WASH123D uses an unstructured three-dimensional (3D) finite element mesh to solve the flow and transport equations in variably-saturated media. Because flow and concentration gradients may be high in the vicinity of an ASR well, the vertical and horizontal resolution of the 3D mesh in the vicinity of the ASR well is important. Meshes that do not have sufficient resolution in the area of interest may not accurately simulate observed conditions in these high gradient areas. On the other hand, meshes that contain too much resolution will require more computational resources, resulting in extended simulation times. The mesh used for this study was based on conceptual geology developed by the Jacksonville District. The horizontal resolution of the mesh at the ASR well is 10 feet. The elements at the ASR well were deleted to allow Cauchy flux boundary conditions to be assigned directly to the interior faces of the mesh, representing the well screen. The mesh resolution expands to 5000 feet along the model perimeter. Vertical mesh resolution varied among the different conceptual geologic units. Increased resolution was used in the confining units directly above and below the ASR injection aquifer (Upper Floridian). This increased resolution allowed the WASH123D model to depict the large head and concentration gradient at the interfaces of these confining units. The final 3D mesh was composed of 112,716 nodes and 212,940 triangular-prism elements. Figures A2a and A2b illustrate the mesh resolution and conceptual geology used for the ASR simulations. The DoD Groundwater Modeling System (GMS) v.5.1 was used to generate the WASH123D mesh.

BOUNDARY CONDITIONS

Boundary conditions were assigned to the finite element model to simulate ASR pumping into the Upper Floridian aquifer. At the ASR well, Cauchy flux boundary conditions were used to simulate injection and extraction flow rates of 5 MGD. These boundary conditions were applied to the element faces representing the well screen within the Upper Floridian Unit (approximate elevation –1,014 to –1,171 ft). The saline concentration of the injected fluid was 150 mg/L. The saline concentration of the fluid at the ASR well during storage and extraction varies with depth and time depending on the relative saline concentration in the surrounding nodes, the extraction rate, and the mixing process in the ASR well. Dirichlet boundary conditions were used to assign the total head along the eastern and western model boundaries. WASH123D converts these assigned heads to equivalent fresh water heads based on the concentration and depth of each node. No-flow boundary conditions were used along the northern and southern model boundaries. Dirichlet boundary conditions were also used to assign the concentration along the model perimeter. Tables A1 and A2 show the

hydraulic and transport properties,respectively, for each geologic unit in the WASH123D model.

EVALUATION OF RESULTS

The WASH123D model simulated a 30-day injection period, followed by a 305-day storage period, and a 30-day recovery period. Prior to performing the transient simulation WASH123D calculates steady state initial hydraulic conditions based on the specified input parameters. The following discusses the results of the WASH123D model during each phase of the simulation.

Initial Condition

Since the WASH123D model is a coupled density dependent code, the initial hydraulic head boundary conditions were converted to equivalent freshwater heads based on the depth and saline concentration at each node. For this simulation, the nodes in the geologic units above the Upper Floridian aquifer were assigned a saline concentration of fresh water (150 mg/L), while the nodes in and below the Upper Floridian aquifer were assigned a saline concentration of seawater (35,000 mg/L). The specified boundary conditions result in a west to east hydraulic gradient. Figure A3a shows a cross sectional view of the concentration profile in the vicinity of the ASR well. The contours on this figure reflect the constant concentration profile used as the initial condition prior to pumping.

Injection Period

Once the initial steady state flow field is generated, the ASR pumping well injects fresh water into the Upper Floridian aquifer at 5 MGD for 30 days. During this injection cycle the hydraulic head at and immediately surrounding the ASR well increases substantially, nearly doubling in magnitude. Figure A3b shows a cross sectional view of the concentration profile in the vicinity of the ASR well at the end of the injection cycle. This figures show that the injected fresh water has displaced the ambient saline water forming a spheroid of lower concentration water in the vicinity of the ASR well. This lower concentration water permeates into the confining units above and below the Upper Floridian aquifer.

Storage Period

After the 30-day injection cycle, the ASR well is turned off for 305 days. During this storage period, the hydraulic conditions stabilize to near steady state conditions. Figure A3c shows a cross sectional view of the concentration profile in the vicinity of the ASR well at the end of the storage period. Although the concentration at the ASR well remains relatively constant, the effects of buoyancy stratification are noticeable. During the storage period, the density effect is the dominate factor in the flow fields simulated by WASH123D. Consequently, the concentrations at the nodes in the lower portion of the Upper Floridian aquifer increase substantially faster than the nodes at the top of the aquifer.

Extraction Period

After the storage period the ASR well extracts at 5 MGD for 30 days. During this extraction cycle the hydraulic head at and immediately surrounding the ASR well decreases substantially. Figure A3d shows a cross sectional view of the concentration profile in the vicinity of the ASR well at the end of the storage period. Up-coning of the higher concentration saline water below the ASR well was observed during extraction. It must be noted that the well screen of injection and extraction in the Upper Floridian aquifer covers the center four vertical elements, rather than all the six vertical elements in the aquifer. This setup allows the mesh to compute for convergent flow fields around the well at the interfaces of the Upper Floridian aquifer and the two aquitards above and below without using high resolution meshes and small time steps when the density effect is strong. Because of this, the salt concentration of nodes in the lower portion of the aquifer in the vicinity of the ASR well increase in concentration faster than the nodes above during the period of extraction due to both diffusion and up-coning.

FUTURE MODEL DEVELOPMENT

During the development of the WASH 123D model, meshes of various vertical and horizontal resolutions were tested. The WASH123D simulations became more computationally stable as the vertical resolution was increased in the geologic units above, below, and containing the ASR well. Additional studies are anticipated that evaluate the effect of various mesh resolutions on computational speed and accuracy.

In addition to the mesh sensitivity simulations, additional modifications to the WASH123D code are anticipated. One modification will be to the algorithm used to calculate the equivalent freshwater head in variable density flow systems. In simulations where higher density fluid is overlain by fluid of a lower density, the current algorithm tends to overestimate the equivalent freshwater head in the higher density solutions. Additional upgrades to address temperature variations on thermal transport will also be incorporated to the WASH123D code. These upgrades in conjunction with WASH123D's current ability to model variably saturated groundwater flow and surface/subsurface flow interactions will enhance WASH123D's ability to model the dynamic flow and transport issues inherent in the ASR program.

ASR Regional Study – Benchscale Modeling

Final Report
July 2006
Prepared by:

Christopher J. Brown, Ph.D., P.E. – USACE
Steve England, P.E. – USACE
Glendon T. Stevens, P.E. - USACE
Hwai-Ping Cheng, Ph.D. – USACE ERDC
Emily Richardson, P.G. - SFWMD

Introduction:

The CERP recommends approximately 333 ASR wells to help with the supply, storage and distribution of water within the South Florida Region. The wells are dual purpose, since they are intended to store excess water during summer wet periods and recover the water during dry winter periods. It is hoped that the technology will provide a dependable water storage mechanism that can supplement surface storage reservoirs and provide water supply to the Lake Okeechobee ecosystem, Everglades ecosystem, agricultural irrigation, urban interests and others. The proposed injection and recovery pumping rate is approximately 1.65 billion gallons per day which is unprecedented in terms of other past or present ASR applications. Currently, only desktop spreadsheet evaluations or analytical solutions can provide an estimate of the aquifer response (e.g., piezometric head increases, fracturing pressures, increased flow) to such a large volume of injected water. A numerical model (or family of models), designed to simulate the regional groundwater system, will serve to make further evaluations of the plan. Porous media models and a discrete fracture network models have been considered but due to the lack of discrete fracture data related to the hydrogeology of south Florida, a porous media model has been pursued.

