas where lateral movement of water would occur. After mapping the geologically anomalous areas, the array was monitored over the course of the test to detect the lateral movement of water. As expected, the ring of electrodes directly adjacent to the infiltration basin showed the first changes in the anomalous areas. One anomalous area adjacent to the northeastern edge of the basin berm and well BO4N11 (designated Area 1 on Figure 4) showed a marked decrease in the potential electric field over time after the addition of water to the basin and prior to the arrival of water in well B04N11. This area was interpreted to be an area of lateral movement of water and the interpretation was confirmed by recovery of water from well BO4N11. Monitoring the array farther from the basin showed two areas where changes in the potential were measured. Area 2 (Figure 4) on the northeastern side of the basin coincides with a geologic anomaly and several wells from which water was recovered and was interpreted as a broad area of lateral water movement along the top of the interbed. The second area (Area 3 on Figure 4) is located on the western side of the basin near well B01N11 and is interpreted as a narrower zone of lateral water migration along the top of the interbed. Confirmation of perched water by water sampling could not be made in this area because wells could not be completed to the top of the interbed due to the presence of a large, subsurface rubble zone. Well B01N11 was the only well on the western side of the basin where water was recovered; however, the array data shows the migration of water in this area. In summary, water appeared to move laterally across the interbed surface and outward from the basin primarily in three areas coinciding with areas of geologic anomalies.

Water Sampling and Analyses

Each of the monitoring wells and lysimeters was frequently sampled in an effort to collect infiltrating water containing tracers. Wells were sampled at least once every 12 hours after the first detection of water. Lysimeters were sampled every 24 hours or when the tension fell below 35kPa. Of the 101 possible water sampling locations, water was recovered from only 30 and ^{75}Se-labeled selenate was detected in 26 of these 30. Nineteen of the 26 wells and lysimeters found to contain tracer produced sufficient data to construct breakthrough curves (BTCs). Neither ^{85}Sr nor ^{160}Tb were detected in any well or lysimeter water sample. However, in situ monitoring with a downhole HPGe detector suggested the presence of ^{85}Sr in a few selected zones (Dunnivant et al. 1994, 1997). Lack of detection of ^{85}Sr and ^{160}Tb in water samples indicated that, for most sampling locations, sufficient contact between the tracers and subsurface materials occurred to retard their transport. However, as previously mentioned, preferential flow may have occurred at a limited number of locations.

Representative BTCs from B-ring wells are shown in Figure 5. Although the BTCs obtained were all for the same tracer (^{75}Se labeled selenate), the shapes of the BTCs varied significantly between different wells and lysimeters. This dissimilarity between breakthrough curve shapes indicated that a variety of different flowpaths ranging from individual fractures to interconnecting flowpaths were present beneath the basin. Figures 5a and 5b show the more classical shaped BTCs represented by the Gaussian or bell shape. Figures 5c and 5d show two BTCs (or one bimodal curve) at one location and can be explained by the presence of two separate flow channels between the basin and monitoring point. It is interesting to note the difference in shapes for each of the bimodal BTCs, specifically the width, which is related to dispersion. Specific conductivities of the sampled water are also shown in Figure 5 and confirm the different source (with respect to flowpath) of each water.

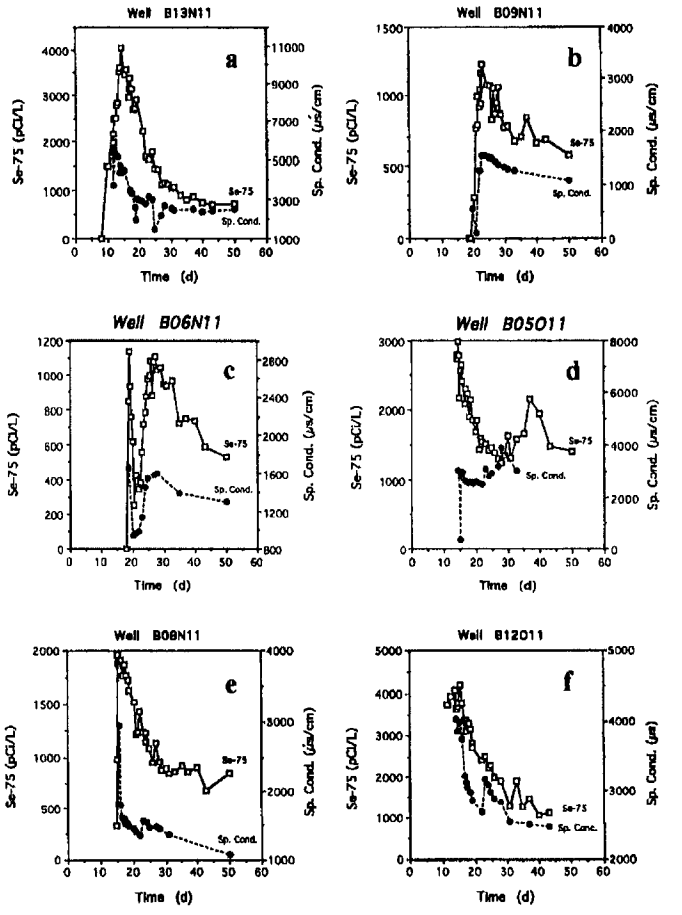

Figure 5. Examples of BTCs for Se-75 labeled selenate and electric conductivity measurements from B-ring wells. Note that time zero in these plots corresponds to the date of tracer addition (July 31, 1994) and not to initial water input to the basin. Figures a and b represent symmetrical or nearly symmetrical BTCs for ^{75}Se. Figures c and d represent bimodel BTCs for ^{75}Se. Figures e and f represent "unexpected" BTCs for ^{75}Se where the first water arriving at the monitoring site contained the highest concentration of ^{75}Se.

A common feature of the BTCs was tailing during the washout phase of the test. Tailing could have been caused by (1) transport in multiple fractures or rubble zones, (2) matrix diffusion, or diffusion from dead-end pores, (3) wall effects in fractures or rubble zones, (4) channeling, (5) mixing in the wells or lysimeters, and (6) the type of tracer input pulse used. Although mixing in the wells and lysimeters was possible, it is doubtful that it was the primary cause of the observed tailing because the degree of tailing varied considerably from well to well and from lysimeter to lysimeter with no apparent relationship between depth of standing water in the wells and degree of tailing observed. It is not possible from the current data set to isolate with certainty which of the first six possible causes was primarily responsible for the observed tailing. It is possible that the observed tailing resulted from a combination of all of these causes.

Several aspects of the data collected confirm the highly complex nature of the system under study. For example, tracer-free water was added to the infiltration basin for six days prior to the addition of tracers; however, the first water observed in several wells contained tracer (Figure 5e and f). Also, tracer-free water was observed in several lysimeters throughout the course of the test. Intervals containing insufficient water for the collection of samples were observed between water bearing zones. In addition, little correlation was observed between distance from the tracer source and tracer arrival time. Arrival times observed for B-ring wells, which were all the same distance from the tracer source, varied from 14.5 to 36.4 days. Results from nested lysimeters showed early arrival of ^{75}Se-labeled selenate at a given location while shallower and deeper lysimeters in the same installation showed significantly later arrival times.

One explanation for the diversity of BTCs and the lack of selenate at some monitoring points is the presence of dead-end fractures and fractures or dense basalt zones not directly or continuously connected to the flow of water. It is possible that some dead-end fractures intercepting the sampling points filled with tracer-free water early in the test, causing subsequent water flow at the origin of the flowpath to be diverted to an adjacent fracture or flowpath. The concomitant arrival of water and selenate at a monitoring point may be due to this diversion of water from these "filled" dead-end flowpaths or short circuiting in the system. These proposed flowpaths are illustrated in Figure 6.

Ten ^{75}Se breakthrough curves were analyzed using a modification of the one-dimensional advective-dispersive transport model (CXTFIT) of Parker and van Genuchten (1984). The nonreactive, one-dimensional model was selected since the flow regime between land surface and the 55 m interbed is best represented by channel flow through fractures and rubble zones. Basically, this program fits the one-dimensional model to the data set and estimates the most probable water velocity and dispersion coefficient. Results from this modeling effort are summarized in Table 2, while a detailed summary of this approach may be found in Dunnivant and Newman

Table 2
Parameter Estimates for ^{75}Se Breakthrough Curves

Location	Vertical Distance (m) from Land Surface	V (m/d) (Estimates from CXTFIT)	Dispersion (m^2/d) Coefficient (Estimates from CXTFIT)	r^2 (Regression Coefficient)	Calculated Dispersivity (m) (Dispersion Coefficient Times Velocity)

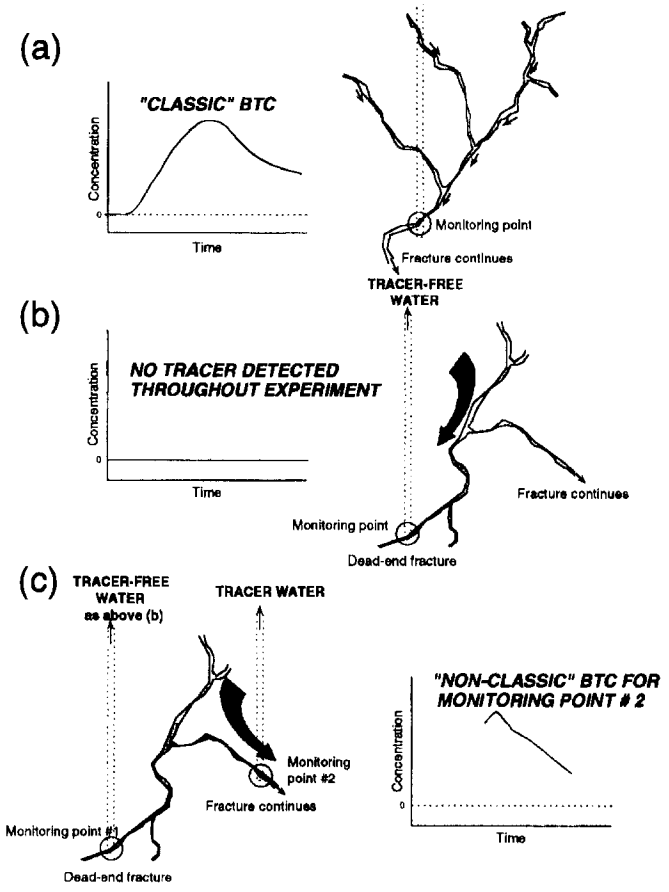

Figure 6. Conceptualization of the subsurface fractures and water flow beneath the basin.

(1996). The model estimated that dispersion coefficients for the fractured basalt regions above the interbed range from 0.079 to 4.15 m^2/d (mean = 1.66 m^2/d, s.d. = 1.72, n = 6), which correspond to longitudinal dispersivity values ranging from 0.176 to 3.92 m (mean = 1.5 m, s.d. = 1.29, n = 6). Water migration velocity (V in Table 2) estimates range from 0.45 to 2.63 m/d (mean = 1.01 m/d, s.d. = 0.81, n = 6). These predicted water velocities are in reasonable agreement with the rate of wetting front advance estimated from neutron probe measurements, especially considering that the velocity estimated from neutron probe measurements is for initial wetting while water samples could not be collected until near saturation conditions were reached, and therefore provide estimates of saturated interstitial velocity.

Results for water flow along the interbed are more difficult to interpret since water first flows through one or more fractured basalt regimes, and upon reaching the interbed flows along topographical lows. Under these conditions, the system is no longer one-dimensional and the flowpath length is the sum of the vertical and horizontal distance from the basin floor to the monitoring point. Water velocities to the B-ring wells range from 2.48 to 7.52 m/d (mean = 5.02 m/d, s.d. = 2.09, n = 4) . Dispersion coefficients range from 0.75 to 209 m^2/d (mean = 27.7 m^2/d, s.d. = 35.12, n = 4) and correspond to dispersivity values ranging from 0.10 to 45.8 m (mean = 16.2 m, s.d. = 20.6, n = 4).

Conclusions

The large-scale aquifer pumping and infiltration test provides the INEEL with a valuable data set for evaluating fate and transport of buried wastes at the RWMC, and also provides a unique data set for researchers interested in migration of water through intermittently saturated heterogeneous systems. Data from the pumping test indicate that the Snake River Plain Aquifer is highly transmissive (1.2×10^5 m^2/d), although water primarily flows from a few highly productive fractures, and is locally unconfined. Data from moisture and tracer monitoring in the vadose zone are summarized in the conceptualization shown in Figure 7. Water appeared to migrate downward through isolated fractures within a cylinder defined by the infiltration basin and did not spread horizontally outside the basin until reaching the 55 m interbed. The average rate of vertical water transport to the 55 m interbed was 5.0 m/day based on neutron probe results and was 1.0 m/d based on analysis of ^{75}Se BTCs. The difference in these two values is probably due to the use of the first arrival of water in the neutron probe technique, while the ^{75}Se-based technique used the mid-point of the BTC to estimate water velocity. These BTCs indicate that a variety of subsurface flowpaths exist, ranging from individual fractures to a complex series of intercon-

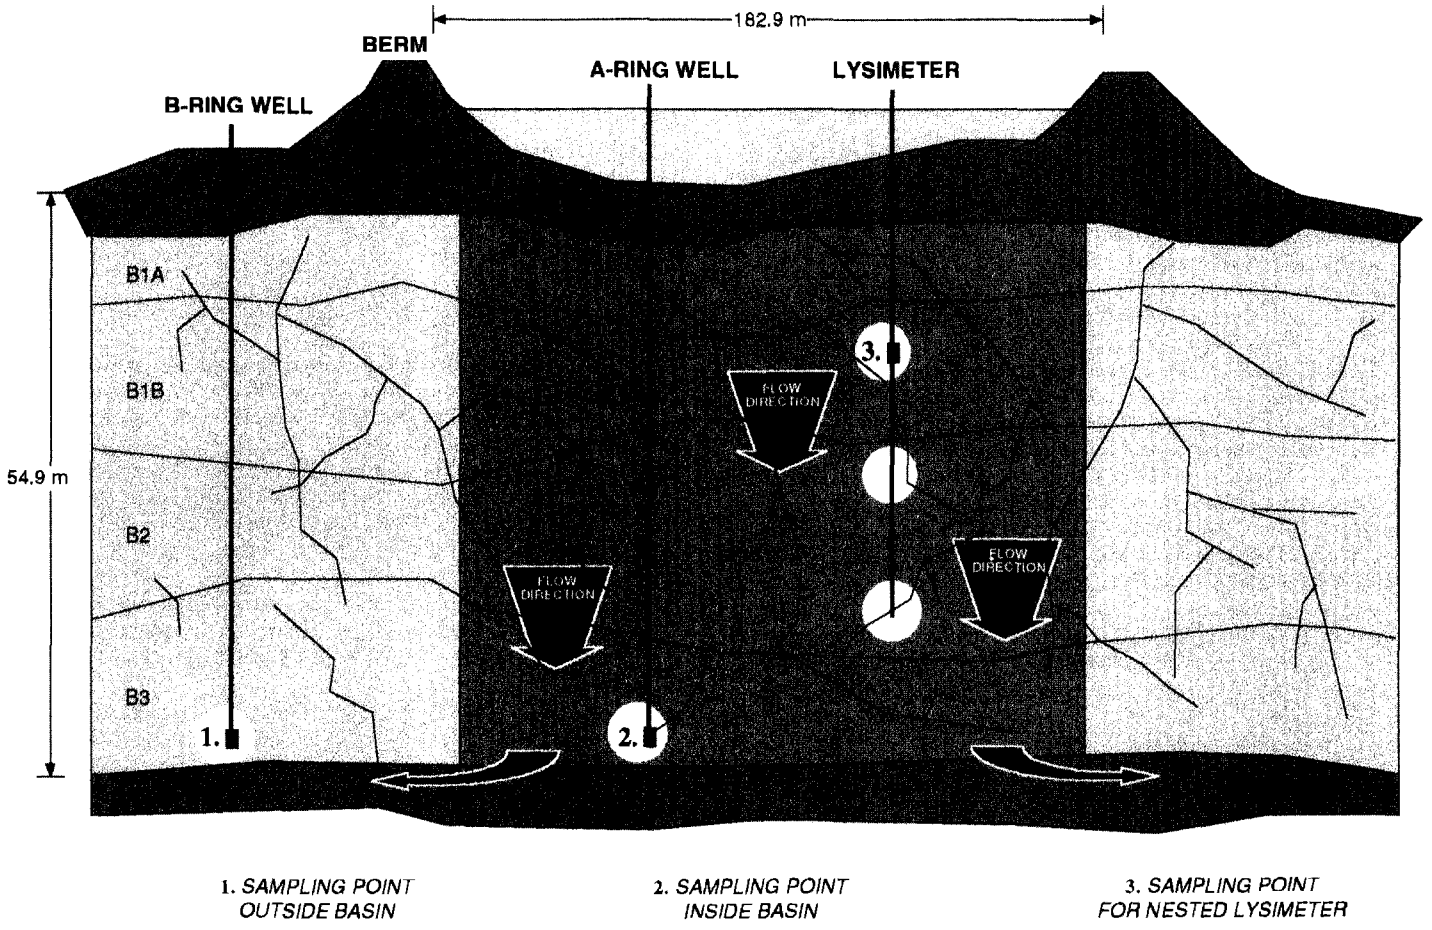

Figure 7. Conceptualization of the overall water flow beneath the basin. B1A, B1B, B2, and B3 represent individual basalt flow units.

nected flowpaths. Not all fractures intercepting monitoring wells or lysimeters produced water or tracer.

As the infiltration test progressed, water reached the 55 m interbed and formed a perched water body that was characterized by DC resistivity measurements and confirmed by recovery of water from monitoring wells. Water moved outward from the basin primarily in three areas coinciding with geological anomalies and with topographic lows on the interbed surface as determined from well logs. In addition, the 55 m interbed appears to impede the migration of water (and tracers). The presence of two similar interbeds below the RWMC suggests that buried waste in the SDA has probably not migrated to the aquifer.

Additional efforts, using an inverse modeling approach, to predict the spatial movement of moisture and estimate the range of dispersivity coefficients in these fractures are summarized in Magnuson (1995) and will be the subject of a subsequent publication. One clear result from this investigation is that a priori prediction of discrete water movement and tracer concentrations is difficult, if not impossible, in the fractured system underlying the INEEL.

Acknowledgments

A test of this magnitude required the efforts of a large number of people. We would like to acknowledge the U.S. DOE-ID, especially Patti Kroupa; program management by Kirk Dooley and Gary Mecham; water sampling by Steve Ugaki, Scott Barrie, and Hollie Gilbert; day-to-day oversight in the field by Pat Boyd, Joe Cook, and Tom Wood; DC resistivity assistance by Denise Psesser and Andy Anderson; numerous tasks performed by 30 dedicated summer students; and Jackie Brower for drafting of figures. This work was supported by the U. S. Department of Energy, Assistant Secretary for Environmental Management, under DOE Idaho Operations Office Contract DE-AC07-94ID13223.

Introduction:

The CERP recommends approximately 333 ASR wells to help with the supply, storage and distribution of water within the South Florida Region. The wells are dual purpose, since they are intended to store excess water during summer wet periods and recover the water during dry winter periods. It is hoped that the technology will provide a dependable water storage mechanism that can supplement surface storage reservoirs and provide water supply to the Lake Okeechobee ecosystem, Everglades ecosystem, agricultural irrigation, urban interests and others. The proposed injection and recovery pumping rate is approximately 1.65 billion gallons per day which is unprecedented in terms of other past or present ASR applications. Currently, only desktop spreadsheet evaluations or analytical solutions can provide an estimate of the aquifer response (e.g., piezometric head increases, fracturing pressures, increased flow) to such a large volume of injected water. A numerical model (or family of models), designed to simulate the regional groundwater system, will serve to make further evaluations of the plan. Porous media models and a discrete fracture network models have been considered but due to the lack of discrete fracture data related to the hydrogeology of south Florida, a porous media model has been pursued.

The CERP blue-print has been presented in a massive regional-scale plan that lacks engineering detail sufficient to construct the project. A large number of the construction features contained in the CERP were designed at various levels of detail based on information that was available during the plan formulation and evaluation phase. Many of the design assumptions for the components were based solely on output from the South Florida Water Management Model (SFWMM), which averages hydrologic conditions across a model comprised of grid cells with lengths and widths of 2 miles by 2 miles. Consequently, the engineering details of the construction features,

including the size and locations are conceptual and require additional studies. In addition, the SFWMM only simulates the Surficial Aquifer System explicitly. The Floridan Aquifer System where the proposed ASR wells would be located is not included. In general, the CERP proposed 200 ASR wells to be sited in the vicinity of Lake Okeechobee with the remaining wells located adjacent to the C-43 reservoir and in the Lower East Coast (specifically, Palm Beach and Broward Counties, Florida). A later effort, the Water Preserve Area (WPA) Feasibility Study, proposed adding additional wells in this area. The exact location and distribution of the proposed CERP ASR wells was never determined as part of the original CERP effort, however, the proposed wells were generally concentrated adjacent to reservoirs or Lake Okeechobee. The WPA Feasibility efforts proposed ASR wells at the C-9 impoundment.

Together with the ASR Pilot Projects and the ASR Contingency Plan, the ASR Regional Study will endeavor to reduce technical uncertainties associated with the proposed CERP ASR plan - a plan that is unprecedented in scale anywhere in the world. A Project Management Plan (PMP) was prepared for the ASR Regional Study in 2003. The center-piece of the ASR Regional Study is the preparation of a series of numerical simulation models. A multitude of issues need to be evaluated using the family of numerical models. The issues include local, sub-regional, and regional-scale concerns counting the following:

1. Regional changes in aquifer heads and flows
2. Regional changes in aquifer water quality TDS, sulfate, and chloride
3. Increased potential for salt-water intrusion caused by ASR pumping
4. Regional impacts to existing well users of the FAS
5. ASR well cluster site selection
6. ASR well cluster design and layout
7. ASR well cluster performance including estimating recovery efficiency
8. ASR well site evaluation of pressure induced changes
9. Localized transport of contaminants including heavy metals or pathogens
10. Localized ASR well pump design (dependent upon the appropriate model resolution)

Initially, a large, peninsula-wide numerical model will be developed. It is envisioned that this model will encompass an area of the Florida peninsula from Polk County south to Florida Bay. This model is intended for use as a planning tool to evaluate potential changes (e.g., head/flow and water quality) within the confined Floridan Aquifer System (FAS), aid in the site selection of ASR well clusters in the vicinity of Lake Okeechobee, adjacent to the C-43 reservoir and in the Lower East Coast area of South Florida, and aid ASR well cluster design and layout. In support of the main model development task, a number of smaller tasks will also be completed prior to or in parallel with the screening model development (e.g., literature search, data compilation, model selection, etc.). Once the Regional Screening Model is completed, more detailed sub-regional and/or local scale models will be developed to evaluate the ASR program in a higher level of detail. Depending upon model code selection and model domain design, all ten of the issues noted above could be evaluated. Table 1 displays the model scale required to address each of the identified issues. Both the sub-regional and regional scale

models should be designed to address as many of the issues listed as possible. In essence, the sooner the issue can be evaluated, the better. Obviously, one possible strategy would be to address the issue in two tiers. First, the regional model could provide planning-level information to address the specific issues. Then, an improved understanding of the issue could be obtained through the development of finer-resolution sub-regional models. For the three local-scale issues identified, only small models with fine horizontal and vertical resolution, will be sufficient to adequately address them.

Table 1. Model scale requirements.

Model Scale Required to Address Specific Issue	**Issues to be addressed as listed above**
Local Scale fine-resolution model	7, 9, 10
Sub-regional moderate-resolution model	1, 2, 3, 4, 6, 8
Regional Scale moderate to coarse resolution model	1, 2, 3, 4, 5, 6, 8

It is anticipated that the model development process will require approximately 1.75 to 2-years to finish and will involve numerous meetings, workshops, and conference calls. A team of model developers will work collaboratively over the internet and through video-conferences. It is expected that the model development effort will involve numerous technical challenges including addressing seawater boundary conditions; determining an appropriate number of model layers and grid/mesh spacing; developing manageable model computer run-times; evaluating vertical aquifer system connections/leakage; testing alternate locations for ASR clusters; developing reasonable ASR recharge and recovery scenarios; and determining whether or not steady state modeling is applicable.

Due to the large scale of the model, computer run-times are expected to be quite long. Therefore, the selection of an appropriate model code is of paramount importance. Consideration will be given to utilizing a fully density-dependent model code if performance tests confirm that such a code would be practical to use at the scale envisioned. Otherwise, consideration will be given to simulating density effects at the seawater boundaries and along the bottom of the model as necessary.

Model Code Bench-scale Testing Scope of Work:

The scope of work for the model development effort presented in the ASR Regional Study PMP recognized that a fully density-dependent code would be ultimately be required to simulate regional changes in aquifer pressure and water quality. This is due to a number of technical considerations including:

- Water exchange between various portions of the FAS
- Water flow and velocity issues near coastal portions of the model
- ASR recovery efficiency is partially dependent upon density stratification effects
- Density directly affects the regional heads and flow within the FAS
- Density is a function of water quality of the aquifer (e.g., function of TDS)

The PMP also considered alternate modeling approaches employing density-dependent boundaries to grossly simulate density affects. Therefore, the development of sub-regional models that possessed the requisite density-dependent capabilities were specified as part of the PMP to ensure the most realistic model simulations could be developed. Alternate modeling approaches may allow some flexibility in the development of a regional model, ensuring that the following constraints are managed:

- Limitations of existing density-dependent model codes
- Concerns about model run times
- Schedule constraints
- Resources available

Ideally, both the Regional Screening Model and the sub-regional models would be fully density-dependent models. Subsequent to completion of the PMP, advances in model codes have made the use of a density-dependent code more feasible as part of the Regional Screening Model development effort. There is concern, however, that the size of the model might limit the feasibility of the fully density-dependent approach due to the constraints listed above, especially model run times. In order to balance the needs of the project with the current technical capabilities of software and hardware, the model development team recommended the development of a bench-scale model to evaluate various model codes and approaches in order to aid the model code selection task.

The primary objectives of the bench-scale modeling effort are:

- Provide an improved estimate of model run times for 36-year simulations
- Provide a preliminary understanding of model development issues relating to resolution requirements, boundary types, and starting conditions
- Uncover model limitations and short comings

An appropriate code for the Regional Screening Model is to be selected on the basis of bench testing of various model codes at a sub-regional or county-wide scale. Although the proposed domain size is still considerably smaller than the anticipated regional model domain, it does provide a firm basis for the extrapolation of model performance to the larger domain. Bench testing of several model codes will provide a solid basis to make an informed decision on model code selection. This course of action will provide the following benefits:

- Aid in determining what class of model (constant density standard flow and transport, uncoupled density-dependent flow and transport, fully density-dependent flow and transport) is required to address CERP ASR issues
- Provide comparison performance metrics for various bench marked codes including relative accuracy, and model stability and run-times
- Aid in the evaluation of hardware needs & pre/post processing requirements

It was envisioned that the benchmark modeling effort would develop several identical (constant density standard flow and transport, uncoupled density-dependent flow and transport, fully density-dependent flow and transport) models covering a much smaller model region than projected for the Regional Screening Model. It was anticipated that a 40 mile X 40 mile area would provide a model domain of sufficient size and complexity to provide a valid test of each proposed model code and allow extrapolation of results to larger regional scales. The scale and design would be similar in size to Palm Beach County, Florida, where many ASR wells are proposed for installation. As part of the ASR Pilot Project Design Report (PPDR), a numerical model of the Palm Beach County area was available. In order to maximize the use of previously developed model tools as suggested by the Interagency Modeling Center (IMC), the USACE provided the Palm Beach County model as the "base" MODFLOW/MT3D model. Using the base model as a guide, four similar "box models" were prepared using four different model codes/approaches. The model was provided "as is" and was not optimized for any particular application.

The four codes were selected in a collaborative fashion among members of the modeling sub-team of the PDT. With the exception of the MODFLOW SWI package, the sub-team members had significant experience with the rest of the models selected. In addition, each of the codes selected was paired with a well-known pre/post-processor software package that simplified the model development process. Lastly, budget considerations limited the task scope to no more than four model codes. If time and budget had allowed, several other established codes would also have been considered, including FEFLOW and SUTRA, for example. The four model codes utilized for the bench-scale study are:

- MODFLOW and MT3DMS using equivalent freshwater heads to represent saltwater boundaries (e.g., constant density flow and transport model)
- SWI (Sea-Water Intrusion) Package for MODFLOW (density dependent vertically integrated flow with interface tracking)
- SEAWAT (fully coupled or uncoupled density-dependent flow and transport)
- WASH123 (fully coupled or uncoupled density-dependent flow and transport)

MODFLOW is a computer program that numerically solves the three-dimensional groundwater flow equation for a porous medium using a finite-difference method (McDonald and Harbaugh, 1988). MT3DMS is a computer program for modeling multi-species solute transport in three-dimensional ground-water systems using multiple solution techniques, including the finite-difference method, the method of characteristics (MOC), and the total-variation-diminishing (TVD) method (Zheng and Wang, 1999). MODFLOW is considered to be the most widely used program for constant-density groundwater flow problems. Key factors in MODFLOW's popularity in the modeling community are its thorough documentation, modular structure, which makes it easy to modify and enhance, and the public availability of the software and source code.

The Sea Water Intrusion (SWI) package is intended for the modeling of regional seawater intrusion with MODFLOW2000 (Bakker and Schaars, 2002). The SWI package utilizes

the Dupuit approximation that neglects vertical resistance to flow in the vertical direction. The vertical pressure distribution is hydrostatic in each aquifer. The advantage of using the Dupuit approximation is it allows multiple aquifer systems with one layer of cells. The vertical pressure distribution is hydrostatic in each aquifer, but this does not mean that there is no vertical flow; the vertical component of flow is computed from the three-dimensional continuity of flow. Variable-density flow may be simulated, through Darcy's Law, as stratified flow or as continuously varying density flow. The basic principle behind the formulation is to solve, during each time step, for the freshwater-head by considering continuity of flow in the entire aquifer, and to solve for the elevations of the interfaces by considering continuity of flow below each surface. Is should also be noted that the effects of dispersion and diffusion are not taken into account. Inversion, saltier (heavier) water above fresher (lighter) water, is also not allowed.

The SEAWAT program (Guo and Langevin, 2002) is a combination of MODFLOW and MT3DMS (Zheng and Wang, 1999) designed to simulate three-dimensional, variable-density, groundwater flow and solute-transport. The program was developed by modifying MODLOW subroutines to solve a variable-density form of the groundwater flow equation and by combining MODFLOW and MT3DMS into a single program. SEAWAT reads and write standard MODFLOW and MT3DMS input and output files, allowing most of the existing pre- and post-processors to facilitate application of the program to a wide range of practical problems. One advantage of SEAWAT is that because it uses MT3DMS to represent solute-transport, the program contains several diverse methods (Eulerian, Langrangian, or mixed) for solving the transport equation including the MOC, an explicit third order total-variation-diminishing (TVD) scheme, and a standard finite-difference method with central-in-space or upstream weighting.

WASH123D (Yeh et al. 1998) is a finite element numerical model designed to simulate variably saturated, variable-density water flow and reactive chemical and sediment transport in watershed systems. It is capable of conceptualizing a watershed system as a combination of 1D river/stream, 2D overland, and 3D subsurface sub-domains. A modified Richards' equation is used to solve for 3D flow when density effect is taken into account. The equation is solved with the Galerkin finite element method. The groundwater flow portion of the code utilizes an adaptation of the FEMWATER code (Lin et al. 1997). WASH123D uses the Lagrangian-Eulerian (LE) method to solve the transport equations. Particle tracking is used in the Lagrangian step to handle the advection term. Other terms (such as sources, sinks, diffusion, and dispersion) are calculated in the Eulerian step, where element matrices are assembled into a global matrix, and matrix solvers are used to solve for the spatial concentration distribution at the end of each time step. A predictor-corrector numerical technique, combined with an adaptive explicit-implicit numerical scheme, is employed to compute reactive transport efficiently and robustly. The use of this methodology allows the numerical stability of WASH123D not to be restricted by the Mesh Courant number. In addition, the Mesh Peclet number is restricted only by computational accuracy, not numerical stability. More detailed discussion on various types of numerical dispersion and how the LE method deals with these types of numerical dispersion are discussed in the referenced papers.

As described previously, each model would include a model boundary consisting of a 40-mile by 40-mile square box. Each model would contain 7 to 20 vertical layers representing the Surficial Aquifer System (SAS), Hawthorn Group confining unit, and the FAS. The four models each adopted the same hydrogeologic conceptual model, utilizing the same aquifers and confining units. Also, all of the model layers were assigned with identical hydraulic parameters (e.g., hydraulic conductivity and storage coefficient) in order to eliminate differences in these properties due to contouring algorithm chosen for each model. The exact number of layers was initially intended to be consistent for the different codes, however, model stability and accuracy requirements required refinement in some cases. Each box model would have identical boundary conditions, starting conditions (head and TDS concentration), influent TDS concentrations (150 mg/l), and aquifer/confining unit parameters. In addition, a common convergence criteria was agreed upon for both flow and transport portions of the models. Five separate cases were developed by the PDT to evaluate relevant ASR modeling issues including mixing, hydrodynamic dispersion, density stratification, upconing, and changes in salinity distribution as a result of ASR injection and/or recovery. The five cases are summarized in Table 2. Additional specific information summarizing each case is available following the table.

Table 2. Bench-scale case summary.

Case Number	**Purpose and basic setup**
IA	One ASR well recharge and recovery 5 MGD from FAS storage zone with TDS of 4,000 mg/l. Minimal upconing or leakage from below. No dispersivity assigned.
IB	One ASR well recharge and recovery 5 MGD from FAS storage zone with TDS of seawater (35,000 mg/l). Minimal upconing or leakage from below. No dispersivity assigned.
IC	One ASR well recharge and recovery 5 MGD from FAS storage zone with TDS of 4,000 mg/l. Major upconing or leakage from below encouraged through confining layer vertical conductivity assignment. No dispersivity assigned.
ID	One ASR well recharge and recovery 5 MGD from FAS storage zone with TDS of 4,000 mg/l. Minimal upconing or leakage from below. Dispersivity assigned with value of 25 feet.
IIA	One ASR well recovering for 5 years continuous to evaluate movement of salt-water interface from coast.