The CERP blue-print has been presented in a massive regional-scale plan that lacks engineering detail sufficient to construct the project. A large number of the construction features contained in the CERP were designed at various levels of detail based on information that was available during the plan formulation and evaluation phase. Many of the design assumptions for the components were based solely on output from the South Florida Water Management Model (SFWMM), which averages hydrologic conditions across a model comprised of grid cells with lengths and widths of 2 miles by 2 miles. Consequently, the engineering details of the construction features,

including the size and locations are conceptual and require additional studies. In addition, the SFWMM only simulates the Surficial Aquifer System explicitly. The Floridan Aquifer System where the proposed ASR wells would be located is not included. In general, the CERP proposed 200 ASR wells to be sited in the vicinity of Lake Okeechobee with the remaining wells located adjacent to the C-43 reservoir and in the Lower East Coast (specifically, Palm Beach and Broward Counties, Florida). A later effort, the Water Preserve Area (WPA) Feasibility Study, proposed adding additional wells in this area. The exact location and distribution of the proposed CERP ASR wells was never determined as part of the original CERP effort, however, the proposed wells were generally concentrated adjacent to reservoirs or Lake Okeechobee. The WPA Feasibility efforts proposed ASR wells at the C-9 impoundment.

Together with the ASR Pilot Projects and the ASR Contingency Plan, the ASR Regional Study will endeavor to reduce technical uncertainties associated with the proposed CERP ASR plan - a plan that is unprecedented in scale anywhere in the world. A Project Management Plan (PMP) was prepared for the ASR Regional Study in 2003. The center-piece of the ASR Regional Study is the preparation of a series of numerical simulation models. A multitude of issues need to be evaluated using the family of numerical models. The issues include local, sub-regional, and regional-scale concerns counting the following:

1. Regional changes in aquifer heads and flows
2. Regional changes in aquifer water quality TDS, sulfate, and chloride
3. Increased potential for salt-water intrusion caused by ASR pumping
4. Regional impacts to existing well users of the FAS
5. ASR well cluster site selection
6. ASR well cluster design and layout
7. ASR well cluster performance including estimating recovery efficiency
8. ASR well site evaluation of pressure induced changes
9. Localized transport of contaminants including heavy metals or pathogens
10. Localized ASR well pump design (dependent upon the appropriate model resolution)

Initially, a large, peninsula-wide numerical model will be developed. It is envisioned that this model will encompass an area of the Florida peninsula from Polk County south to Florida Bay. This model is intended for use as a planning tool to evaluate potential changes (e.g., head/flow and water quality) within the confined Floridan Aquifer System (FAS), aid in the site selection of ASR well clusters in the vicinity of Lake Okeechobee, adjacent to the C-43 reservoir and in the Lower East Coast area of South Florida, and aid ASR well cluster design and layout. In support of the main model development task, a number of smaller tasks will also be completed prior to or in parallel with the screening model development (e.g., literature search, data compilation, model selection, etc.). Once the Regional Screening Model is completed, more detailed sub-regional and/or local scale models will be developed to evaluate the ASR program in a higher level of detail. Depending upon model code selection and model domain design, all ten of the issues noted above could be evaluated. Table 1 displays the model scale required to address each of the identified issues. Both the sub-regional and regional scale

models should be designed to address as many of the issues listed as possible. In essence, the sooner the issue can be evaluated, the better. Obviously, one possible strategy would be to address the issue in two tiers. First, the regional model could provide planning-level information to address the specific issues. Then, an improved understanding of the issue could be obtained through the development of finer-resolution sub-regional models. For the three local-scale issues identified, only small models with fine horizontal and vertical resolution, will be sufficient to adequately address them.

Table 1. Model scale requirements.

Model Scale Required to Address Specific Issue	**Issues to be addressed as listed above**
Local Scale fine-resolution model	7, 9, 10
Sub-regional moderate-resolution model	1, 2, 3, 4, 6, 8
Regional Scale moderate to coarse resolution model	1, 2, 3, 4, 5, 6, 8

It is anticipated that the model development process will require approximately 1.75 to 2-years to finish and will involve numerous meetings, workshops, and conference calls. A team of model developers will work collaboratively over the internet and through video-conferences. It is expected that the model development effort will involve numerous technical challenges including addressing seawater boundary conditions; determining an appropriate number of model layers and grid/mesh spacing; developing manageable model computer run-times; evaluating vertical aquifer system connections/leakage; testing alternate locations for ASR clusters; developing reasonable ASR recharge and recovery scenarios; and determining whether or not steady state modeling is applicable.

Due to the large scale of the model, computer run-times are expected to be quite long. Therefore, the selection of an appropriate model code is of paramount importance. Consideration will be given to utilizing a fully density-dependent model code if performance tests confirm that such a code would be practical to use at the scale envisioned. Otherwise, consideration will be given to simulating density effects at the seawater boundaries and along the bottom of the model as necessary.

Model Code Bench-scale Testing Scope of Work:

The scope of work for the model development effort presented in the ASR Regional Study PMP recognized that a fully density-dependent code would be ultimately be required to simulate regional changes in aquifer pressure and water quality. This is due to a number of technical considerations including:

- Water exchange between various portions of the FAS
- Water flow and velocity issues near coastal portions of the model
- ASR recovery efficiency is partially dependent upon density stratification effects
- Density directly affects the regional heads and flow within the FAS
- Density is a function of water quality of the aquifer (e.g., function of TDS)

The PMP also considered alternate modeling approaches employing density-dependent boundaries to grossly simulate density affects. Therefore, the development of sub-regional models that possessed the requisite density-dependent capabilities were specified as part of the PMP to ensure the most realistic model simulations could be developed. Alternate modeling approaches may allow some flexibility in the development of a regional model, ensuring that the following constraints are managed:

- Limitations of existing density-dependent model codes
- Concerns about model run times
- Schedule constraints
- Resources available

Ideally, both the Regional Screening Model and the sub-regional models would be fully density-dependent models. Subsequent to completion of the PMP, advances in model codes have made the use of a density-dependent code more feasible as part of the Regional Screening Model development effort. There is concern, however, that the size of the model might limit the feasibility of the fully density-dependent approach due to the constraints listed above, especially model run times. In order to balance the needs of the project with the current technical capabilities of software and hardware, the model development team recommended the development of a bench-scale model to evaluate various model codes and approaches in order to aid the model code selection task.

The primary objectives of the bench-scale modeling effort are:

- Provide an improved estimate of model run times for 36-year simulations
- Provide a preliminary understanding of model development issues relating to resolution requirements, boundary types, and starting conditions
- Uncover model limitations and short comings

An appropriate code for the Regional Screening Model is to be selected on the basis of bench testing of various model codes at a sub-regional or county-wide scale. Although the proposed domain size is still considerably smaller than the anticipated regional model domain, it does provide a firm basis for the extrapolation of model performance to the larger domain. Bench testing of several model codes will provide a solid basis to make an informed decision on model code selection. This course of action will provide the following benefits:

- Aid in determining what class of model (constant density standard flow and transport, uncoupled density-dependent flow and transport, fully density-dependent flow and transport) is required to address CERP ASR issues
- Provide comparison performance metrics for various bench marked codes including relative accuracy, and model stability and run-times
- Aid in the evaluation of hardware needs & pre/post processing requirements

It was envisioned that the benchmark modeling effort would develop several identical (constant density standard flow and transport, uncoupled density-dependent flow and transport, fully density-dependent flow and transport) models covering a much smaller model region than projected for the Regional Screening Model. It was anticipated that a 40 mile X 40 mile area would provide a model domain of sufficient size and complexity to provide a valid test of each proposed model code and allow extrapolation of results to larger regional scales. The scale and design would be similar in size to Palm Beach County, Florida, where many ASR wells are proposed for installation. As part of the ASR Pilot Project Design Report (PPDR), a numerical model of the Palm Beach County area was available. In order to maximize the use of previously developed model tools as suggested by the Interagency Modeling Center (IMC), the USACE provided the Palm Beach County model as the "base" MODFLOW/MT3D model. Using the base model as a guide, four similar "box models" were prepared using four different model codes/approaches. The model was provided "as is" and was not optimized for any particular application.