Case IA: Transient Model Simulation - One ASR well injecting 5 MGD into FAS in center of box for 30 days, followed by 305 day storage period, followed by 30 days of recovery at 5 MGD. The starting TDS of the FAS storage zone was assigned to be 4,000 mg/l, the TDS of the Middle FAS Confining Unit will be 35,000 mg/l, and the Middle FAS flow zone was assigned 35,000 mg/l. The Middle FAS Confining Unit was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between aquifer units. The Surficial Aquifer System (SAS) was assigned a constant head of 20 feet. The Hawthorn Group Clay (Intermediate Confining Unit) was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between the SAS and the Upper FAS. Prior to simulation start up, the model was run with the regional gradient to steady state conditions. The regional gradient was assigned from west to east at 0.0001 and is considered representative of the Upper FAS. The steady state gradient of 0.0001 was used to assign the starting heads of the Upper FAS for the one year simulation. The dispersivity tensor was assigned a value of zero in order to evaluate the degree of numerical dispersion produced from each code.
The purpose of Case 1A was to evaluate model code ability to simulate aquifer pressure changes, salinity changes due to conservative mixing, salinity changes due to hydrodynamic dispersion, and relative degree of numerical dispersion introduced. Since there was no known ASR case studies that have evaluated this issue, the comparison of numerical dispersion was relative in nature and assumed that the TVD solution was the most accurate as determined from previous publications. The flows between layers and to and from boundaries were also of interest. Landscape Figure 1 below (at the end of the report after the report appendices) depicts the assigned model parameters in detail for both the MODFLOW based models as well as the WASH123 model.

Case IB: Transient Model Simulation - One ASR well injecting 5 MGD into FAS in center of box for 30 days, followed by 305 day storage period, followed by 30 days of recovery at 5 MGD. The starting TDS of the FAS storage zone was assigned to be 35,000 mg/l, the TDS of the Middle FAS Confining Unit will be 35,000 mg/l, and the Middle FAS flow zone was assigned 35,000 mg/l. The Middle FAS Confining Unit was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between aquifer units. The Surficial Aquifer System (SAS) was assigned a constant head of 20 feet. The Hawthorn Group Clay (Intermediate Confining Unit) was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between the SAS and the Upper FAS. Prior to simulation start up, the model was run with the regional gradient to steady state conditions. The regional gradient was assigned from west to east at 0.0001 and is considered representative of the Upper FAS. The steady state gradient of 0.0001 was used to assign the starting heads of the Upper FAS for the one year simulation. The dispersivity tensor was assigned a value of zero in order to evaluate the degree of numerical dispersion produced from each code.

The purpose of Case 1B was to evaluate model code ability to simulate aquifer pressure changes, salinity changes due to conservative mixing, salinity changes due to hydrodynamic dispersion, and degree of buoyancy stratification that occurs during the storage period. The flows between layers and to and from boundaries were also of

interest. Landscape Figure 2 below depicts the assigned model parameters in detail for both the MODFLOW based models as well as the WASH123 model.

Case IC: Transient Model Simulation – One ASR well injecting 5 MGD into FAS in center of box for 30 days, followed by 305 day storage period, followed by 30 days of recovery at 5 MGD. The starting TDS of the FAS storage zone was assigned to be 4,000 mg/l, the TDS of the Middle FAS Confining Unit will be 35,000 mg/l, and the Middle FAS flow zone was assigned 35,000 mg/l. The Middle FAS Confining Unit was assigned a vertical conductivity of 1 feet per day to ensure leakage between the aquifer units. The Surficial Aquifer System (SAS) was assigned a constant head of 20 feet. The Hawthorn Group Clay (Intermediate Confining Unit) was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between the SAS and the Upper FAS. Prior to simulation start up, the model was run with the regional gradient to steady state conditions. The regional gradient was assigned from west to east at 0.0001 and is considered representative of the Upper FAS. The steady state gradient of 0.0001 was used to assign the starting heads of the Upper FAS for the one year simulation. The dispersivity tensor was assigned a value of zero in order to evaluate the degree of numerical dispersion produced from each code.

The purpose of Case 1C was to evaluate model code ability to simulate aquifer pressure changes, salinity changes due to conservative mixing, salinity changes due to hydrodynamic dispersion, and degree of density-driven upconing. The flows between layers and to and from boundaries were also of interest. Landscape Figure 3 below depicts the assigned model parameters in detail for both the MODFLOW based models as well as the WASH123 model.

Case ID: Transient Model Simulation - One ASR well injecting 5 MGD into FAS in center of box for 30 days, followed by 305 day storage period, followed by 30 days of recovery at 5 MGD. The starting TDS of the FAS storage zone was assigned to be 4,000 mg/l, the TDS of the Middle FAS Confining Unit will be 35,000 mg/l, and the Middle FAS flow zone was assigned 35,000 mg/l. The Middle FAS Confining Unit was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between aquifer units. The Surficial Aquifer System (SAS) was assigned a constant head of 20 feet. The Hawthorn Group Clay (Intermediate Confining Unit) was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between the SAS and the Upper FAS. Prior to simulation start up, the model was run with the regional gradient to steady state conditions. The regional gradient was assigned from west to east at 0.0001 and is considered representative of the Upper FAS. The steady state gradient of 0.0001 was used to assign the starting heads of the Upper FAS for the one year simulation. The dispersivity tensor was assigned a value of 25 feet in order to evaluate the model run times using a realistic amount of hydrodynamic dispersion.

The purpose of Case 1D was to evaluate model code ability to simulate aquifer pressure changes, salinity changes due to conservative mixing, salinity changes due to hydrodynamic dispersion, and degree of hydrodynamic dispersion introduced. The flows between layers and to and from boundaries were also of interest. Landscape Figure 4

below depicts the assigned model parameters in detail for both the MODFLOW based models as well as the WASH123 model.

Case IIA: Transient Model Simulation – Transient Model Simulation - One ASR well withdrawing 5 MGD from the Upper FAS in center of box for five years. The starting TDS of the FAS storage zone was assigned to be 4,000 mg/l, the TDS of the Middle FAS Confining Unit will be 35,000 mg/l, and the Middle FAS flow zone was assigned 35,000 mg/l. All units at the eastern boundary of the model were assigned a starting head of zero. The starting concentration of TDS in all model layers was based upon an approximation of the Ghyben-Herzberg relationship to define the 35,000 mg/l isochlor. The Middle FAS Confining Unit was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between aquifer units. The Surficial Aquifer System (SAS) was assigned a constant head of 20 feet. The Hawthorn Group Clay (Intermediate Confining Unit) was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between the SAS and the Upper FAS.

The purpose of Case IIA was to evaluate model code ability to simulate pumping induced regional changes in the three-dimensional salinity distribution.

Groundwater Model Testing and Comparison Protocols

Groundwater model testing has been the subject of multiple past studies and papers. Testing of groundwater simulation codes may take several forms including:

- Benchmarking against known analytical solutions
- Intra-code comparisons using different code functions and same stresses to emulate the same system response
- Inter-code comparisons simulating same stresses and systems
- Comparisons with field or laboratory data

One thing sorely lacking amongst the published literature is an approved or recommended protocol to perform the various comparisons. One such study was prepared by van der Heijde and Danzer (1997) for the United States EPA. This paper proposes a systematic evaluation and testing methodology or protocol that could be applicable to the bench-scale modeling effort. Although the bench-scale modeling effort was designed to test and compare model codes, it was not meant to be a full-scale code-testing and evaluation protocol; therefore, some of the evaluations recommended by van der Heijde and Danzer were not completed. Van der Heijde and Danzer recommend including an evaluation of code functionality and performance. Code functionality is defined as the set of functions and features which the code offers the user in terms of model framework geometry, simulated processes, boundary conditions, and analytical and operational capacities (van der Heijde and Danzer, page 2). Performance evaluations are aimed at determining the characteristics of the model code in terms of:

- Computational accuracy
- Reliability (convergence and stability of solution algorithms)

- Sensitivity for grid orientation, grid resolution, or time discretization
- Efficiency of coded algorithms (code execution time and memory/storage requirements)
- Resources required for model setup and analysis

First, all of the codes were evaluated for their overall functionality to address specific ASR issues discussed above. The overall code functionality was addressed based upon existing information available for each code, PDT experience, and published papers or case studies. Each issue requires a basic set of model development and analysis functions. These various functions are outlined in Table 3 along with qualitative scoring of each model code.

In reviewing Table 3, all codes could provide some of the functionality required to evaluate all relevant ASR issues to be studied. SEAWAT and WASH123 provide the highest overall functionality for the questions to be answered with the model. Table 4 provides a list of other general functions that are required of each model along with a qualitative score for each. In general all of the codes can provide much of the basic functionality required for the ASR Regional Study, however, SEAWAT and WASH123 provide the best overall functionality desired for the study.

Table 3. Required model functionality

Specific ASR Project Issue	**Desired Functionality**	**Modflow/MT3D**	**SEAWAT**	**WASH123**	**SWI**
Regional changes in aquifer heads and flows	1. Simulate head changes in region around proposed ASR well clusters	X	X	X	X
	2. Simulate flows from ASR wells, existing FAS user wells, boundaries, and between aquifers	X	X	X	X
Regional changes in aquifer water quality	1. Simulate water quality changes in region around proposed ASR wells, existing FAS user wells, boundaries, and between aquifers	X	X	X	
	2. Simulate density changes as a result		X	X	X
Increased potential for salt-water intrusion caused by ASR pumping	1. Simulate potential movement of salt-water wedge due to ASR recovery activities		X	X	X
	2. Simulate potential movement of salt-water wedge due to ASR recharge activities		X	X	X
Regional impacts to	1. Evaluate increases or decreases in head or water quality at existing well users	X	X	X	X

existing well users of the FAS	caused by ASR activity				
ASR well cluster site selection	1. Simulate superposition effects caused by multiple ASR wells recharging or recovering. Site ASR well clusters in order to minimize superposition effects and potential impacts on users. 2. Site selection is heavily influenced by all proposed well fields operating at same time (e.g., boundary effects are important in this instance).	X X	X X	X X	X X
ASR well cluster design and layout	1. Evaluate design and layout issues at one ASR cluster. 2. Varying horizontal resolution probably required.	X X	X X	X X	X X
ASR well cluster performance including estimating recovery efficiency	1. Evaluate ASR well cluster recovery efficiency and performance. 2. Evaluate upconing potential at each cluster site. 3. Evaluate density stratification at each cluster site.	X	X X X	X X X	 X
ASR well site evaluation of pressure induced changes	1. Evaluate aquifer pressure at each proposed ASR well, 1 mile distant from ASR well cluster, and at other FAS user wells. 2. Evaluate pressure changes within the Hawthorn Group at ASR well cluster.	X X	X X	X X	X
Localized transport of contaminants including heavy metals or pathogens	1. Evaluate transport of potential “bad actors” including heavy metals such as arsenic, nickel, and fluoride. 2. Evaluate conservative transport and reactive transport of pathogens.	X X	X X	X X	
Localized ASR well pump design	1. Evaluate aquifer pressure at each well and in entire well cluster.	X	X	X	X

Table 4. Additional model functionalities required.

Desired Functionality	Modflow/MT3D	SEAWAT	WASH123	SWI
Incorporate irregular geometry	X	X	X	X
Incorporate varying vertical model resolution and multiple layers	X	X	X	
Incorporate varying aquifer properties	X	X	X	X
Incorporate rainfall and recharge	X	X	X	X
Incorporate leakage between layers	X	X	X	X
Incorporate Dirichlet and Cauchy boundary types	X	X	X	X**
Incorporate constant and transient boundary conditions	X	X	X	X
Incorporate injection and recovery wells	X	X	X	X
Simulate advection, dispersion, and mixing	X	X	X	
Simulate contaminant decay or natural attenuation	X	X	X	
Simulate density-dependent flow		X	X	X

** - is capable for flow but not transport

An important consideration in any of model code is its overall credibility and suitability (van der Heijde and Kanzer, 1997). Therefore, the level at which the code has been tested is an important component in the decision-making process. Given the issues to be addressed with the ASR regional model, it is clear that groundwater hydraulics, conventional contaminant transport, and density-dependent flow concerns will all require critical contemplation. To aid in this determination, the PDT reviewed existing publications and past benchmarking cases in order to compile a list of tested problems. In addition, the PDT performed additional benchmarking against published analytical solutions. The PDT prepared several simple benchmarking tests to evaluate groundwater hydraulics and conventional contaminant transport. Both the finite-difference (MODFLOW/MT3DMS) and finite-element models (WASH123) were first tested using a series of groundwater hydraulics cases including pumping from a confined aquifer (Theis, 1935) and pumping from a leaky-confined aquifer (Hantush and Jacob, 1953). Since the ASR regional model will be simulating changes in head and flow caused by well pumping, the PDT felt this was a valuable test to evaluate. Then both predominant model types were tested using a conventional contaminant transport case (Ogata, 1970). The results of the Theis and Ogata benchmarking tests are available in figures 1 and 2. Each figure compares the numerical model results versus exact analytical solutions. Both the MODFLOW/MT3DMS and WASH123 numerical model results compare very favorably to the analytical solutions. The WASH123 code was further tested against both the “Elder problem” and the “Henry problem” with results available in Appendix A. All of these tests indicate that all of the codes tested appear to solve the governing equations accurately.

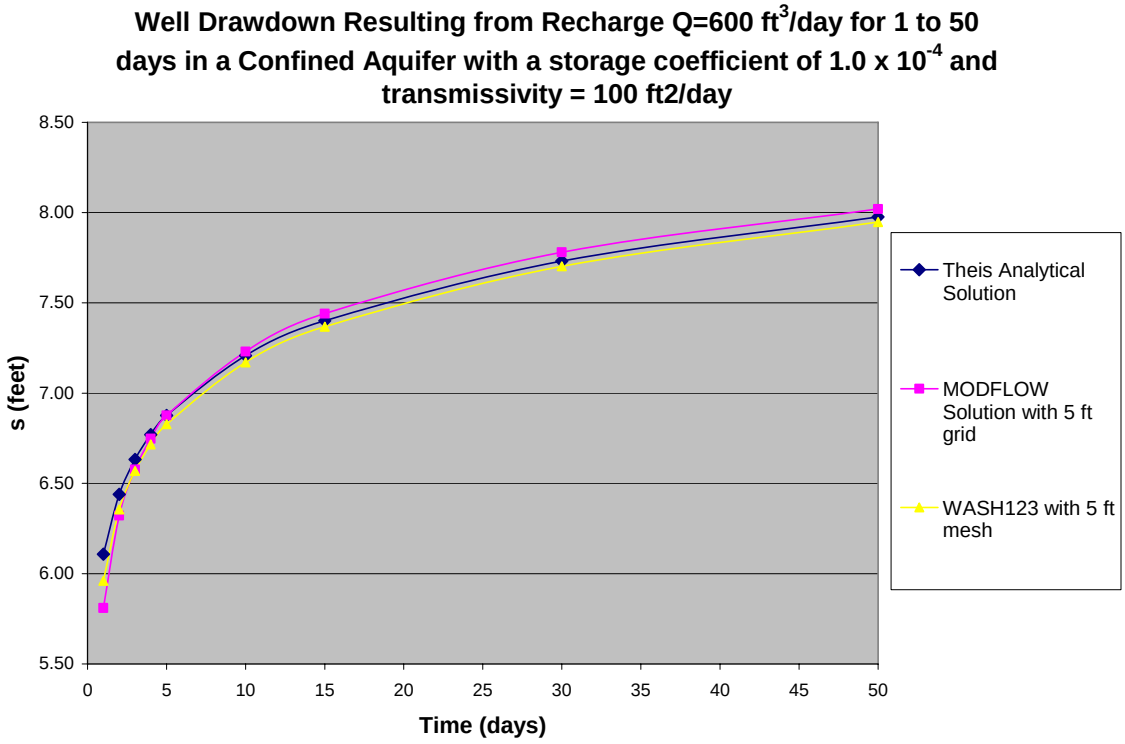

Figure 1. Theis confined aquifer benchmarking case comparing numerical model results to exact solution.

For variable-density groundwater flow, there are a suite of benchmark problems that have been designed to test the ability of a numerical code to accurately simulate the complex flow and transport dynamics associated with density dependent flow. Table 5 lists these commonly used benchmark problems and shows which codes have been tested to date. It should be noted that neither the SWI or the WASH123 codes have been tested as thoroughly as the SEAWAT code mainly due to their relatively young age. It is anticipated that both SWI and WASH123 will be tested against many of the remaining variable-density benchmark problems in the future as the codes become utilized by more users. Appendix A provides additional information on the variable-density test cases completed using WASH123.