The four codes were selected in a collaborative fashion among members of the modeling sub-team of the PDT. With the exception of the MODFLOW SWI package, the sub-team members had significant experience with the rest of the models selected. In addition, each of the codes selected was paired with a well-known pre/post-processor software package that simplified the model development process. Lastly, budget considerations limited the task scope to no more than four model codes. If time and budget had allowed, several other established codes would also have been considered, including FEFLOW and SUTRA, for example. The four model codes utilized for the bench-scale study are:

- MODFLOW and MT3DMS using equivalent freshwater heads to represent saltwater boundaries (e.g., constant density flow and transport model)
- SWI (Sea-Water Intrusion) Package for MODFLOW (density dependent vertically integrated flow with interface tracking)
- SEAWAT (fully coupled or uncoupled density-dependent flow and transport)
- WASH123 (fully coupled or uncoupled density-dependent flow and transport)

MODFLOW is a computer program that numerically solves the three-dimensional groundwater flow equation for a porous medium using a finite-difference method (McDonald and Harbaugh, 1988). MT3DMS is a computer program for modeling multi-species solute transport in three-dimensional ground-water systems using multiple solution techniques, including the finite-difference method, the method of characteristics (MOC), and the total-variation-diminishing (TVD) method (Zheng and Wang, 1999). MODFLOW is considered to be the most widely used program for constant-density groundwater flow problems. Key factors in MODFLOW's popularity in the modeling community are its thorough documentation, modular structure, which makes it easy to modify and enhance, and the public availability of the software and source code.

The Sea Water Intrusion (SWI) package is intended for the modeling of regional seawater intrusion with MODFLOW2000 (Bakker and Schaars, 2002). The SWI package utilizes

the Dupuit approximation that neglects vertical resistance to flow in the vertical direction. The vertical pressure distribution is hydrostatic in each aquifer. The advantage of using the Dupuit approximation is it allows multiple aquifer systems with one layer of cells. The vertical pressure distribution is hydrostatic in each aquifer, but this does not mean that there is no vertical flow; the vertical component of flow is computed from the three-dimensional continuity of flow. Variable-density flow may be simulated, through Darcy's Law, as stratified flow or as continuously varying density flow. The basic principle behind the formulation is to solve, during each time step, for the freshwater-head by considering continuity of flow in the entire aquifer, and to solve for the elevations of the interfaces by considering continuity of flow below each surface. Is should also be noted that the effects of dispersion and diffusion are not taken into account. Inversion, saltier (heavier) water above fresher (lighter) water, is also not allowed.

The SEAWAT program (Guo and Langevin, 2002) is a combination of MODFLOW and MT3DMS (Zheng and Wang, 1999) designed to simulate three-dimensional, variable-density, groundwater flow and solute-transport. The program was developed by modifying MODLOW subroutines to solve a variable-density form of the groundwater flow equation and by combining MODFLOW and MT3DMS into a single program. SEAWAT reads and write standard MODFLOW and MT3DMS input and output files, allowing most of the existing pre- and post-processors to facilitate application of the program to a wide range of practical problems. One advantage of SEAWAT is that because it uses MT3DMS to represent solute-transport, the program contains several diverse methods (Eulerian, Langrangian, or mixed) for solving the transport equation including the MOC, an explicit third order total-variation-diminishing (TVD) scheme, and a standard finite-difference method with central-in-space or upstream weighting.

WASH123D (Yeh et al. 1998) is a finite element numerical model designed to simulate variably saturated, variable-density water flow and reactive chemical and sediment transport in watershed systems. It is capable of conceptualizing a watershed system as a combination of 1D river/stream, 2D overland, and 3D subsurface sub-domains. A modified Richards' equation is used to solve for 3D flow when density effect is taken into account. The equation is solved with the Galerkin finite element method. The groundwater flow portion of the code utilizes an adaptation of the FEMWATER code (Lin et al. 1997). WASH123D uses the Lagrangian-Eulerian (LE) method to solve the transport equations. Particle tracking is used in the Lagrangian step to handle the advection term. Other terms (such as sources, sinks, diffusion, and dispersion) are calculated in the Eulerian step, where element matrices are assembled into a global matrix, and matrix solvers are used to solve for the spatial concentration distribution at the end of each time step. A predictor-corrector numerical technique, combined with an adaptive explicit-implicit numerical scheme, is employed to compute reactive transport efficiently and robustly. The use of this methodology allows the numerical stability of WASH123D not to be restricted by the Mesh Courant number. In addition, the Mesh Peclet number is restricted only by computational accuracy, not numerical stability. More detailed discussion on various types of numerical dispersion and how the LE method deals with these types of numerical dispersion are discussed in the referenced papers.

As described previously, each model would include a model boundary consisting of a 40-mile by 40-mile square box. Each model would contain 7 to 20 vertical layers representing the Surficial Aquifer System (SAS), Hawthorn Group confining unit, and the FAS. The four models each adopted the same hydrogeologic conceptual model, utilizing the same aquifers and confining units. Also, all of the model layers were assigned with identical hydraulic parameters (e.g., hydraulic conductivity and storage coefficient) in order to eliminate differences in these properties due to contouring algorithm chosen for each model. The exact number of layers was initially intended to be consistent for the different codes, however, model stability and accuracy requirements required refinement in some cases. Each box model would have identical boundary conditions, starting conditions (head and TDS concentration), influent TDS concentrations (150 mg/l), and aquifer/confining unit parameters. In addition, a common convergence criteria was agreed upon for both flow and transport portions of the models. Five separate cases were developed by the PDT to evaluate relevant ASR modeling issues including mixing, hydrodynamic dispersion, density stratification, upconing, and changes in salinity distribution as a result of ASR injection and/or recovery. The five cases are summarized in Table 2. Additional specific information summarizing each case is available following the table.

Table 2. Bench-scale case summary.

Case Number	**Purpose and basic setup**
IA	One ASR well recharge and recovery 5 MGD from FAS storage zone with TDS of 4,000 mg/l. Minimal upconing or leakage from below. No dispersivity assigned.
IB	One ASR well recharge and recovery 5 MGD from FAS storage zone with TDS of seawater (35,000 mg/l). Minimal upconing or leakage from below. No dispersivity assigned.
IC	One ASR well recharge and recovery 5 MGD from FAS storage zone with TDS of 4,000 mg/l. Major upconing or leakage from below encouraged through confining layer vertical conductivity assignment. No dispersivity assigned.
ID	One ASR well recharge and recovery 5 MGD from FAS storage zone with TDS of 4,000 mg/l. Minimal upconing or leakage from below. Dispersivity assigned with value of 25 feet.
IIA	One ASR well recovering for 5 years continuous to evaluate movement of salt-water interface from coast.

Case IA: Transient Model Simulation - One ASR well injecting 5 MGD into FAS in center of box for 30 days, followed by 305 day storage period, followed by 30 days of recovery at 5 MGD. The starting TDS of the FAS storage zone was assigned to be 4,000 mg/l, the TDS of the Middle FAS Confining Unit will be 35,000 mg/l, and the Middle FAS flow zone was assigned 35,000 mg/l. The Middle FAS Confining Unit was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between aquifer units. The Surficial Aquifer System (SAS) was assigned a constant head of 20 feet. The Hawthorn Group Clay (Intermediate Confining Unit) was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between the SAS and the Upper FAS. Prior to simulation start up, the model was run with the regional gradient to steady state conditions. The regional gradient was assigned from west to east at 0.0001 and is considered representative of the Upper FAS. The steady state gradient of 0.0001 was used to assign the starting heads of the Upper FAS for the one year simulation. The dispersivity tensor was assigned a value of zero in order to evaluate the degree of numerical dispersion produced from each code.
The purpose of Case 1A was to evaluate model code ability to simulate aquifer pressure changes, salinity changes due to conservative mixing, salinity changes due to hydrodynamic dispersion, and relative degree of numerical dispersion introduced. Since there was no known ASR case studies that have evaluated this issue, the comparison of numerical dispersion was relative in nature and assumed that the TVD solution was the most accurate as determined from previous publications. The flows between layers and to and from boundaries were also of interest. Landscape Figure 1 below (at the end of the report after the report appendices) depicts the assigned model parameters in detail for both the MODFLOW based models as well as the WASH123 model.

Case IB: Transient Model Simulation - One ASR well injecting 5 MGD into FAS in center of box for 30 days, followed by 305 day storage period, followed by 30 days of recovery at 5 MGD. The starting TDS of the FAS storage zone was assigned to be 35,000 mg/l, the TDS of the Middle FAS Confining Unit will be 35,000 mg/l, and the Middle FAS flow zone was assigned 35,000 mg/l. The Middle FAS Confining Unit was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between aquifer units. The Surficial Aquifer System (SAS) was assigned a constant head of 20 feet. The Hawthorn Group Clay (Intermediate Confining Unit) was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between the SAS and the Upper FAS. Prior to simulation start up, the model was run with the regional gradient to steady state conditions. The regional gradient was assigned from west to east at 0.0001 and is considered representative of the Upper FAS. The steady state gradient of 0.0001 was used to assign the starting heads of the Upper FAS for the one year simulation. The dispersivity tensor was assigned a value of zero in order to evaluate the degree of numerical dispersion produced from each code.

The purpose of Case 1B was to evaluate model code ability to simulate aquifer pressure changes, salinity changes due to conservative mixing, salinity changes due to hydrodynamic dispersion, and degree of buoyancy stratification that occurs during the storage period. The flows between layers and to and from boundaries were also of

interest. Landscape Figure 2 below depicts the assigned model parameters in detail for both the MODFLOW based models as well as the WASH123 model.

Case IC: Transient Model Simulation – One ASR well injecting 5 MGD into FAS in center of box for 30 days, followed by 305 day storage period, followed by 30 days of recovery at 5 MGD. The starting TDS of the FAS storage zone was assigned to be 4,000 mg/l, the TDS of the Middle FAS Confining Unit will be 35,000 mg/l, and the Middle FAS flow zone was assigned 35,000 mg/l. The Middle FAS Confining Unit was assigned a vertical conductivity of 1 feet per day to ensure leakage between the aquifer units. The Surficial Aquifer System (SAS) was assigned a constant head of 20 feet. The Hawthorn Group Clay (Intermediate Confining Unit) was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between the SAS and the Upper FAS. Prior to simulation start up, the model was run with the regional gradient to steady state conditions. The regional gradient was assigned from west to east at 0.0001 and is considered representative of the Upper FAS. The steady state gradient of 0.0001 was used to assign the starting heads of the Upper FAS for the one year simulation. The dispersivity tensor was assigned a value of zero in order to evaluate the degree of numerical dispersion produced from each code.

The purpose of Case 1C was to evaluate model code ability to simulate aquifer pressure changes, salinity changes due to conservative mixing, salinity changes due to hydrodynamic dispersion, and degree of density-driven upconing. The flows between layers and to and from boundaries were also of interest. Landscape Figure 3 below depicts the assigned model parameters in detail for both the MODFLOW based models as well as the WASH123 model.

Case ID: Transient Model Simulation - One ASR well injecting 5 MGD into FAS in center of box for 30 days, followed by 305 day storage period, followed by 30 days of recovery at 5 MGD. The starting TDS of the FAS storage zone was assigned to be 4,000 mg/l, the TDS of the Middle FAS Confining Unit will be 35,000 mg/l, and the Middle FAS flow zone was assigned 35,000 mg/l. The Middle FAS Confining Unit was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between aquifer units. The Surficial Aquifer System (SAS) was assigned a constant head of 20 feet. The Hawthorn Group Clay (Intermediate Confining Unit) was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between the SAS and the Upper FAS. Prior to simulation start up, the model was run with the regional gradient to steady state conditions. The regional gradient was assigned from west to east at 0.0001 and is considered representative of the Upper FAS. The steady state gradient of 0.0001 was used to assign the starting heads of the Upper FAS for the one year simulation. The dispersivity tensor was assigned a value of 25 feet in order to evaluate the model run times using a realistic amount of hydrodynamic dispersion.

The purpose of Case 1D was to evaluate model code ability to simulate aquifer pressure changes, salinity changes due to conservative mixing, salinity changes due to hydrodynamic dispersion, and degree of hydrodynamic dispersion introduced. The flows between layers and to and from boundaries were also of interest. Landscape Figure 4

below depicts the assigned model parameters in detail for both the MODFLOW based models as well as the WASH123 model.

Case IIA: Transient Model Simulation – Transient Model Simulation - One ASR well withdrawing 5 MGD from the Upper FAS in center of box for five years. The starting TDS of the FAS storage zone was assigned to be 4,000 mg/l, the TDS of the Middle FAS Confining Unit will be 35,000 mg/l, and the Middle FAS flow zone was assigned 35,000 mg/l. All units at the eastern boundary of the model were assigned a starting head of zero. The starting concentration of TDS in all model layers was based upon an approximation of the Ghyben-Herzberg relationship to define the 35,000 mg/l isochlor. The Middle FAS Confining Unit was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between aquifer units. The Surficial Aquifer System (SAS) was assigned a constant head of 20 feet. The Hawthorn Group Clay (Intermediate Confining Unit) was assigned a vertical conductivity of 0.001 feet per day to ensure minimal leakage between the SAS and the Upper FAS.

The purpose of Case IIA was to evaluate model code ability to simulate pumping induced regional changes in the three-dimensional salinity distribution.

Groundwater Model Testing and Comparison Protocols

Groundwater model testing has been the subject of multiple past studies and papers. Testing of groundwater simulation codes may take several forms including:

- Benchmarking against known analytical solutions
- Intra-code comparisons using different code functions and same stresses to emulate the same system response
- Inter-code comparisons simulating same stresses and systems
- Comparisons with field or laboratory data

One thing sorely lacking amongst the published literature is an approved or recommended protocol to perform the various comparisons. One such study was prepared by van der Heijde and Danzer (1997) for the United States EPA. This paper proposes a systematic evaluation and testing methodology or protocol that could be applicable to the bench-scale modeling effort. Although the bench-scale modeling effort was designed to test and compare model codes, it was not meant to be a full-scale code-testing and evaluation protocol; therefore, some of the evaluations recommended by van der Heijde and Danzer were not completed. Van der Heijde and Danzer recommend including an evaluation of code functionality and performance. Code functionality is defined as the set of functions and features which the code offers the user in terms of model framework geometry, simulated processes, boundary conditions, and analytical and operational capacities (van der Heijde and Danzer, page 2). Performance evaluations are aimed at determining the characteristics of the model code in terms of:

- Computational accuracy
- Reliability (convergence and stability of solution algorithms)

- Sensitivity for grid orientation, grid resolution, or time discretization
- Efficiency of coded algorithms (code execution time and memory/storage requirements)
- Resources required for model setup and analysis

First, all of the codes were evaluated for their overall functionality to address specific ASR issues discussed above. The overall code functionality was addressed based upon existing information available for each code, PDT experience, and published papers or case studies. Each issue requires a basic set of model development and analysis functions. These various functions are outlined in Table 3 along with qualitative scoring of each model code.