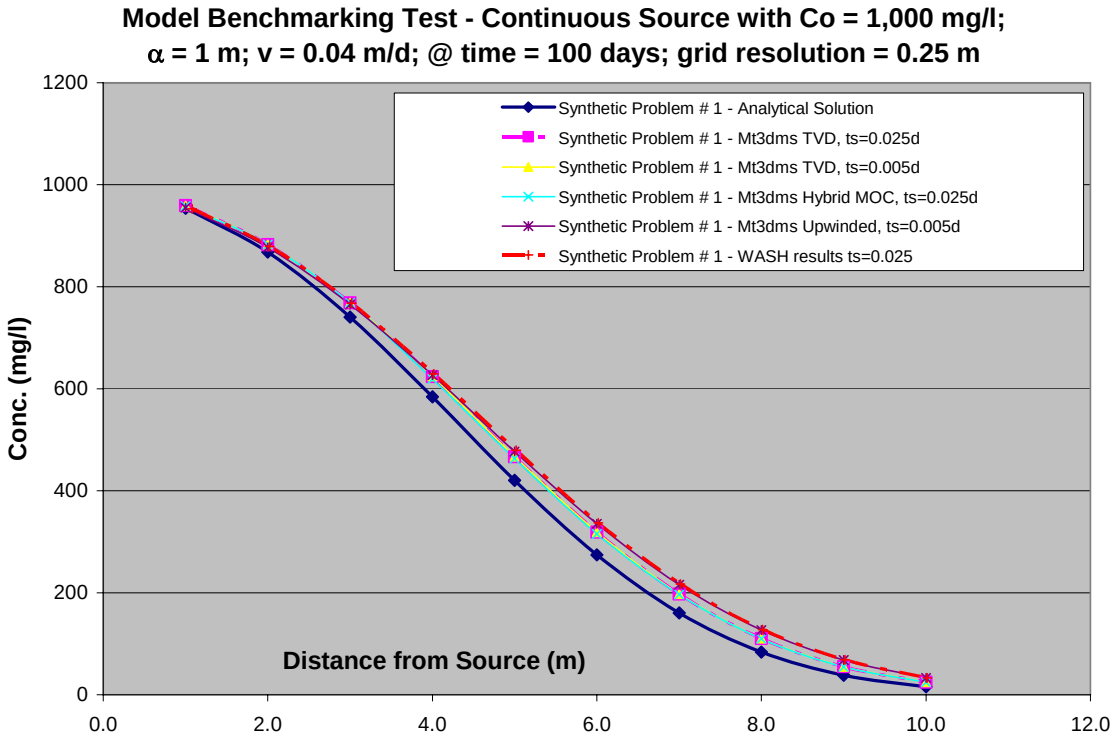

Figure 2. Ogata continuous source benchmarking case comparing numerical model results to exact solution.

Table 5. Variable-density benchmark problems.

Benchmark Problem	**SWI**	**SEAWAT**	**WASH123**
Box Problems		X	
Henry Case 1	NA	X	X
Henry Case 2	NA	X	X
Elder	NA	X	X
HYDROCOIN	NA	X	
Immiscible Fluid Rotation	X	X	
Rotating Interface	X		
Rotating Brackish Zone		X	
Upconing Beneath a Pumping Well	X		
Salt Pool 1	NA	X	
Salt Pool 10	NA	X	

NA – not applicable since SWI cannot simulate hydrodynamic dispersion

The overall performance assessment was measured through application of the various bench-scale cases completed as well as previous benchmarking work completed in support of each code. The performance assessment was measured against metrics listed previously including:

- Computational accuracy
- Reliability (convergence and stability of solution algorithms)
- Sensitivity for grid orientation, grid resolution, or time discretization
- Efficiency of coded algorithms (code execution time and memory/storage requirements)
  - Model run times were computed for all 5 ASR cases
  - Storage requirements were evaluated for all 5 ASR cases
- Resources required for model setup and analysis including
  - Pre and post processing effort
  - Computer type or hardware required
  - General ease of use for new modelers

Model Code Bench-scale Testing Results:

The four model codes were tested extensively using the five case studies outlined previously in this memorandum. Multiple contaminant transport algorithms were tested using both the existing MODFLOW/MT3DMS model and the SEAWAT model (e.g., central-difference solution and the TVD solution). WASH123 and SWI only provide one contaminant transport algorithm. Each of the codes revealed significant advantages and disadvantages. A comparison of performance metrics for each code is provided in the following sections of this memorandum. Appendix A and B of this memorandum contains additional information concerning the WASH123 results and the SEAWAT/SWI results.

Resources Required for Model Setup and Analysis

General Ease of Use

All of the model codes evaluated required significant user knowledge and experience in order to successfully utilize the model. The MODFLOW/MT3DMS, SEAWAT, and WASH123 models are all somewhat difficult to master but all three can link with readily available pre and post processors. The exception to this is the SWI code. The SWI model can be run independently but the results must be imported into a post-processor. The importation of the data requires some re-working of output files and required companion files. In general, table 6 lists the qualitative "ease of use" for each code along with pre/post processor tools utilized. In general, all of the codes rank similarly for this category.

Table 6. Model Code Ease of use.

Model Code	**Ease of Use (Easy, Moderate, or Difficult)**	**Compatible Pre and Post Processor**
MODFLOW/MT3DMS	Moderate	Groundwater Modeling System (GMS) ® Groundwater Vistas Argus Visual MODFLOW PMWIN, Modelviewer
SEAWAT	Moderate	Groundwater Vistas Argus Visual MODFLOW PMWIN, Modelviewer
WASH123	Moderate	GMS
SWI	Moderate	Argus, MATLAB

Required Time for Pre and Post Processing

All of the model codes required time for both pre and post processing of simulation results. The MODFLOW/MT3DMS, SEAWAT, and WASH123 models all link directly to relevant pre and post processing software packages. As discussed previously, the GMS and Groundwater Vistas software packages were utilized. Each software package provides an intuitive graphical user interface (GUI) that allows rapid data manipulation, formatting, and output preparation. Both software packages are widely used in the groundwater modeling community of practice. One advantage of the GMS is that it is freely available to the Corps of Engineers, its partners and its sponsors. Although the overall expense may be minor, the Groundwater Vistas, Argus, and Visual Modflow software must be purchased separately for team members to utilize effectively.

The required time for pre and post processing is probably least for the MODFLOW/MT3DMS code and greatest for the SWI code due to reformatting issues already discussed. Table 7 lists a qualitative assessment of the pre and post processing time for each code considered.

Table 7. Time for pre and post processing.

Model Code	**Pre and Post Processing Time (Low is less than 4 hours, Moderate is 4 to 8 hours, High is greater than 8 hours)**	**Pre and Post Processing Software Used**
MODFLOW/MT3DMS	Low	Groundwater Modeling System (GMS) ® Groundwater Vistas

		Argus Visual MODFLOW PMWIN
SEAWAT	Low	Groundwater Vistas Argus Visual MODFLOW PMWIN
WASH123	Moderate	GMS
SWI	Moderate	None can be used directly

Computer Type or Hardware Required

All of the model codes considered could be run on personal computer, however, when consideration is given to the proposed application (e.g., a large regional scale model), all of the models would likely require workstations to ensure computational efficiency. Since SWI does not calculate contaminant transport equations, it probably requires the least hardware demands. Obviously, for coarse resolution models, a regional model may be able to be run on a newer personal computer (2 years old or less with 2.6 GHz or faster processor and at least 1 GB of resident memory) also. Table 8 provides a comparison of required hardware.

Table 8. Computer Type/Hardware Requirements.

Model Code	**Hardware Required for small model**	**Hardware Required for regional model**
MODFLOW/MT3DMS	Personal computer	Workstation
SEAWAT	Personal computer	Workstation
WASH123	Personal computer	Workstation
SWI	Personal computer	Personal computer

Efficiency of coded algorithms (code execution time and memory/storage requirements)

Model Run Times and Storage Requirements

As part of the performance assessment of the model codes, model simulation times were measured for the various case studies. Since the models were run on different workstations with divergent processing architecture, an effort was undertaken to "normalize" the simulation times through standardized computer industry comparisons. Several independent information technology forums provide processor performance comparisons for different software applications. One of these provides the information for free at the internet site www.spec.org. Information provided at the site includes both base and peak processor speeds for different tasks. Table 9 provides a comparison of both metrics for the computer workstations utilized for the study. The exact workstation

utilized to run the SEAWAT and SWI simulations was not listed at spec.org site so an average of three similar computers was selected to be representative. Then the base processor speeds were normalized against 1,000 to provide simulation run time "factors" to be applied to the actual raw simulation times for each case.

Table 9. Workstation performance metrics from www.spec.org.

Computer	Base Floating Point Speed	Peak Floating Point Speed
Optiplex Computer, 2.66 GHz, 1GB Ram	919	927
Dell GX280 Computer, 3.60 GHz P4, 2GB Ram	1905	1916
Dell WS Computer, 3.06 GHz P4, 2GB Ram	1092	1103
Intel 3.46 GHz P4, 3GB Ram	1719	1724
AVG 3 Computers	1572	1581
XI Computer, AMD 148 Opteron Chip	1393	1490

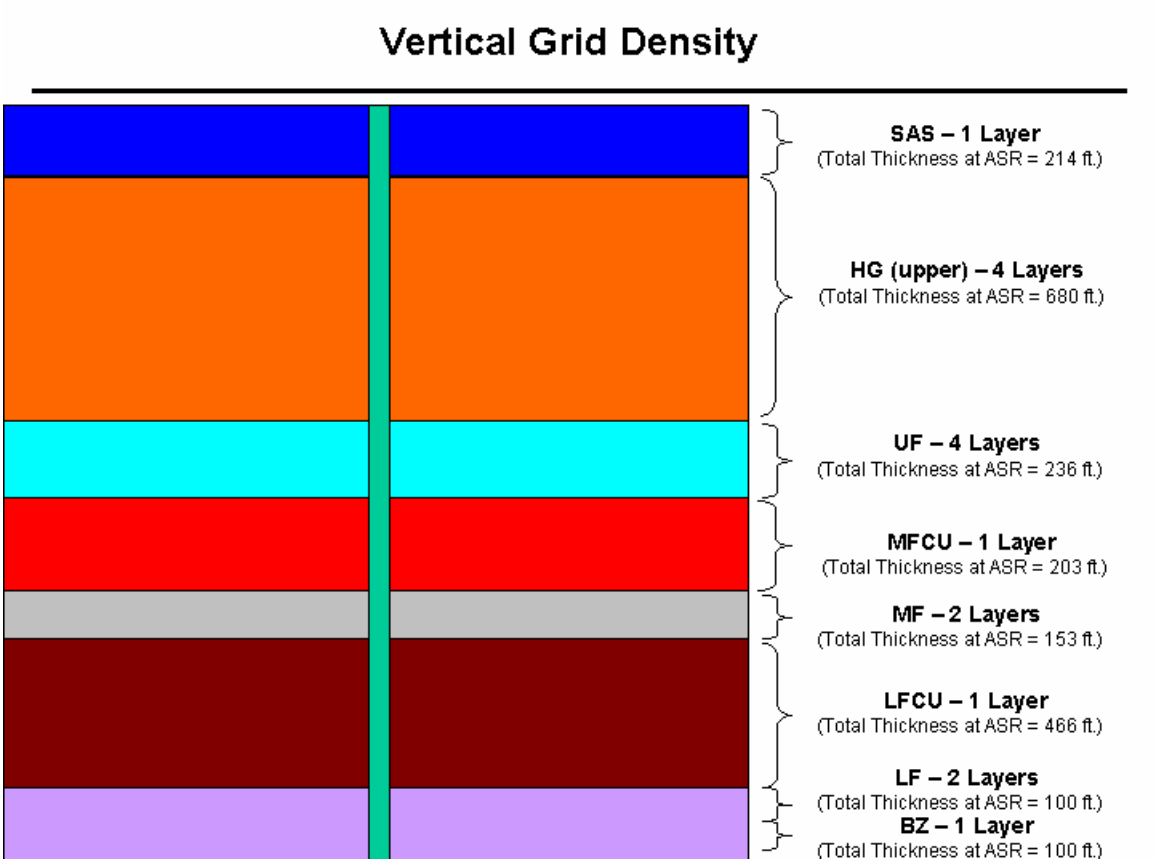
The factors applied were 0.919 for the MODFLOW/MT3DMS models, 1.572 for the SEAWAT and SWI models, and 1.393 for the WASH123 models. In essence, the normalized run times would be reduced for the MODFLOW/MT3DMS models and increased for all of the other models. Based upon information contained on this site and an inventory of workstation hardware utilized for the ASR Benchmark study, a set of normalized simulation times were developed. Table 10 lists all of the normalized model run times for the study as well as the runtime per model calculation point. The fastest and slowest runtime per calculation point is highlighted in the table. The fastest times are highlighted in pink while the slowest times are shown in yellow. The normalized model run times were also formulated from model runs that had identical convergence criteria and similar time-step sizes. The time-step size required to ensure stability was code dependent but efforts were made to ensure the final time-step size was similar for all codes. Given the complexity of the models and domain size (County size), model run times were generally long.

Table 10. Normalized model simulation run times.

RUN 1A	Run Times (min)	Normalized Run Times	Normalized Run Time per Calculation Point
MODFLOW/MT3DMS - Upwind	217	199	1.3E-03
MODFLOW/MT3DMS - TVD	463	425	2.8E-03
SEAWAT - Upwind	55.84	88	5.8E-04
SEAWAT - TVD	3838.5	6034	4.0E-02
WASH123	330	460	4.1E-03
SWI	18.75	29	3.1E-04
RUN 1B	**Run Times (min)**	**Normalized Run Times**	**Normalized Run Time per Calculation Point**
MODFLOW/MT3DMS - Upwind	217	199	1.3E-03
MODFLOW/MT3DMS - TVD	466	428	2.8E-03
SEAWAT - Upwind	56.19	88	5.8E-04
SEAWAT - TVD	3864.95	6076	4.0E-02
WASH123	420	585	5.2E-03
SWI	15.27	24	2.5E-04
RUN 1C	**Run Times (min)**	**Normalized Run Times**	**Normalized Run Time per Calculation Point**
MODFLOW/MT3DMS - Upwind	217	199	1.3E-03
MODFLOW/MT3DMS - TVD	467	429	2.8E-03
SEAWAT - Upwind	57	90	5.9E-04
SEAWAT - TVD	3878.2	6097	4.0E-02
WASH123	330	460	4.1E-03
SWI	19.71	31	3.2E-04
RUN 1D	**Run Times (min)**	**Normalized Run Times**	**Normalized Run Time per Calculation Point**
MODFLOW/MT3DMS - Upwind	2157	1982	1.3E-02
MODFLOW/MT3DMS - TVD	4320	3970	2.6E-02
SEAWAT - Upwind	58.96	93	6.1E-04
SEAWAT - TVD	3929	6176	4.1E-02
WASH123	329	458	4.1E-03
RUN 2A	**Run Times (min)**	**Normalized Run Times**	**Normalized Run Time per Calculation Point**
SEAWAT - Upwind	767	1206	8.0E-03
SEAWAT - TVD	11171	17561	1.2E-01
WASH123	522	727	6.5E-03
SWI	11	15	1.6E-04

Generally, the SEAWAT TVD solution resulted in the longest normalized simulation times while the SWI resulted in the shortest. The TVD solution scheme in MT3D (and thus SEAWAT) required unreasonably short transport time step lengths for an accurate solution. Due to project time constraints, no attempt was made to resolve the issue, but it is possible that the issue could be fixed, in which case, the runtimes could reduced. Since both finite-difference models (MODFLOW/MT3DMS, SEAWAT, and SWI) and finite-element (WASH123) models were utilized in the study, further examination of the run time per calculation point is important. The WASH123 model had 112,716 calculation points versus 151,000 for the other models tested. A key difference to be noted is that the WASH123 model provided greater vertical resolution (30 layers) but varying horizontal resolution as compared to the other finite-difference models (16 vertical layers). When considering the horizontal resolution of the two model types, the WASH123 model resulted in fewer computational points than the comparable finite-difference model due to the flexible mesh design advantage that is inherent in finite-element formulations. This may be an important consideration in the design of the regional model. Figure 3 depicts the finite-difference model vertical resolution while Figure 4 depicts the comparable finite-element model vertical resolution.

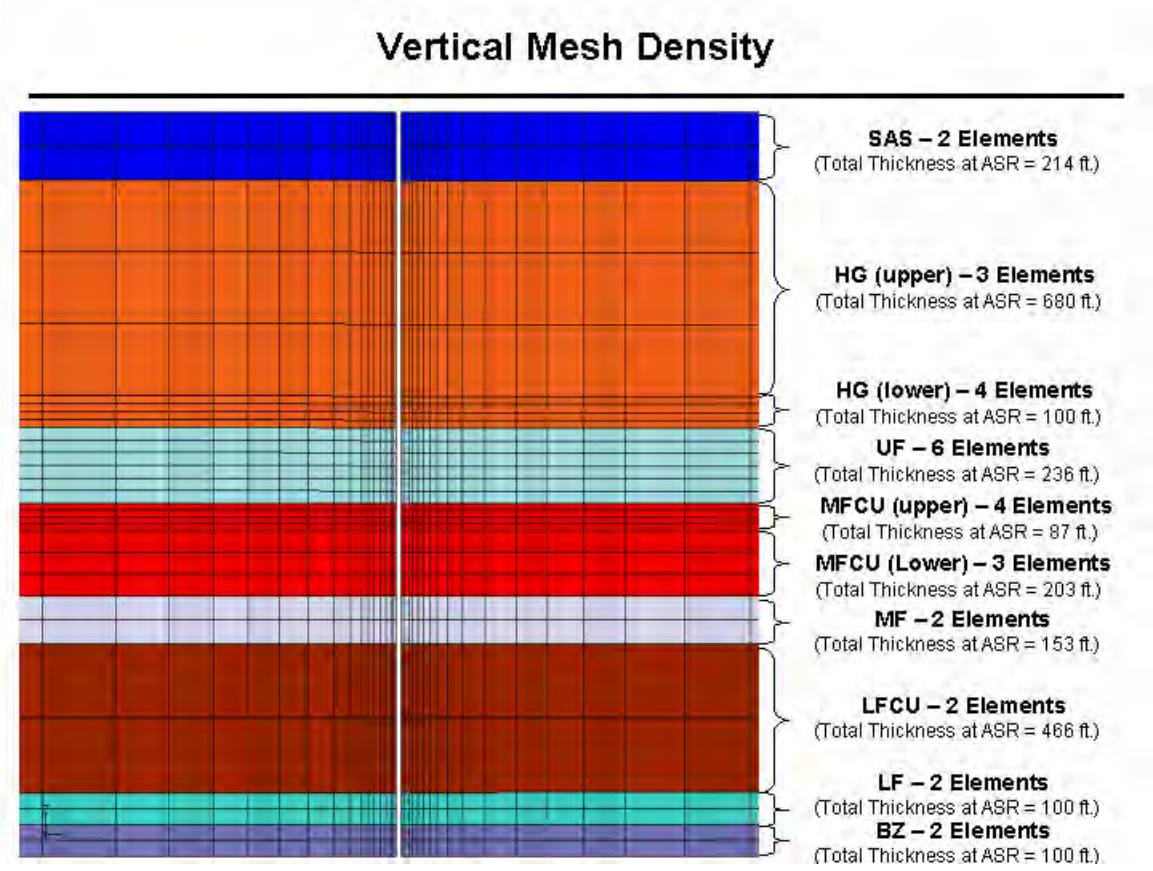
Figure 3. Finite-difference model vertical resolution.