In reviewing Table 3, all codes could provide some of the functionality required to evaluate all relevant ASR issues to be studied. SEAWAT and WASH123 provide the highest overall functionality for the questions to be answered with the model. Table 4 provides a list of other general functions that are required of each model along with a qualitative score for each. In general all of the codes can provide much of the basic functionality required for the ASR Regional Study, however, SEAWAT and WASH123 provide the best overall functionality desired for the study.

Table 3. Required model functionality

Specific ASR Project Issue	**Desired Functionality**	**Modflow/MT3D**	**SEAWAT**	**WASH123**	**SWI**
Regional changes in aquifer heads and flows	1. Simulate head changes in region around proposed ASR well clusters	X	X	X	X
	2. Simulate flows from ASR wells, existing FAS user wells, boundaries, and between aquifers	X	X	X	X
Regional changes in aquifer water quality	1. Simulate water quality changes in region around proposed ASR wells, existing FAS user wells, boundaries, and between aquifers	X	X	X	
	2. Simulate density changes as a result		X	X	X
Increased potential for salt-water intrusion caused by ASR pumping	1. Simulate potential movement of salt-water wedge due to ASR recovery activities		X	X	X
	2. Simulate potential movement of salt-water wedge due to ASR recharge activities		X	X	X
Regional impacts to	1. Evaluate increases or decreases in head or water quality at existing well users	X	X	X	X

existing well users of the FAS	caused by ASR activity				
ASR well cluster site selection	1. Simulate superposition effects caused by multiple ASR wells recharging or recovering. Site ASR well clusters in order to minimize superposition effects and potential impacts on users. 2. Site selection is heavily influenced by all proposed well fields operating at same time (e.g., boundary effects are important in this instance).	X X	X X	X X	X X
ASR well cluster design and layout	1. Evaluate design and layout issues at one ASR cluster. 2. Varying horizontal resolution probably required.	X X	X X	X X	X X
ASR well cluster performance including estimating recovery efficiency	1. Evaluate ASR well cluster recovery efficiency and performance. 2. Evaluate upconing potential at each cluster site. 3. Evaluate density stratification at each cluster site.	X	X X X	X X X	 X
ASR well site evaluation of pressure induced changes	1. Evaluate aquifer pressure at each proposed ASR well, 1 mile distant from ASR well cluster, and at other FAS user wells. 2. Evaluate pressure changes within the Hawthorn Group at ASR well cluster.	X X	X X	X X	X
Localized transport of contaminants including heavy metals or pathogens	1. Evaluate transport of potential “bad actors” including heavy metals such as arsenic, nickel, and fluoride. 2. Evaluate conservative transport and reactive transport of pathogens.	X X	X X	X X	
Localized ASR well pump design	1. Evaluate aquifer pressure at each well and in entire well cluster.	X	X	X	X

Table 4. Additional model functionalities required.

Desired Functionality	Modflow/MT3D	SEAWAT	WASH123	SWI
Incorporate irregular geometry	X	X	X	X
Incorporate varying vertical model resolution and multiple layers	X	X	X	
Incorporate varying aquifer properties	X	X	X	X
Incorporate rainfall and recharge	X	X	X	X
Incorporate leakage between layers	X	X	X	X
Incorporate Dirichlet and Cauchy boundary types	X	X	X	X**
Incorporate constant and transient boundary conditions	X	X	X	X
Incorporate injection and recovery wells	X	X	X	X
Simulate advection, dispersion, and mixing	X	X	X	
Simulate contaminant decay or natural attenuation	X	X	X	
Simulate density-dependent flow		X	X	X

** - is capable for flow but not transport

An important consideration in any of model code is its overall credibility and suitability (van der Heijde and Kanzer, 1997). Therefore, the level at which the code has been tested is an important component in the decision-making process. Given the issues to be addressed with the ASR regional model, it is clear that groundwater hydraulics, conventional contaminant transport, and density-dependent flow concerns will all require critical contemplation. To aid in this determination, the PDT reviewed existing publications and past benchmarking cases in order to compile a list of tested problems. In addition, the PDT performed additional benchmarking against published analytical solutions. The PDT prepared several simple benchmarking tests to evaluate groundwater hydraulics and conventional contaminant transport. Both the finite-difference (MODFLOW/MT3DMS) and finite-element models (WASH123) were first tested using a series of groundwater hydraulics cases including pumping from a confined aquifer (Theis, 1935) and pumping from a leaky-confined aquifer (Hantush and Jacob, 1953). Since the ASR regional model will be simulating changes in head and flow caused by well pumping, the PDT felt this was a valuable test to evaluate. Then both predominant model types were tested using a conventional contaminant transport case (Ogata, 1970). The results of the Theis and Ogata benchmarking tests are available in figures 1 and 2. Each figure compares the numerical model results versus exact analytical solutions. Both the MODFLOW/MT3DMS and WASH123 numerical model results compare very favorably to the analytical solutions. The WASH123 code was further tested against both the “Elder problem” and the “Henry problem” with results available in Appendix A. All of these tests indicate that all of the codes tested appear to solve the governing equations accurately.

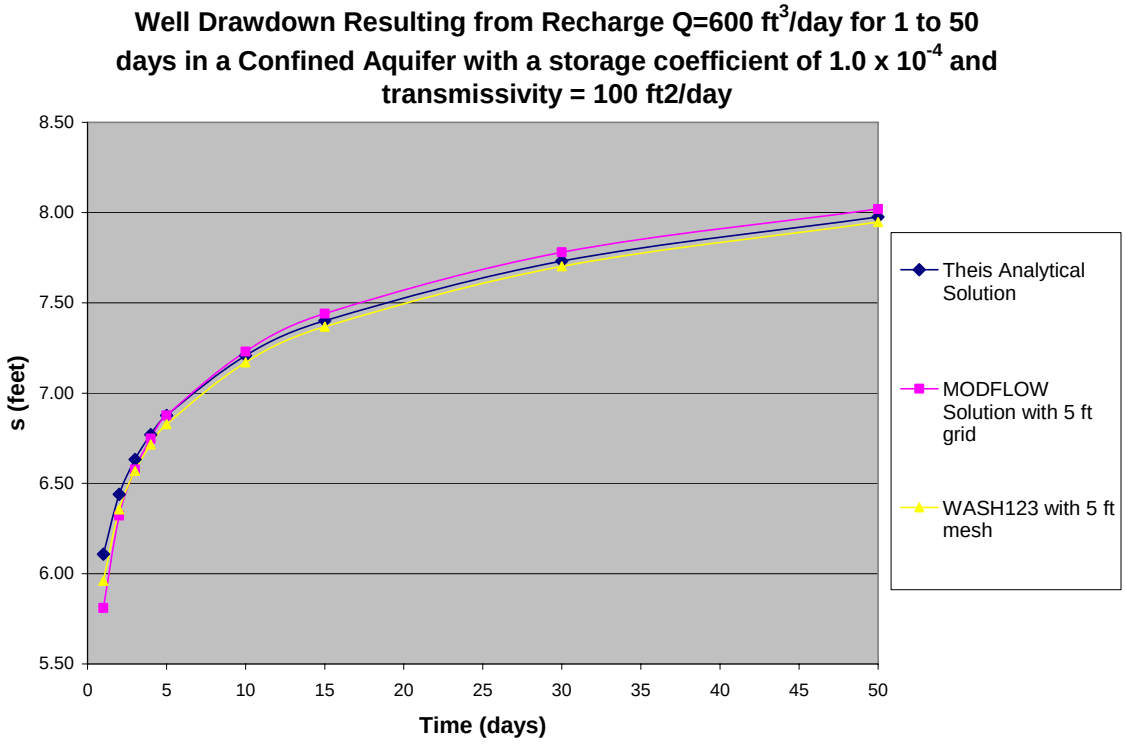

Figure 1. Theis confined aquifer benchmarking case comparing numerical model results to exact solution.

For variable-density groundwater flow, there are a suite of benchmark problems that have been designed to test the ability of a numerical code to accurately simulate the complex flow and transport dynamics associated with density dependent flow. Table 5 lists these commonly used benchmark problems and shows which codes have been tested to date. It should be noted that neither the SWI or the WASH123 codes have been tested as thoroughly as the SEAWAT code mainly due to their relatively young age. It is anticipated that both SWI and WASH123 will be tested against many of the remaining variable-density benchmark problems in the future as the codes become utilized by more users. Appendix A provides additional information on the variable-density test cases completed using WASH123.

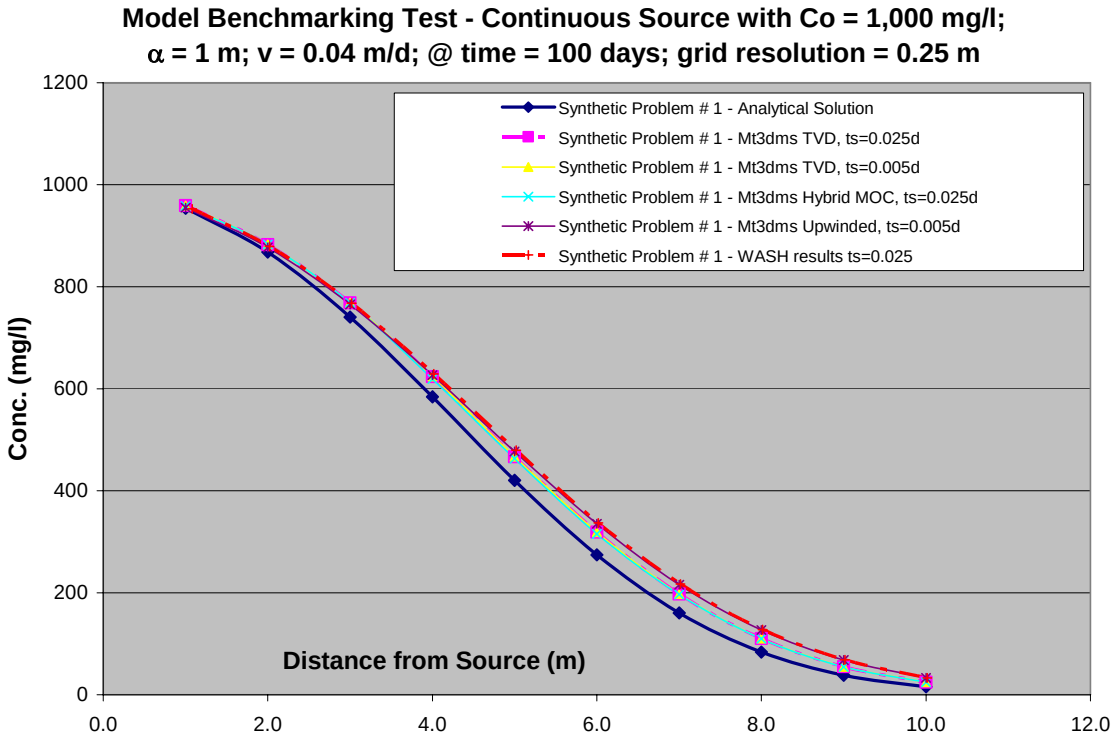

Figure 2. Ogata continuous source benchmarking case comparing numerical model results to exact solution.

Table 5. Variable-density benchmark problems.

Benchmark Problem	**SWI**	**SEAWAT**	**WASH123**
Box Problems		X	
Henry Case 1	NA	X	X
Henry Case 2	NA	X	X
Elder	NA	X	X
HYDROCOIN	NA	X	
Immiscible Fluid Rotation	X	X	
Rotating Interface	X		
Rotating Brackish Zone		X	
Upconing Beneath a Pumping Well	X		
Salt Pool 1	NA	X	
Salt Pool 10	NA	X	

NA – not applicable since SWI cannot simulate hydrodynamic dispersion

The overall performance assessment was measured through application of the various bench-scale cases completed as well as previous benchmarking work completed in support of each code. The performance assessment was measured against metrics listed previously including:

- Computational accuracy
- Reliability (convergence and stability of solution algorithms)
- Sensitivity for grid orientation, grid resolution, or time discretization
- Efficiency of coded algorithms (code execution time and memory/storage requirements)
  - Model run times were computed for all 5 ASR cases
  - Storage requirements were evaluated for all 5 ASR cases
- Resources required for model setup and analysis including
  - Pre and post processing effort
  - Computer type or hardware required
  - General ease of use for new modelers

Model Code Bench-scale Testing Results:

The four model codes were tested extensively using the five case studies outlined previously in this memorandum. Multiple contaminant transport algorithms were tested using both the existing MODFLOW/MT3DMS model and the SEAWAT model (e.g., central-difference solution and the TVD solution). WASH123 and SWI only provide one contaminant transport algorithm. Each of the codes revealed significant advantages and disadvantages. A comparison of performance metrics for each code is provided in the following sections of this memorandum. Appendix A and B of this memorandum contains additional information concerning the WASH123 results and the SEAWAT/SWI results.

Resources Required for Model Setup and Analysis

General Ease of Use

All of the model codes evaluated required significant user knowledge and experience in order to successfully utilize the model. The MODFLOW/MT3DMS, SEAWAT, and WASH123 models are all somewhat difficult to master but all three can link with readily available pre and post processors. The exception to this is the SWI code. The SWI model can be run independently but the results must be imported into a post-processor. The importation of the data requires some re-working of output files and required companion files. In general, table 6 lists the qualitative "ease of use" for each code along with pre/post processor tools utilized. In general, all of the codes rank similarly for this category.

Table 6. Model Code Ease of use.

Model Code	**Ease of Use (Easy, Moderate, or Difficult)**	**Compatible Pre and Post Processor**
MODFLOW/MT3DMS	Moderate	Groundwater Modeling System (GMS) ® Groundwater Vistas Argus Visual MODFLOW PMWIN, Modelviewer
SEAWAT	Moderate	Groundwater Vistas Argus Visual MODFLOW PMWIN, Modelviewer
WASH123	Moderate	GMS
SWI	Moderate	Argus, MATLAB

Required Time for Pre and Post Processing

All of the model codes required time for both pre and post processing of simulation results. The MODFLOW/MT3DMS, SEAWAT, and WASH123 models all link directly to relevant pre and post processing software packages. As discussed previously, the GMS and Groundwater Vistas software packages were utilized. Each software package provides an intuitive graphical user interface (GUI) that allows rapid data manipulation, formatting, and output preparation. Both software packages are widely used in the groundwater modeling community of practice. One advantage of the GMS is that it is freely available to the Corps of Engineers, its partners and its sponsors. Although the overall expense may be minor, the Groundwater Vistas, Argus, and Visual Modflow software must be purchased separately for team members to utilize effectively.