For all of the models, storage requirements were moderate and highly dependent upon model resolution, time-step size, and outputs designated. In general, large capacity hard

drives available on personal computers and work stations should be sufficient to handle requirements of the regional model development.

Figure 4. Finite-element model vertical resolution.



Time and resource constraints did not allow a systematic evaluation of each code's dependence upon grid resolution or time discretization to ensure accuracy. The time discretization was evaluated in a gross sense in order to minimize model run times, however, only minimal checks were completed to determine the effect on model accuracy. As the various case studies were completed, it was also determined that the vertical discretization of the model was very important for both the model stability and accuracy. This was especially true around the ASR wells where steep velocity gradients led to model oscillations and instability in some instances. Future ASR modeling efforts should carefully consider vertical discretization-related accuracy and stability issues.

Comparison of Simulation Results for Computational Accuracy and Reliability

Model simulation output from the four model codes was then compared to determine differences in numerical error, relative accuracy, stability, and flexibility. As the ASR cases were hypothetical, an examination of the actual accuracy of each model code was

not possible. However, an assumption was made that the SEAWAT TVD solution was the most accurate based upon past analysis and publications noted in the literature. Limited accuracy assessments as compared to known analytical solutions were also completed and discussed earlier in this report. Table 11 lists a qualitative assessment of the stability of each model code based upon all model results. None of the codes experienced major convergence problems but three of the model codes did experience some minor oscillations. It should be noted that the oscillations were most likely attributed to insufficient horizontal and vertical model resolution. Therefore, it is expected that the oscillations could be minimized or eliminated through more judicious model design.

Table 11. Stability Assessment.

Model Code	**Stability Assessment** Score A – No stability issues Score B – Minor Oscillations Score C – Did not converge
MODFLOW/MT3DMS – Upwinded	A
MODFLOW/TM3DMS – TVD	B
SEAWAT – Upwinded	A
SEAWAT – TVD	B
WASH123	A
SWI	B

The overall relative accuracy assessment is presented for each case and discussed in turn.

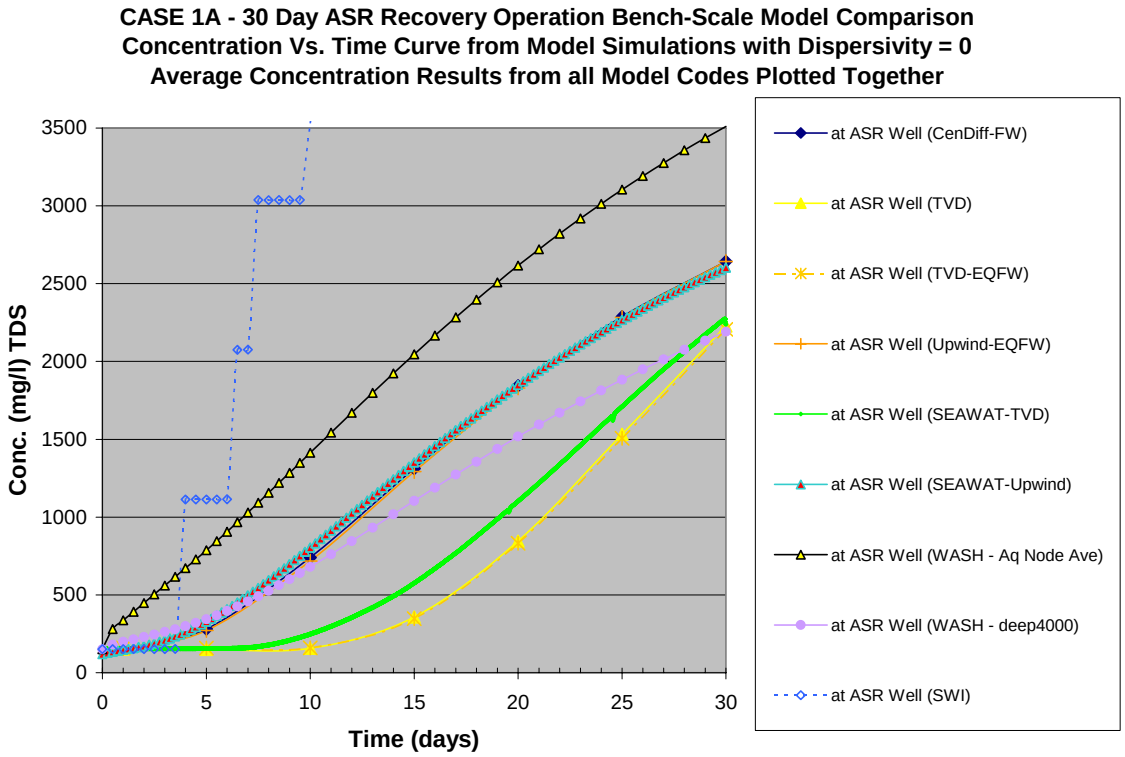
For Case 1A, comparisons were made at the ASR well and at different radii from the ASR well. Figure 5 depicts results from the different codes for concentrations versus time estimates during the 30-day ASR recovery period. It should be noted that the recovery curves represent average concentrations at the ASR well location.

For all of the ensuing figures, a naming convention is employed for each of the various model runs, model codes, and contaminant transport solution algorithms. The primary names are listed as follows:

- CenDiff-FW is a MODFLOW/MT3DMS simulation using the Central difference weighting algorithm
- TVD is a MODFLOW/MT3DMS simulation using the total variation diminishing scheme
- EQFW or FW are simulations using “equivalent freshwater heads” on the model boundaries rather than simulating true density-dependent flow
- SEAWAT-TVD are simulations using SEAWAT with the TVD scheme
- SEAWAT-Upwind are simulations using SEAWAT with the upwinded backward difference weighting algorithm
- WASH-Aq Node Ave are simulations using WASH123 and averaging the concentrations of the model aquifer nodes

- WASH-deep4000 are simulations using WASH123 and modifying the confining unit initial condition concentrations to mimic calculations performed by MT3DMS

Figure 5. Model simulation results for Case 1A at the ASR well.



In examining the simulation results at the ASR well, it is apparent that the model codes, along with the various contaminant transport algorithms, result in a wide variation of concentration versus time predictions. During a real ASR recovery event, the recovery would be ceased once the TDS concentration exceeded a threshold value of 500 mg/l. In reviewing the simulation results, the number of days of recovery before exceeding 500 mg/l can be readily observed.

For the MODFLOW/MT3DMS solutions, two general results are observed. First, solutions using the TVD algorithm (using either uncorrected heads or density corrected/EQFW heads) predict that 500 mg/l level would be exceeded after 17 days. Using the central-difference or upwinding algorithms result in exceedance after 7 days. Since a dispersivity value of zero was utilized for Case 1A, the main difference between the TVD solution and the other finite-difference solutions is suspected to result from truncation error or so-called “numerical dispersion”. This finding is consistent with previous work completed by Merritt (1986; 1993). Merritt found that the predicted amount of freshwater recovered from an ASR well is sensitive to the contaminant transport solution selected for the simulation. In addition, Merrit (1993) noted that the

estimate of freshwater recovered is somewhat sensitive to vertical model resolution and the algorithm utilized to simulate vertical flow and dispersion. For ASR simulations involving large concentrated injection and recovery rates, the apparent degree of dispersion would also be greatly dependent upon local flow velocities.

For the two SEAWAT solutions, a similar pattern emerged. The TVD solution predicted that the 500 mg/l water quality threshold would be exceeded after approximately 14 days, whereas the upwinded solution predicted exceedance after 7 days. Since SEAWAT is a finite-difference model with the same geometry as the MODFLOW/MT3DMS model, the differences between the two solutions are also caused by numerical error. Another interesting finding is that the comparable upwinded solutions between non-density model and the density-dependent SEAWAT model are almost identical, suggesting that the numerical dispersion issues mask the density related differences. When a similar comparison is completed for the constant-density TVD solution versus the density-dependent SEAWAT TVD solution, there is a notable difference of 3 less days of ASR recovery for the SEAWAT TVD solution probably due to buoyancy stratification effects. This finding reveals that density stratification during the 305 day ASR storage period does marginally affect the predicted results. It would be expected that longer storage periods would result in additional stratification effects that would further reduce the amount of freshwater that would be recovered.

The WASH123 results also show variation between two different model simulations. The first simulation (WASH – Aq node avg) predicts that the water quality threshold of 500 mg/l would be exceeded after 2.5 days. The second simulation (WASH- deep4000) predicts an exceedance of the threshold after approximately 8 days. The only difference between these solutions is the assignment of the starting concentrations within the Middle Floridan Confining Unit (MFCU). The first simulation includes an assignment of 35,000 for all nodes within the MFCU, while the second simulation includes an assignment of 4,000 mg/l for upper nodes and 35,000 mg/l for lower nodes. The second simulation is thought to be equivalent to the finite-difference runs since the starting concentration for those runs is assigned at the cell center rather than at the cell edge. Further review of the second simulation (WASH – deep4000) still reveals that the concentration versus time curve is generally between the finite-difference upwinded and TVD solutions. It is likely that the WASH123 results are also subject to numerical dispersion. Woods (2004) noted similar numerical dispersion problems with the finite-element model SUTRA (Voss and Provost, 2002). Future improvements to WASH123 will utilize the “local zooming and peak-valley capturing algorithm as outlined by Cheng et al. (1998). These improvements should further minimize numerical errors.

The SWI result shows major differences as compared to the other model simulation results. The SWI simulation predicts that the water quality threshold of 500 mg/l would be exceeded after 4 days. Also, the slope of the concentration versus time curve is much steeper than any other simulation result. Since the SWI code was originally designed for regional sea water intrusion issues, this result is not surprising. Since the SWI code was designed based upon an interface approach, it was not designed to simulate dispersion.

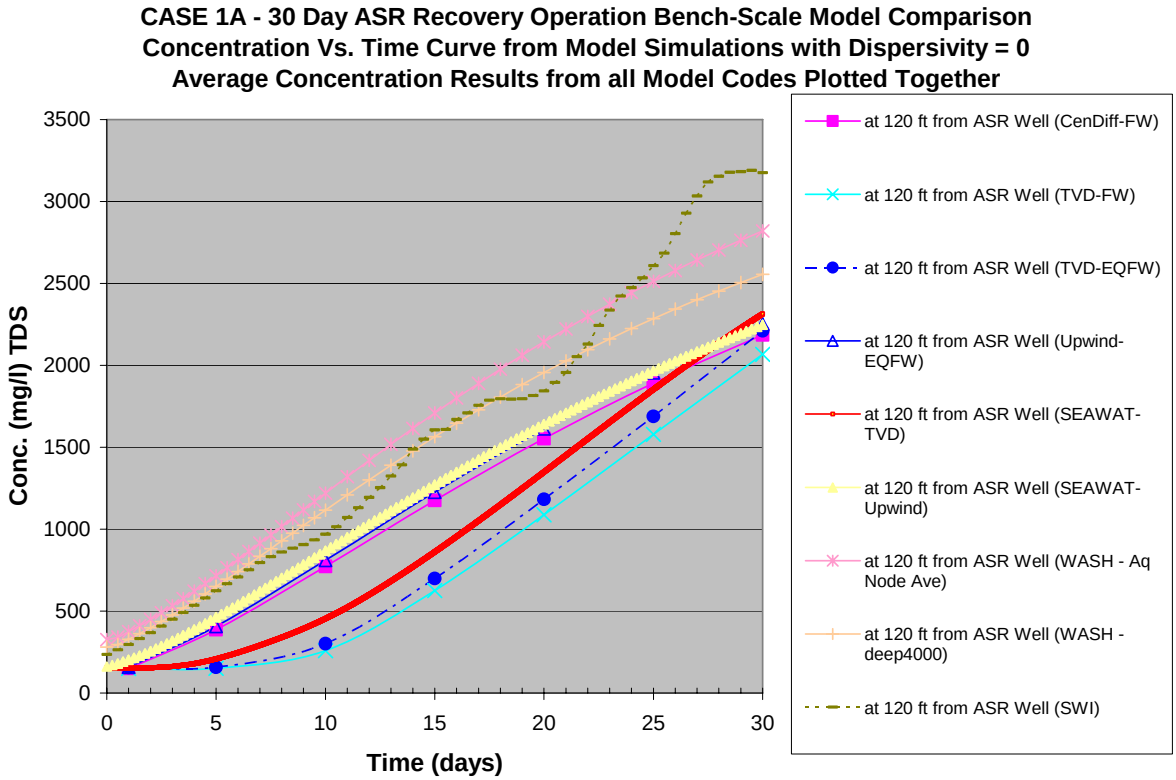
Therefore, it is unclear if the SWI results are the "most accurate" or if the Dupuit approach implemented in SWI is resulting in unrealistic concentration increases.

Since no known ASR analytical solutions were available, a full accuracy assessment of the Case 1A results is not possible. The results clearly do show that the four codes predict a wide range of concentration estimates. It is theorized that the code results would converge and be more similar if the following improvements were incorporated:

- Additional horizontal resolution around the ASR well
- Additional vertical resolution within the storage zone and below the storage zone
- Lower well pumping rates would reduce the steep vertical gradients at the ASR well minimizing errors associated with the velocity field

Similar data plots were produced for a theoretical monitoring well approximately 120 feet distant from the ASR well. Figure 6 displays the simulation results from the various model codes and contaminant transport solutions during the 30-day ASR recovery period. At this radius (near the edge of the freshwater bubble), the effects of buoyancy stratification are probably more pronounced such that the differences among the various codes is likely due to a combination of numerical dispersion and the degree of buoyancy stratification predicted by the code.

Figure 6. Model simulation results for Case 1A at monitoring well 120 feet away.



Generally, the simulation results can be subdivided into three groups. The TVD results from the MODFLOW/MT3DMS and SEAWAT models predict lower TDS concentrations over the first 15 days of ASR recovery as compared to the other model simulations. The WASH123 and the SWI model codes predict the highest TDS concentrations over the first 15 days of ASR recovery. The central-difference and upwinded solutions fall between the TVD and WASH123/SWI results. The "spread" of model results is less pronounced than at the ASR well as presented in figure 5. This also suggests that errors associated with the velocity field and the model resolution are larger at the pumping well location than 120 feet distant. Since dispersivities were assigned a value of zero, model stability was also an important issue. Some oscillations were seen in the results of all model codes with the exception of the WASH123 code and finite-difference upwinded solutions as discussed previously. Some of these are evident in the SWI results.

For Case 1B, comparisons were made at the ASR well and at different radii from the ASR well. Since Case 1B assigns a seawater TDS concentration in the ASR storage zone, more significant density effects were noted. Figure 7 depicts results from the different codes for concentrations versus time estimates during the entire 30-day ASR recovery period. Figure 8 depicts results from the different codes for concentrations versus time estimates during the entire 365-day ASR simulation period, including recharge for 30 days, storage for 305 days, and recovery for 30 days. It should be noted that the concentration curves represent average concentrations at the ASR well location for Figure 7, while discrete model layers are depicted in Figure 8.

Figure 7. Model simulation results at ASR well for Case 1B during ASR recovery period.

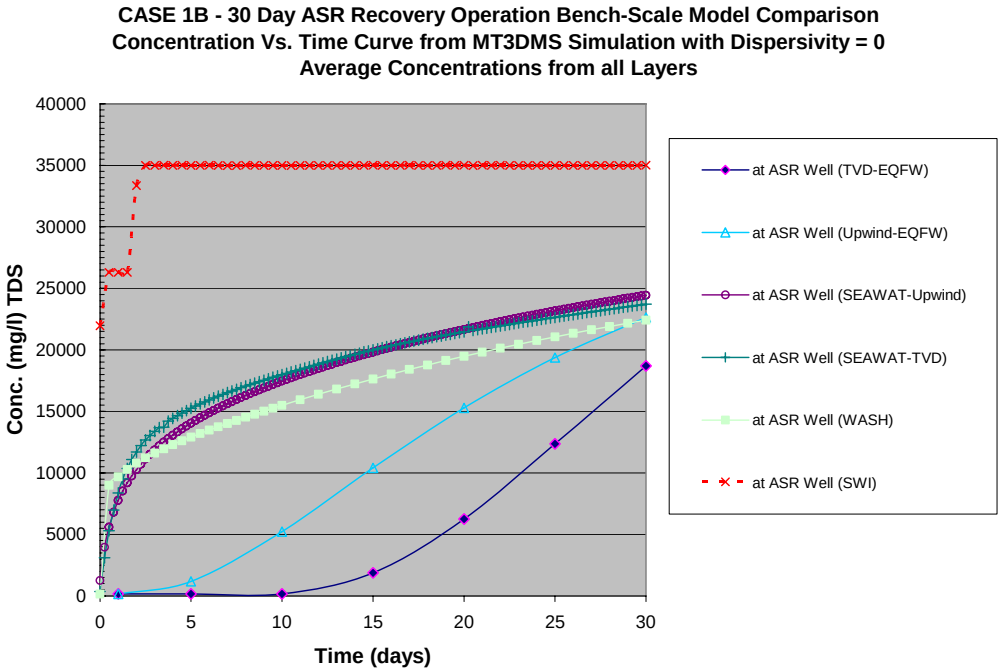


Figure 8. Model simulation results at ASR well for Case 1B during entire simulation period.