The required time for pre and post processing is probably least for the MODFLOW/MT3DMS code and greatest for the SWI code due to reformatting issues already discussed. Table 7 lists a qualitative assessment of the pre and post processing time for each code considered.

Table 7. Time for pre and post processing.

Model Code	**Pre and Post Processing Time (Low is less than 4 hours, Moderate is 4 to 8 hours, High is greater than 8 hours)**	**Pre and Post Processing Software Used**
MODFLOW/MT3DMS	Low	Groundwater Modeling System (GMS) ® Groundwater Vistas

		Argus Visual MODFLOW PMWIN
SEAWAT	Low	Groundwater Vistas Argus Visual MODFLOW PMWIN
WASH123	Moderate	GMS
SWI	Moderate	None can be used directly

Computer Type or Hardware Required

All of the model codes considered could be run on personal computer, however, when consideration is given to the proposed application (e.g., a large regional scale model), all of the models would likely require workstations to ensure computational efficiency. Since SWI does not calculate contaminant transport equations, it probably requires the least hardware demands. Obviously, for coarse resolution models, a regional model may be able to be run on a newer personal computer (2 years old or less with 2.6 GHz or faster processor and at least 1 GB of resident memory) also. Table 8 provides a comparison of required hardware.

Table 8. Computer Type/Hardware Requirements.

Model Code	**Hardware Required for small model**	**Hardware Required for regional model**
MODFLOW/MT3DMS	Personal computer	Workstation
SEAWAT	Personal computer	Workstation
WASH123	Personal computer	Workstation
SWI	Personal computer	Personal computer

Efficiency of coded algorithms (code execution time and memory/storage requirements)

Model Run Times and Storage Requirements

As part of the performance assessment of the model codes, model simulation times were measured for the various case studies. Since the models were run on different workstations with divergent processing architecture, an effort was undertaken to "normalize" the simulation times through standardized computer industry comparisons. Several independent information technology forums provide processor performance comparisons for different software applications. One of these provides the information for free at the internet site www.spec.org. Information provided at the site includes both base and peak processor speeds for different tasks. Table 9 provides a comparison of both metrics for the computer workstations utilized for the study. The exact workstation

utilized to run the SEAWAT and SWI simulations was not listed at spec.org site so an average of three similar computers was selected to be representative. Then the base processor speeds were normalized against 1,000 to provide simulation run time "factors" to be applied to the actual raw simulation times for each case.

Table 9. Workstation performance metrics from www.spec.org.

Computer	Base Floating Point Speed	Peak Floating Point Speed
Optiplex Computer, 2.66 GHz, 1GB Ram	919	927
Dell GX280 Computer, 3.60 GHz P4, 2GB Ram	1905	1916
Dell WS Computer, 3.06 GHz P4, 2GB Ram	1092	1103
Intel 3.46 GHz P4, 3GB Ram	1719	1724
AVG 3 Computers	1572	1581
XI Computer, AMD 148 Opteron Chip	1393	1490

The factors applied were 0.919 for the MODFLOW/MT3DMS models, 1.572 for the SEAWAT and SWI models, and 1.393 for the WASH123 models. In essence, the normalized run times would be reduced for the MODFLOW/MT3DMS models and increased for all of the other models. Based upon information contained on this site and an inventory of workstation hardware utilized for the ASR Benchmark study, a set of normalized simulation times were developed. Table 10 lists all of the normalized model run times for the study as well as the runtime per model calculation point. The fastest and slowest runtime per calculation point is highlighted in the table. The fastest times are highlighted in pink while the slowest times are shown in yellow. The normalized model run times were also formulated from model runs that had identical convergence criteria and similar time-step sizes. The time-step size required to ensure stability was code dependent but efforts were made to ensure the final time-step size was similar for all codes. Given the complexity of the models and domain size (County size), model run times were generally long.

Table 10. Normalized model simulation run times.

RUN 1A	Run Times (min)	Normalized Run Times	Normalized Run Time per Calculation Point
MODFLOW/MT3DMS - Upwind	217	199	1.3E-03
MODFLOW/MT3DMS - TVD	463	425	2.8E-03
SEAWAT - Upwind	55.84	88	5.8E-04
SEAWAT - TVD	3838.5	6034	4.0E-02
WASH123	330	460	4.1E-03
SWI	18.75	29	3.1E-04
RUN 1B	**Run Times (min)**	**Normalized Run Times**	**Normalized Run Time per Calculation Point**
MODFLOW/MT3DMS - Upwind	217	199	1.3E-03
MODFLOW/MT3DMS - TVD	466	428	2.8E-03
SEAWAT - Upwind	56.19	88	5.8E-04
SEAWAT - TVD	3864.95	6076	4.0E-02
WASH123	420	585	5.2E-03
SWI	15.27	24	2.5E-04

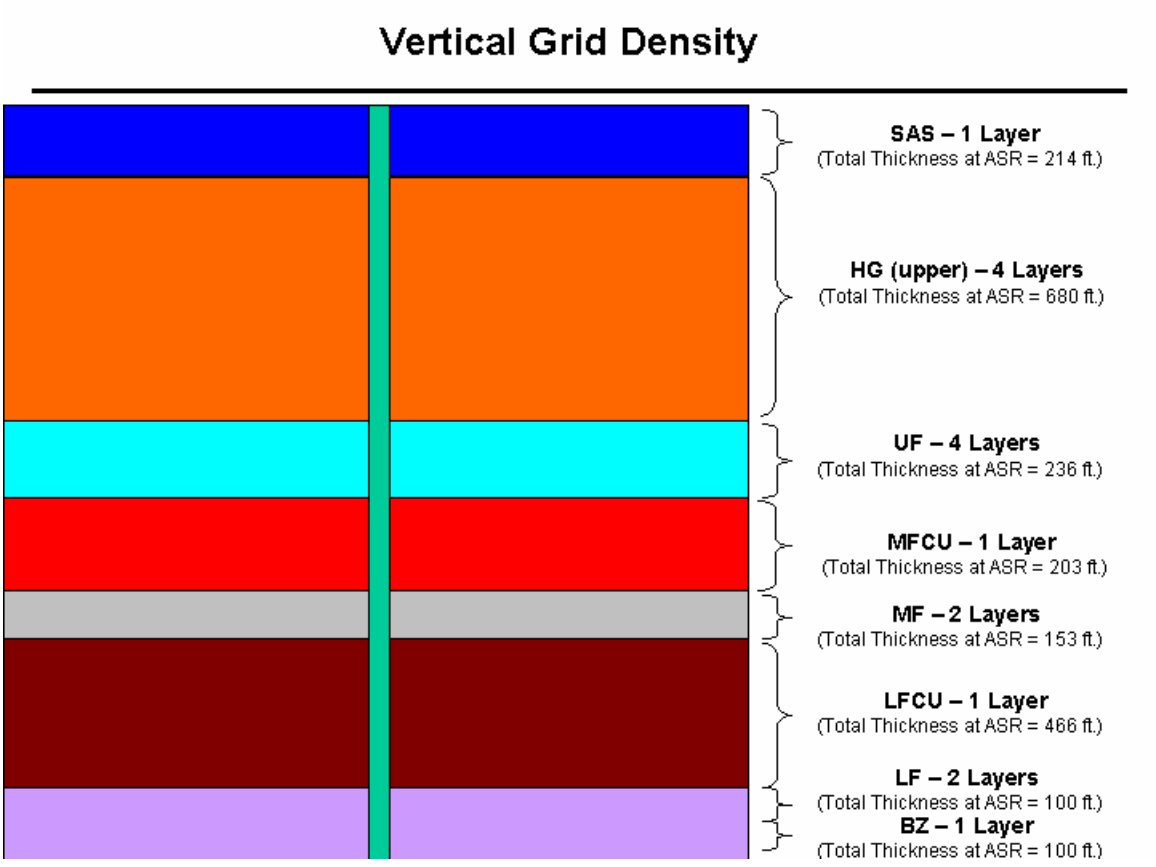
WASH123	329	458	4.1E-03
RUN 2A	**Run Times (min)**	**Normalized Run Times**	**Normalized Run Time per Calculation Point**
SEAWAT - Upwind	767	1206	8.0E-03
SEAWAT - TVD	11171	17561	1.2E-01
WASH123	522	727	6.5E-03
SWI	11	15	1.6E-04