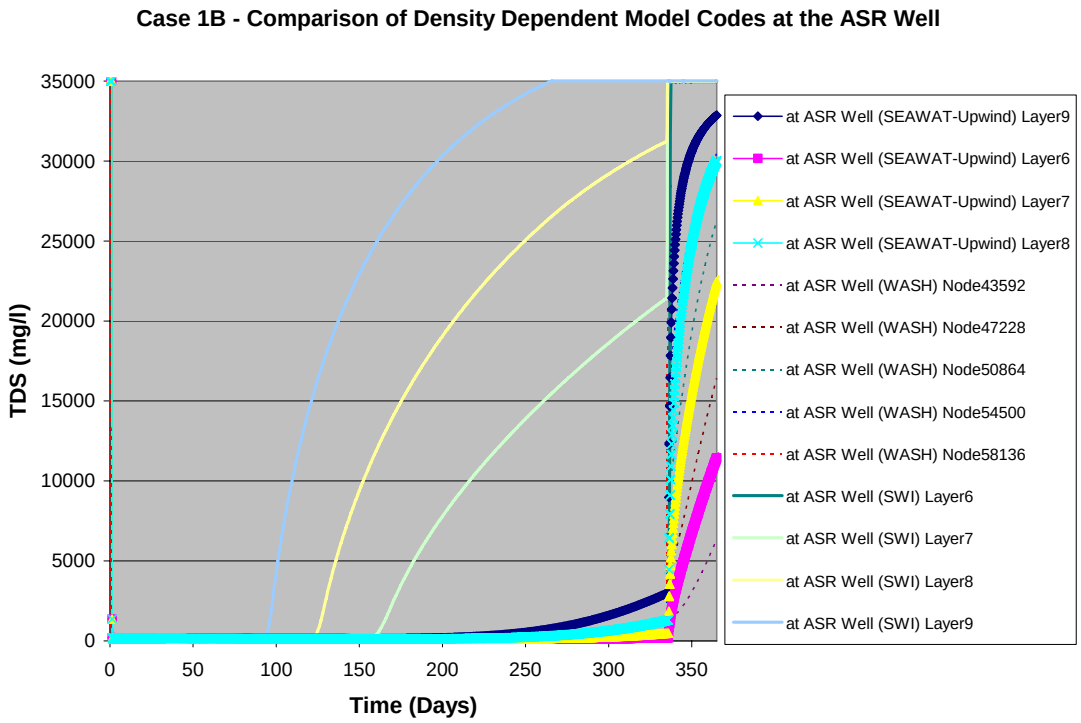

In reviewing Figure 7, it is evident that the results vary widely between the different codes. First, the non-density dependent simulations greatly underestimate the TDS concentration at the ASR well as compared to the other model codes. Both of the SEAWAT solutions and the WASH123 solution exhibit similar concentration versus time curves. The SWI results seem to overestimate the TDS concentrations at the ASR well location. The SWI code was originally designed for implementation at coastal boundaries, therefore the results may be misleading. Since the SWI code was not designed to model concentration changes around active pumping wells, it may not be the best tool for evaluating changes around the ASR well.

For Figure 8, only the density dependent capable model codes were investigated. Figure 8 clearly depicts large differences between the SEAWAT/WASH123 results versus the SWI results. Both SEAWAT and WASH123 predict moderate buoyancy stratification during the 305-day storage period as compared to the major buoyancy stratification predicted by SWI. In general, at the ASR well, the results predicted by SEAWAT and WASH123 are very similar. Both codes clearly demonstrate the capability to evaluate changes in water quality due to density stratification effects. Figure 9 depicts the results at a theoretical monitoring well located approximately 120 feet distant from the ASR well.

Figure 9. Model simulation results at 120 feet distant from the ASR well for Case 1B during entire simulation period.

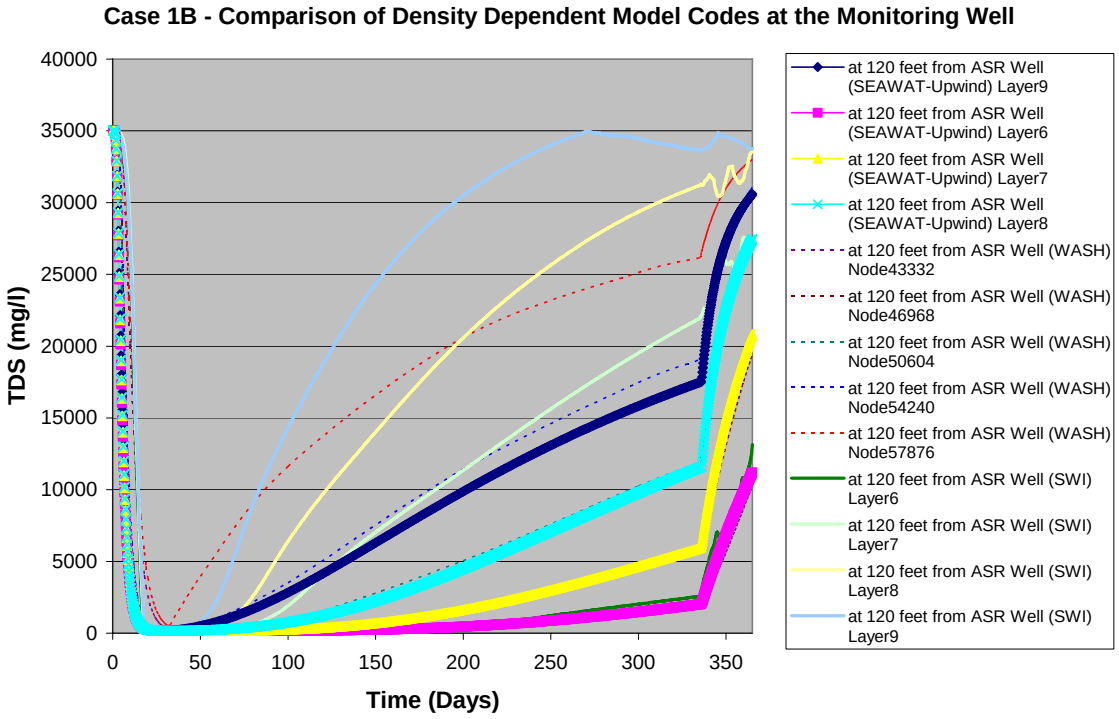

Figure 9 reveals that at the monitoring well located 120 feet from the ASR well, the SWI simulation predicts a higher degree of density stratification than the comparable SEAWAT TVD solution. The WASH123 results tend to fall in the middle of the SWI and SEAWAT results. During the 30-day recovery period, both the SEAWAT and WASH123 results exhibit similar shaped recovery curves as compared to the SWI simulation that appears to have some minor oscillations during the recovery duration. Figures 10 to 16 depict spatial concentration differences between the SEAWAT and WASH123 results for selected time steps during the one-year simulation period. The contour maps were developed from three sets of model output for the center of the aquifer storage zone. Each set of model output data was then contoured to a new two-dimensional mesh using an "inverse distance weighted" algorithm. The contouring resulted in minor oscillations in each dataset but did not inhibit the overall comparison of the results. The contour maps compare the spatial concentration differences at the middle of the ASR storage zone. The figures clearly show that both the finite-difference (upwinded or central difference) and WASH123 solutions are subject to moderate to high numerical dispersion and possibly more significant density stratification. WASH123 appears to have the highest numerical error with the upwinded solution exhibiting moderate to high error while the TVD solution had the smallest error. The SWI code was not included in this comparison since it does not have the capability to model hydrodynamic dispersion. It should also be noted that the finite-difference and WASH123 solutions are similar at day 365 as shown on Figures 15 and 16. The finite-difference and WASH123 results at day 365 both have a similar concentration gradient or

radius where seawater concentrations have been lowered at least 500 mg/l. The comparable radius for the TVD solution is much smaller. One notable difference is that the WASH123 solution displays more concentric contours, although curiously the circles are not centered on the ASR well, while the finite-difference results are heavily influenced by the grid resolution and bias. However, the WASH123 results also appear to be heavily influenced by mesh effects. As was mentioned previously, each of the models could have been improved through the incorporation of additional horizontal and vertical resolution around the ASR well.

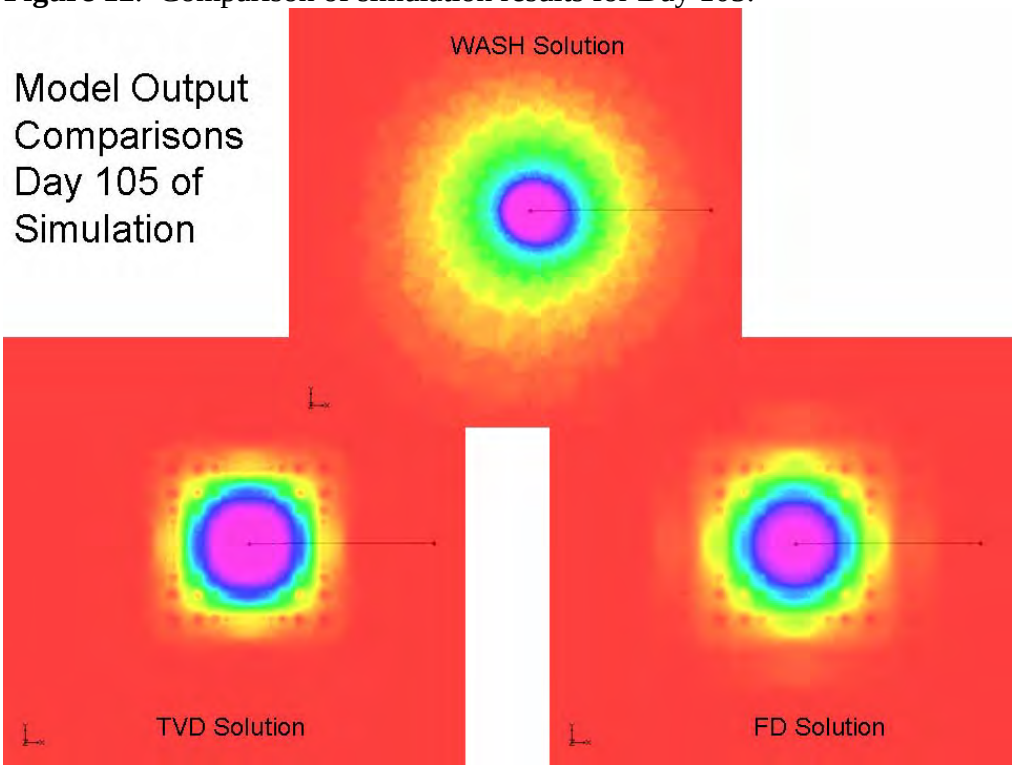

Figure 13. Comparison of simulation results for Day 335.

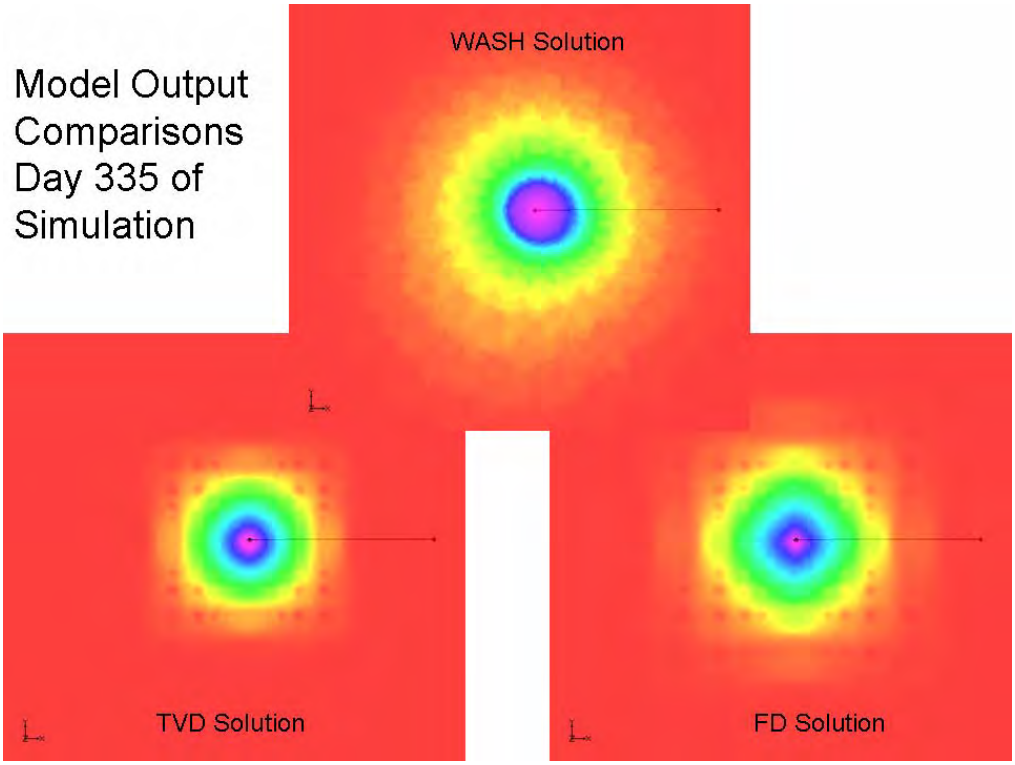

Figure 14. Comparison of simulation results for Day 350.

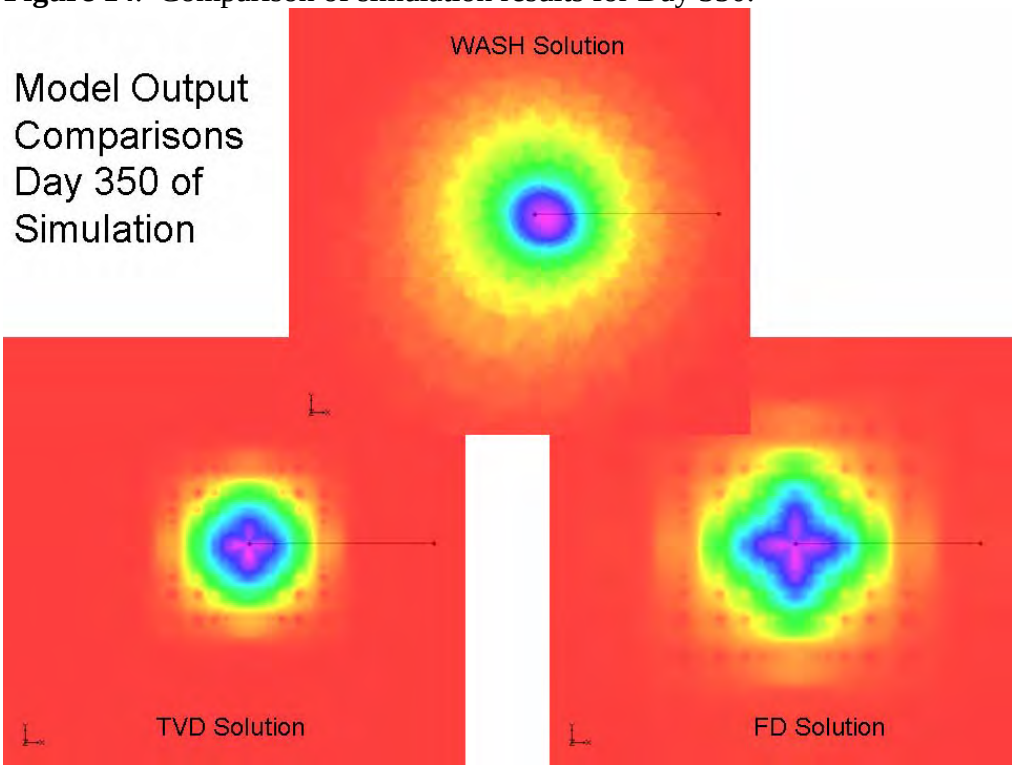

Figure 15. Comparison of simulation results for Day 365.

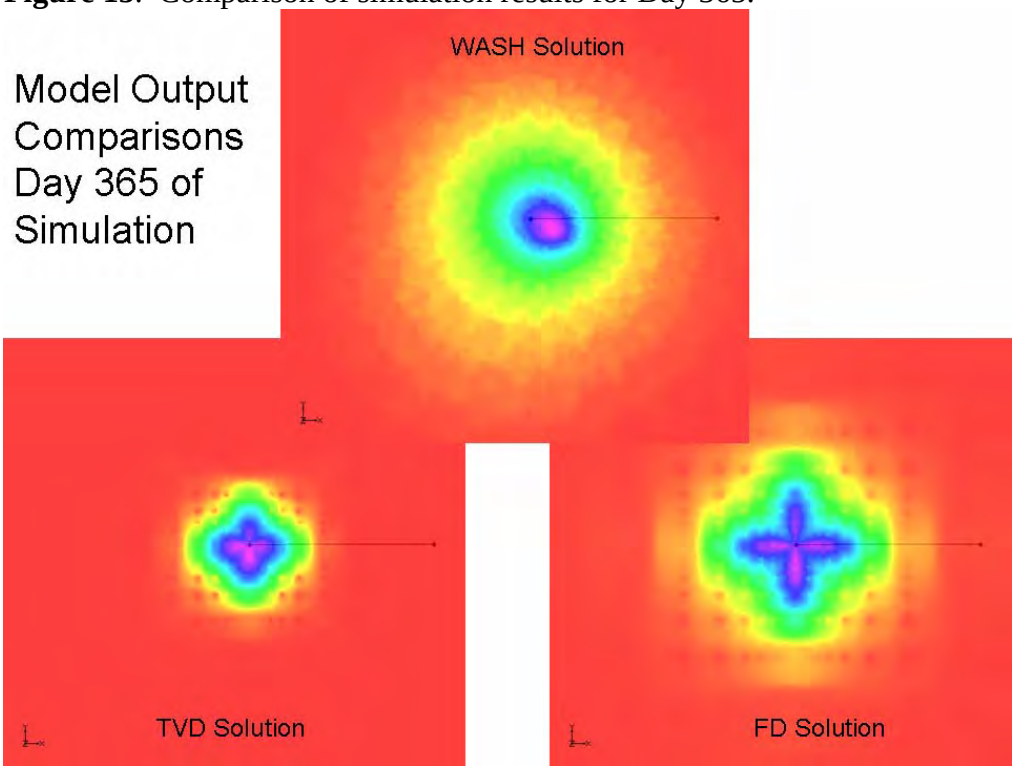

Figure 16. Comparison of simulation results for Day 365 with radius marker.

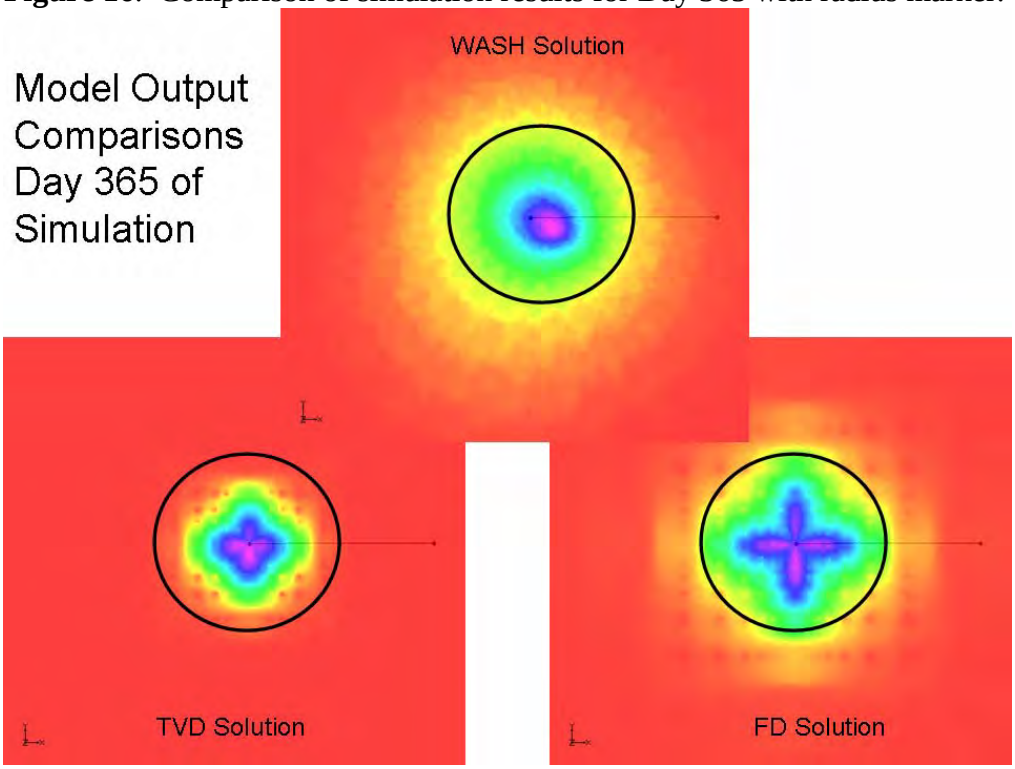
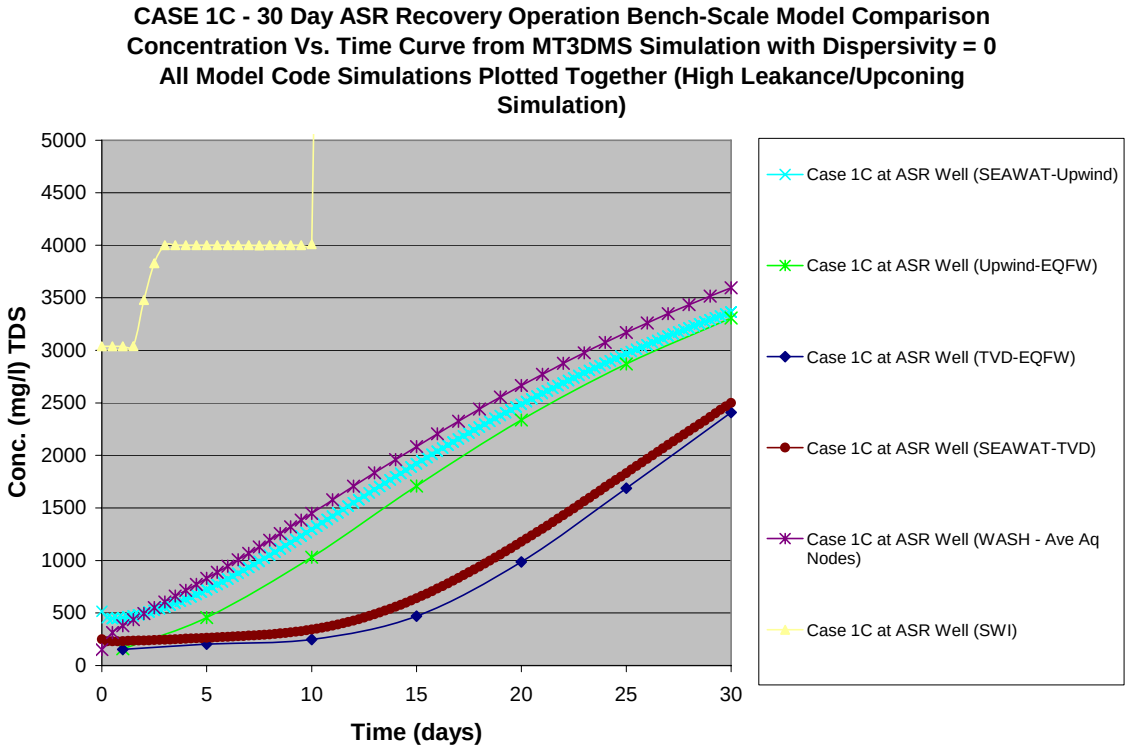


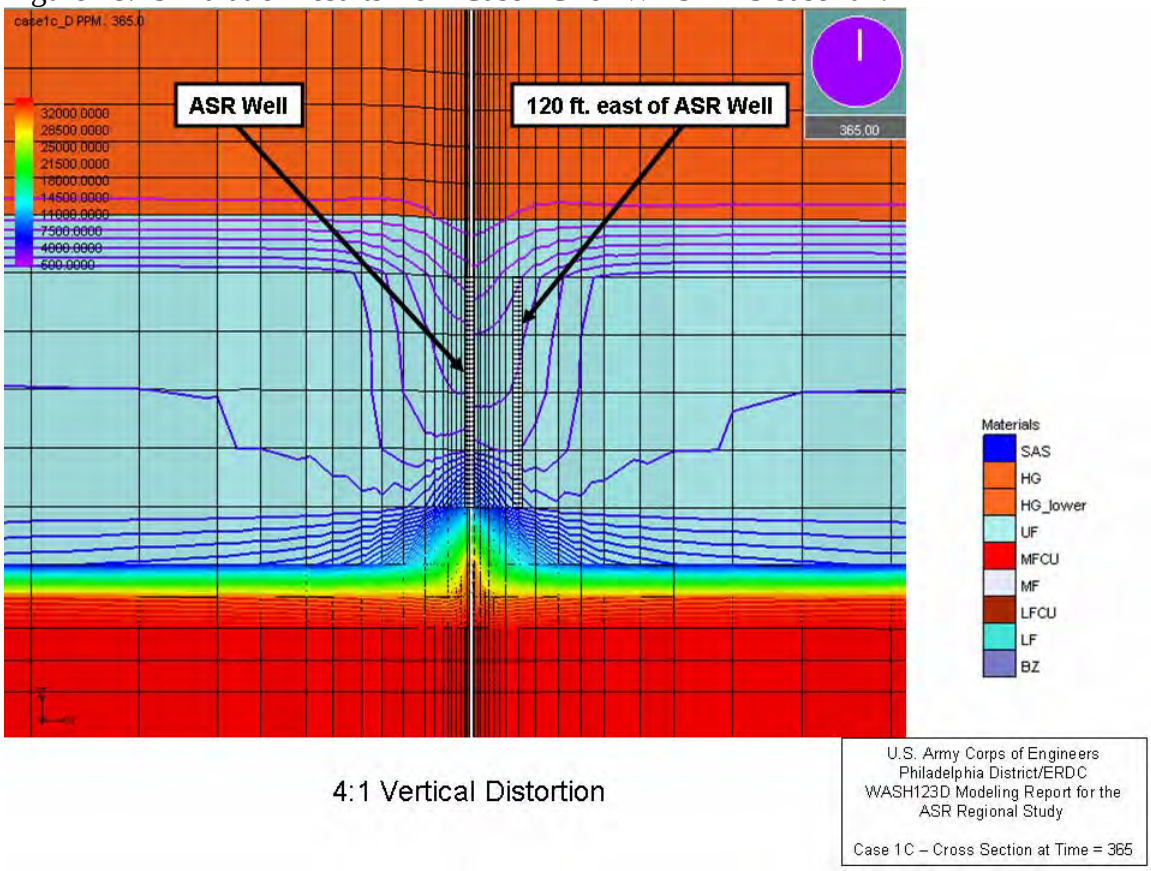
For Case 1C, the model simulation results were similar to those of Case 1A except that density-dependent upconing was encouraged to occur within the models due to assignment of much higher hydraulic conductivity within the MFCU as compared to the assignment for Case 1A. Figure 17 depicts the simulation results for the various model codes and contaminant transport solutions for Case 1C at the ASR well during the 30-day recovery period.

Figure 17. Simulation results for Case 1C at the ASR well during the recovery period.



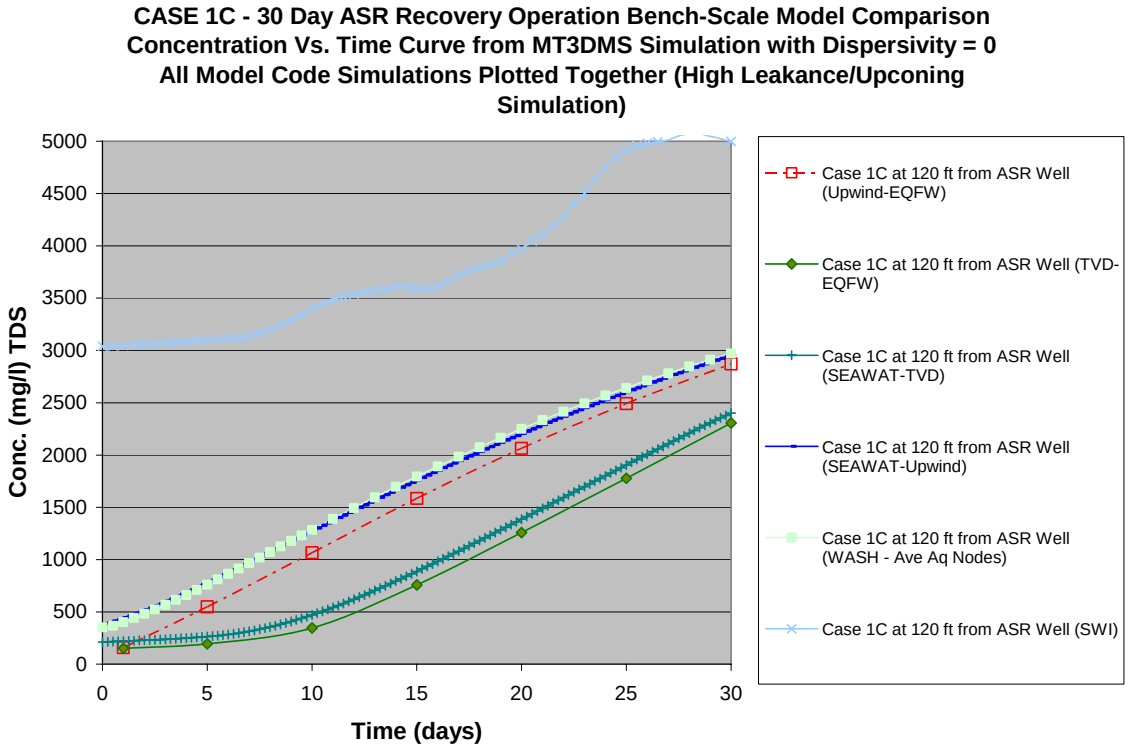
The results reveal three distinct groups of data. The SWI results clearly show predicted TDS concentrations that are considerably higher than the other codes. The TVD results from both the MODFLOW/MT3DMS and SEAWAT models predict the lowest TDS concentrations. The MODFLOW/MT3DMS and SEAWAT upwinded results and the WASH123 results fall between the TVD and the SWI results. It should be noted that the WASH123 results depict saltwater upconing more clearly than the other codes. The WASH123 results for Case 1C are shown on Figure 18.

Figure 18. Simulation results from Case 1C for WASH123 base run.



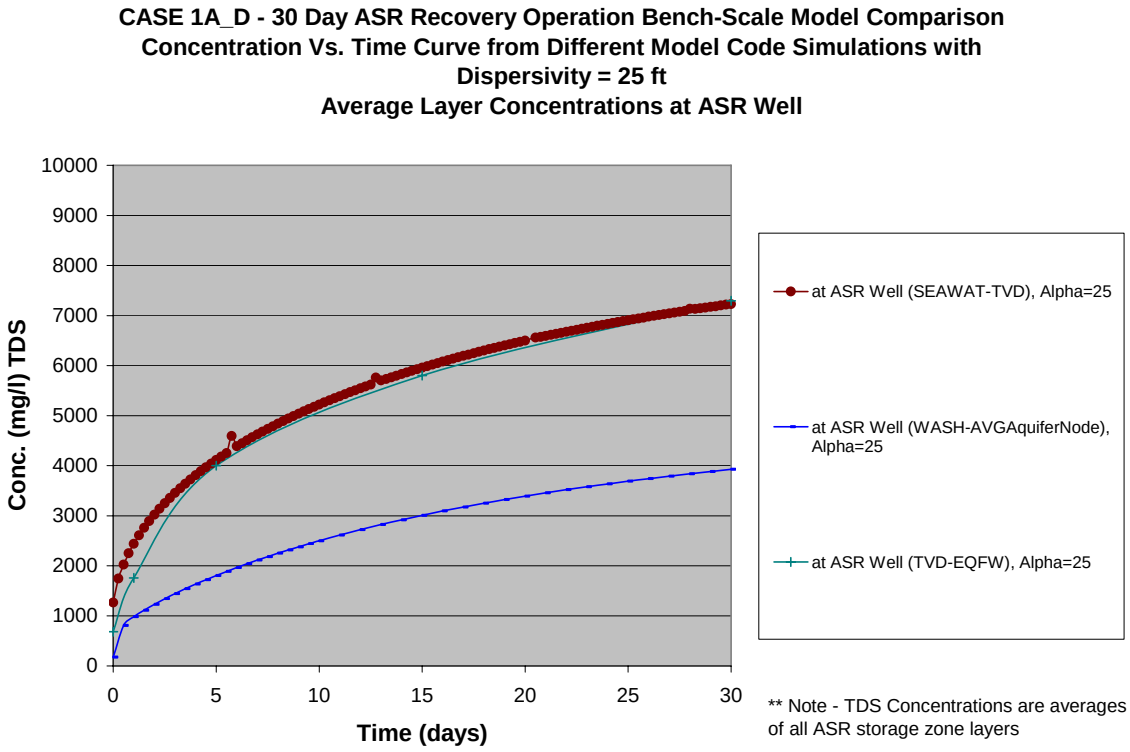
Although not completed for the study, an additional WASH123 run optimizing the boundary assignment of the MFCU (similar to WASH deep4000 for Case 1A) may have resulted in lower predicted TDS concentrations and less severe upconing. Figure 19 depicts similar model simulation comparisons for a theoretical monitoring well located 120 feet distant from the ASR well. The same three distinct data groups are visible.

Figure 19. Simulation results for Case 1C at 120 feet from the ASR well during the recovery period.



For Case 1D, the results were similar to Case 1A except that real dispersion was simulated through the assignment of 25 feet for the longitudinal dispersivity and transverse dispersivity. For Case 1D only the MODFLOW/MT3DMS, SEAWAT and WASH123 codes were compared since SWI does simulate hydrodynamic dispersion. Figure 19 depicts the results of the three comparisons. The MODFLOW/MT3DMS and SEAWAT results are very similar and predict higher TDS concentrations than the WASH123 simulation results. All three model codes predict TDS concentrations to quickly elapse the 500 mg/l regulatory limit following the long 305 day storage period. The MODFLOW/MT3DMS and SEAWAT results also predict concentrations at the ASR well in excess of 4,000 mg/l suggesting either upconing or significant numerical error.

Figure 19. Simulation results for Case 1D at the ASR well during the recovery period.



For Case 2A, the results for the SEAWAT, SWI, and WASH123 codes are all very similar. All three codes appear capable of handling any salt-water intrusion issues that may need to be simulated in the future as part of the ASR Regional Model.

Conclusions and Recommendations:

This benchscale study was developed to evaluate the potential for various model codes to provide answers to issues confronting the ASR Regional Study team. The benchscale study was developed and carried out by an interagency PDT. During the conduct of the study, problems and difficulties were encountered that limited the value of the study to address all goals outlined in the original plan. In general, the main problem was that the test models should have contained more horizontal and vertical model resolution to adequately simulate the cases selected. In addition, one or more benchmark problems with known solutions should have been thoroughly evaluated as part of this study to better ascertain the accuracy limitations of the various codes. An unfortunate consequence of the present work is that there really is no way to tell which code or solution mechanism provides the most accurate result. These shortcomings have been acknowledged and discussed in this report. However, even with the shortcomings identified, the study is valuable. The study also clearly indicated that the important issues

to be addressed for the ASR Regional Study represent three different scales of problem. Therefore, ultimately, three different model scales will be required to address them.

This benchscale study was useful in comparing four different model codes under consideration for use in development of a regional ASR model. The four codes tested represented a reasonable range of code options available and were selected based upon PDT members overall familiarity with the codes. Other codes such as SUTRA and FEFLOW were also considered but rejected. SUTRA has been used for past ASR simulation studies so that some of its advantages and disadvantages were already known. FEFLOW is a proprietary code from Europe that would have been difficult to procure for U.S. Government work efforts. Each code exhibited both strengths and weaknesses. All of the codes provide much of the model functionality desired for the ASR Regional Study team with the SEAWAT and WASH123 codes providing the best overall functionality. All of the codes were determined to be easy to moderately difficult to use, while all codes with the exception of SWI probably require workstation class computers to efficiently develop and calibrate a large regional model. Effective pre and post-processors can be utilized directly by all model codes with the exception of SWI.

A few notable lessons learned can be gleaned from the completed work efforts including the following:

- Where ASR wells with large injection or recovery rates are to be modeled, additional horizontal and vertical model resolution is necessary
- The combination of steep head gradients and sharp concentration fronts present very challenging model simulations
- Comparing code results to known published solutions is recommended even though no “ASR solutions” are currently available
- The initial goal to compare four identical models was a worthy one but ultimately difficult due to different stability requirements for the four codes

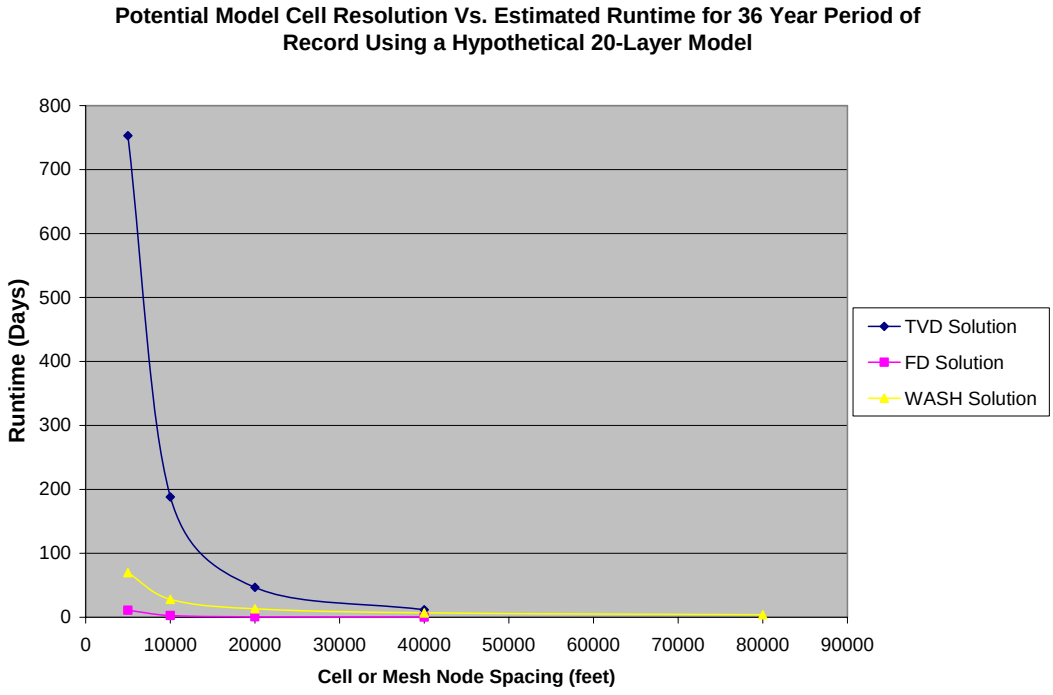
Overall the SWI code had the shortest run times while the SEAWAT (with TVD solution) had the longest run times. The SEAWAT (with upwinded finite-difference solution) and WASH123 fell in between. In general, based upon the results of the benchscale studies, the SEAWAT TVD code is approximately 7 times slower than the WASH123 code and the WASH123 code is approximately 10 times slower than the SEAWAT Upwind code. Due to geometry advantages inherent in finite-element codes, a model designed with WASH123 could have less calculation points than a comparable finite-difference code. Therefore, the run time difference between the SEAWAT Upwind and WASH123 would be reduced considerably. Based upon the results of the benchscale modeling, model run times were extrapolated for identical hypothetical models with 100,000 calculation points using either SEAWAT or WASH123. Run time estimates were calculated for 1 year transient simulations and 36 year transient simulations (similar to CERP modeling period). These are presented in Table 12. It should be noted that the predicted run-times for the SEAWAT TVD solution could be reduced if time step size could be increased. A code improvement of the TVD solution, allowing for larger step sizes, may be feasible in the future.

Table 12. Hypothetical Model Run Times for the ASR Regional Study.

Model Code	Projected Run Time for 1 Year Simulation (Days)	Projected Run Time for 36 Year Simulation (Days)
SEAWAT TVD	2.84	102
WASH123	0.41	14
SEAWAT Upwind	0.04	1.4

The SWI code is approximately twice as fast as the SEAWAT Upwind code but the SWI code does not have a capability to simulate hydrodynamic dispersion, a key ASR performance consideration for the CERP. The SWI code does appear useful for quick evaluations of possible salt-water intrusion episodes caused by ASR recovery. It may also be useful as a screening model tool. If the SWI code is eliminated from consideration, the WASH123 or SEAWAT codes would be the best candidates for use in the ASR Regional Model study. Based upon the results of the benchscale tests completed, a further analysis of potential run times for the ASR Regional Model were prepared assuming the domain would cover approximately 34,000 square miles and the model would contain 20 vertical layers with varying degree of horizontal resolution. Figure 20 depicts projected model run times for the SEAWAT code (TVD and Upwinded Finite Difference Solutions) and the WASH123 code. Also, it was assumed that the full CERP 36-year period of record would be run for each code. Scale up from the benchscale model domain size (County size) to the regional domain is generally straight forward using a simple domain size ratio and assuming additional vertical model resolution.

Figure 20. Estimated Model Run Times for the ASR Regional Model



The SEAWAT (with upwinded finite-difference solution) and WASH123 codes appear to be subjected to the highest amount of numerical dispersion of the codes considered. A portion of the numerical dispersion most likely could be eliminated through better model grid or mesh design allowing for additional resolution in the vertical direction. In addition, accuracy could be further improved for these codes through improved horizontal grid or mesh resolution. It appears that the concentration changes around the ASR well are focused within 250 feet of the ASR well. Therefore, it may be appropriate to maintain a constant horizontal grid or mesh resolution within that radius, increasing grid or mesh size at a reasonable bias beyond 250 feet.

All codes seem capable of simulating density-stratification as evidenced in Case 1B. The accuracy of the codes for this case is unknown however, since no known analytical solution is available to provide a comparison or check. Qualitatively, the SEAWAT (TVD solution) and the WASH123 results appear very similar to each other so it is surmised they probably have a similar accuracy for this case. For Case 1C, the WASH123 code revealed more clear density upconing as compared to the other codes. Since no analytical solution was available for comparison, it is unknown if the simulation results are more representative than the other codes tested.

For Case 1D, the MT3DMS and SEAWAT codes predicted much higher concentrations at the ASR wellhead than the WASH123 code. It is unclear why the differences are so large for this case. Again, the vertical grid resolution may have been insufficient to ensure the highest accuracies of the velocity field around the ASR well. Inaccuracies in the vertical velocity field may have resulted in more significant contaminant transport errors for the model codes. For Case 2A, all the codes tested produced reasonable results and seem capable of simulating cases of salt-water intrusion.

Weighing all of the factors and considering improvements that could be made to the model grid or mesh for future models, it appears that either the SEAWAT (Upwinded finite-different Solution) or the WASH123 codes would be appropriate to utilize for the ASR Regional Study model development effort. Both codes appear to solve the requisite flow and transport equations adequately as well as providing a back stop of published comparisons against density-dependent case studies. SEAWAT appears to be the most widely tested code of the two but recent efforts conducted at the ERDC aim to lessen the gap here. Each of the codes also have inherent disadvantages including long model run times due to small time-step requirements for contaminant transport models. One strategy that was considered valuable was the employment of both model codes to study the same ASR problems thus ensuring a higher degree of reliability in overall conclusions and future recommendations. Using both codes to “bracket” the most likely issues and solutions would go a long way towards better overall decision making for the ASR program. For smaller domain models, the SEAWAT (TVD Solution) code could be utilized to minimize numerical errors and provide the best estimate of ASR recovery efficiency. The SWI code should not be utilized unless hydrodynamic dispersion can be ignored for the particular problem under consideration.

In order to address the maximum number of ASR questions as rapidly as possible, it is recommended that two models be developed simultaneously for the ASR Regional Study. As discussed above, the two codes would enable the PDT to bracket the cogent issues related to potential ASR system impacts and expected benefits. The two codes would provide a much needed measure of decision making reliability. First, a coarse resolution regional model should be developed with horizontal model resolution of 5,000 to 10,000 feet. The coarse model would be developed using the SEAWAT upwinded code and would be utilized to evaluate system groundwater exchange/flows and the movement of the salt-water interface. This model would be calibrated using existing water level and water quality information within the study area along with contour maps showing the depth to the salt-water interface. Long-term simulations of the salt-water interface would be required to simulate current steady-state conditions and concentrations. Therefore, this model needs to run rapidly in order to complete the numerous simulations required. A key advantage of this approach would be the large number of sensitivity tests that could be completed. This would result in a more reliable model calibration of heads and concentrations at the Florida coastline.

Second, a variable resolution regional model should be developed with horizontal model resolution of 100 to 250 feet around the proposed ASR wells increasing to 10,000 feet in the far reaches of the study area. This model would be developed using the WASH123 code and would take advantage of the geometry advantages of a finite-element code such that the model mesh would have varying resolution across the model domain. In essence, finer resolution could be employed at the areas of interest while far-field areas would be modeled with coarse resolution. This model would build upon calibration results achieved for the SEAWAT model by calibrating against seasonal water levels and water quality as well as utilizing transient calibration at existing ASR and well sites where aquifer test or ASR cycle testing data is available. It is believed that at least ten to fifteen such sites would have the necessary data to support this more rigorous calibration effort.

Based upon the model domain of 34,000 square miles, an estimate was made of the number of computational points for each model versus resolution. The SEAWAT grid would be a minimum of 5,000 feet horizontal resolution while the WASH123 mesh would be the same coarse resolution at the model exterior but with 1,000 feet resolution around Lake Okeechobee (key area of interest for the CERP). Table 13 lists the number of computational points for a 1 layer model at different horizontal resolutions. Based upon the benchscale study, the PDT has determined that the regional model should be limited to less than 500,000 computational points to ensure more reasonable run times. In reviewing Table 13, it is important to note that at 5,000 feet of horizontal resolution, both model codes would be similar but WASH123 would have finer resolution around the Lake Okeechobee study area. As resolutions become coarser, SEAWAT clearly results in less computational time. In order to stay within the prescribed number of computational points, the overall ASR regional study model resolution should be limited to minimum of 7,500 to 10,000 feet.

Table 13. Model resolution vs. # of computational points for a one layer model

Horizontal Resolution (feet)	# Grid Points	# Mesh Nodes
5,000	37,704	34,443
10,000	9,426	13,935
20,000	2,356	6,207

Both models would be developed by the same team and would utilize all of the same model input data sets (e.g., water levels, starting conditions, hydrogeology, water quality, and boundary conditions) in order to maximize synergy between the two development efforts. Both models would be combined into a single modeling report for review by an external ITR team. Ultimately, these two models and a very fine-resolution model would represent a "family" of models that could help the ASR Regional PDT address all of the outstanding technical issues identified previously. In addition, this family of models would be utilized to optimize the final design of the entire CERP system of wells.

Abstract Aquifer Storage and Recovery (ASR) is the storage of fresh water in an aquifer via injection during times when water is available, and recovery of the water from the same aquifer via pumping during times when it is needed. ASR is expected to provide a cost-effective solution to many of the world's water management needs: storing water during times of flood or when water quality is good, and recovering it later during emergencies or times of water shortage, or when water quality from the source may be poor. ASR systems can usually meet water management needs at less than half the capital cost of other water supply alternatives. When compared to other alternatives that require construction of water treatment plants and surface reservoirs to meet increasing peak demands, potential cost savings have been anticipated. Besides, ASR has been recognized to have less impact on the environment, aquatic and terrestrial ecosystems. When water is stored deep underground in brackish aquifers, however, the mixing of the saline water that is originally in the brackish aquifer and the fresh water that is injected into the aquifer may degrade the water quality of the stored water and reduce the volume of the available fresh water in the following recovery periods of time. The mixing can be modeled by both the diffusion and the dispersion transport processes. Although both the diffusive and the dispersive fluxes are proportional to concentration gradient, the dispersion coefficients are highly dependent on the flow velocity, whereas the diffusion coefficients are independent of the flow velocity. Therefore in the evaluation of brackish aquifer storage recovery (BASR), whatever factor that would significantly affect the flow velocity in the brackish aquifer during both the injection and withdrawal periods should be accounted for in the associated evaluation models. In this paper, we will demonstrate how BASR can be modeled with the WASH123D numerical model that computes saline transport and density-dependent flow in a watershed system which can be conceptualized as a combination of 1D channel network, 2D overland regimes, and 3D subsurface media. A hypothetical example that includes various model parameters, *e.g.*, pumping rate, hydraulic conductivities, porosity, and

dispersivities will be employed to detail the model setup and conduct a sensitivity analysis.

INTRODUCTION

Aquifer Storage and Recovery (ASR) is one of the proposed alternatives recommended by the Comprehensive Everglades Restoration Plan (CERP). The goal of ASR in the South Florida Region is to help with water supply, storage, and distribution. The ASR Regional Study will include numerical groundwater models in order to evaluate the effectiveness of ASR. For this phase of the project, four box models (~ 40 miles x 40 miles x 2340 ft) were developed using the WASH123D finite element code. Each of the four "cases" is intended to evaluate modeling code performance under different hydraulic conditions. The following paper details the WASH123D model construction and summarizes the simulation results for one of the CERP box models.

WASH123D CODE

WASH123D is a finite element numerical model designed to simulate variably saturated, variable-density water flow and reactive chemical and sediment transport in watershed systems. It is capable of conceptualizing a watershed system as a combination of 1D river/stream, 2D overland, and 3D subsurface sub-domains. A modified Richards' equation is used to solve for 3D flow when density effect is taken into account. The equation is solved with the Galerkin finite element method. WASH123D uses the Lagrangian-Eulerian (LE) method to solve the transport equations. Particle tracking is used in the Lagrangian step to handle the advection term. Other terms (such as sources, sinks, diffusion, and dispersion) are calculated in the Eulerian step, where element matrices are assembled into a global matrix, and matrix solvers are used to solve for the spatial concentration distribution at the end of each time step. A predictor-corrector numerical technique, combined with an adaptive explicit-implicit numerical scheme, is employed to compute reactive transport efficiently and robustly. The use of this methodology allows the numerical stability of WASH123D not to be restricted by the Mesh Courant number. In addition, the Mesh Peclet number is restricted only by computational accuracy, not numerical stability. More detailed discussion on various types of numerical dispersion and how the LE method deals with these types of numerical dispersion are discussed in the referenced papers.

Since computational accuracy is dependent on the time step size used in the simulation, a sensitivity analysis was performed to evaluate the variations in the time-step size on model results. For this sensitivity analysis the time step of the injection and extraction cycles were varied between 0.05 and 5 days. The results of this analysis, presented in Figure A1, indicate that the change of the computational result becomes insignificant as the time step size is reduced to

below 0.5 days. Therefore, a time step size of 0.5 days was used during the injection and extraction cycles for all simulations in this study.

MESH DEVELOPMENT