Generally, the SEAWAT TVD solution resulted in the longest normalized simulation times while the SWI resulted in the shortest. The TVD solution scheme in MT3D (and thus SEAWAT) required unreasonably short transport time step lengths for an accurate solution. Due to project time constraints, no attempt was made to resolve the issue, but it is possible that the issue could be fixed, in which case, the runtimes could reduced. Since both finite-difference models (MODFLOW/MT3DMS, SEAWAT, and SWI) and finite-element (WASH123) models were utilized in the study, further examination of the run time per calculation point is important. The WASH123 model had 112,716 calculation points versus 151,000 for the other models tested. A key difference to be noted is that the WASH123 model provided greater vertical resolution (30 layers) but varying horizontal resolution as compared to the other finite-difference models (16 vertical layers). When considering the horizontal resolution of the two model types, the WASH123 model resulted in fewer computational points than the comparable finite-difference model due to the flexible mesh design advantage that is inherent in finite-element formulations. This may be an important consideration in the design of the regional model. Figure 3 depicts the finite-difference model vertical resolution while Figure 4 depicts the comparable finite-element model vertical resolution.

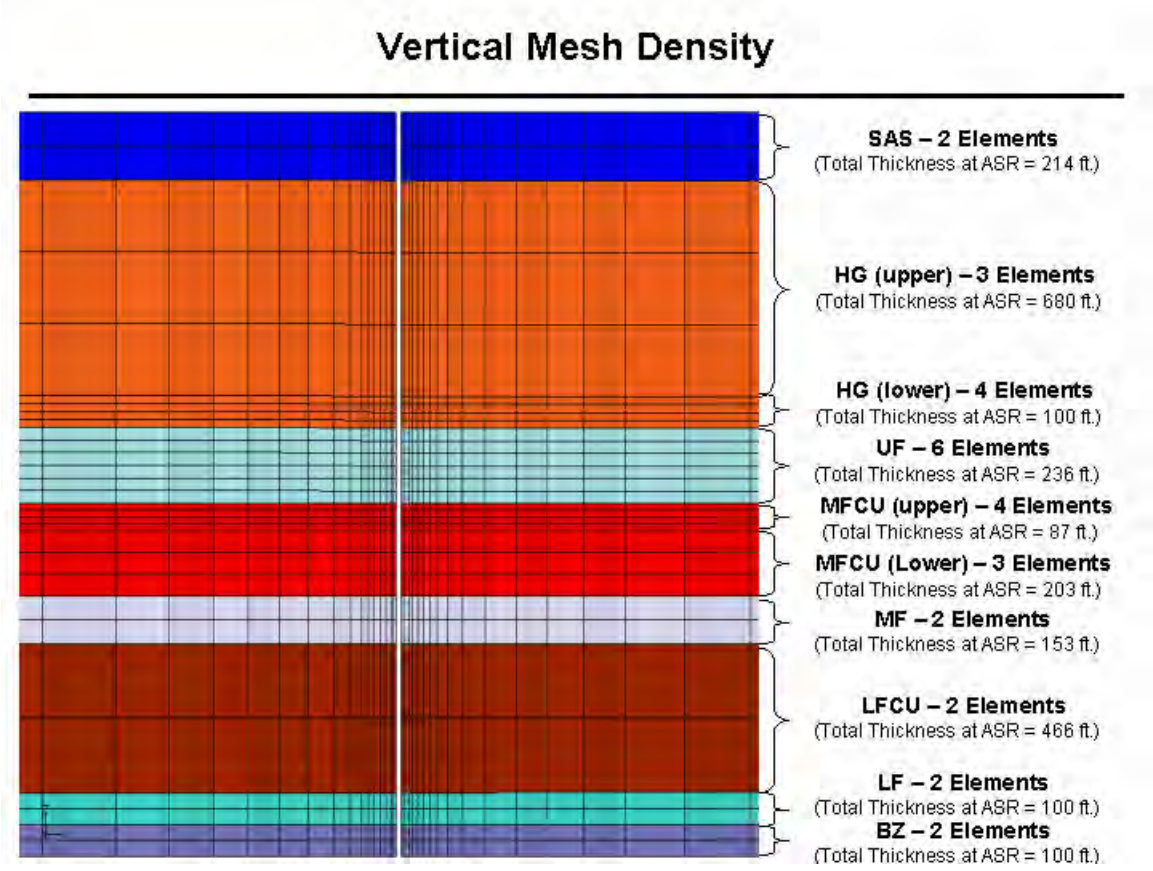
Figure 3. Finite-difference model vertical resolution.



For all of the models, storage requirements were moderate and highly dependent upon model resolution, time-step size, and outputs designated. In general, large capacity hard

drives available on personal computers and work stations should be sufficient to handle requirements of the regional model development.

Figure 4. Finite-element model vertical resolution.



Time and resource constraints did not allow a systematic evaluation of each code's dependence upon grid resolution or time discretization to ensure accuracy. The time discretization was evaluated in a gross sense in order to minimize model run times, however, only minimal checks were completed to determine the effect on model accuracy. As the various case studies were completed, it was also determined that the vertical discretization of the model was very important for both the model stability and accuracy. This was especially true around the ASR wells where steep velocity gradients led to model oscillations and instability in some instances. Future ASR modeling efforts should carefully consider vertical discretization-related accuracy and stability issues.

Comparison of Simulation Results for Computational Accuracy and Reliability

Model simulation output from the four model codes was then compared to determine differences in numerical error, relative accuracy, stability, and flexibility. As the ASR cases were hypothetical, an examination of the actual accuracy of each model code was

not possible. However, an assumption was made that the SEAWAT TVD solution was the most accurate based upon past analysis and publications noted in the literature. Limited accuracy assessments as compared to known analytical solutions were also completed and discussed earlier in this report. Table 11 lists a qualitative assessment of the stability of each model code based upon all model results. None of the codes experienced major convergence problems but three of the model codes did experience some minor oscillations. It should be noted that the oscillations were most likely attributed to insufficient horizontal and vertical model resolution. Therefore, it is expected that the oscillations could be minimized or eliminated through more judicious model design.

Table 11. Stability Assessment.

Model Code	**Stability Assessment** Score A – No stability issues Score B – Minor Oscillations Score C – Did not converge
MODFLOW/MT3DMS – Upwinded	A
MODFLOW/TM3DMS – TVD	B
SEAWAT – Upwinded	A
SEAWAT – TVD	B
WASH123	A
SWI	B

The overall relative accuracy assessment is presented for each case and discussed in turn.

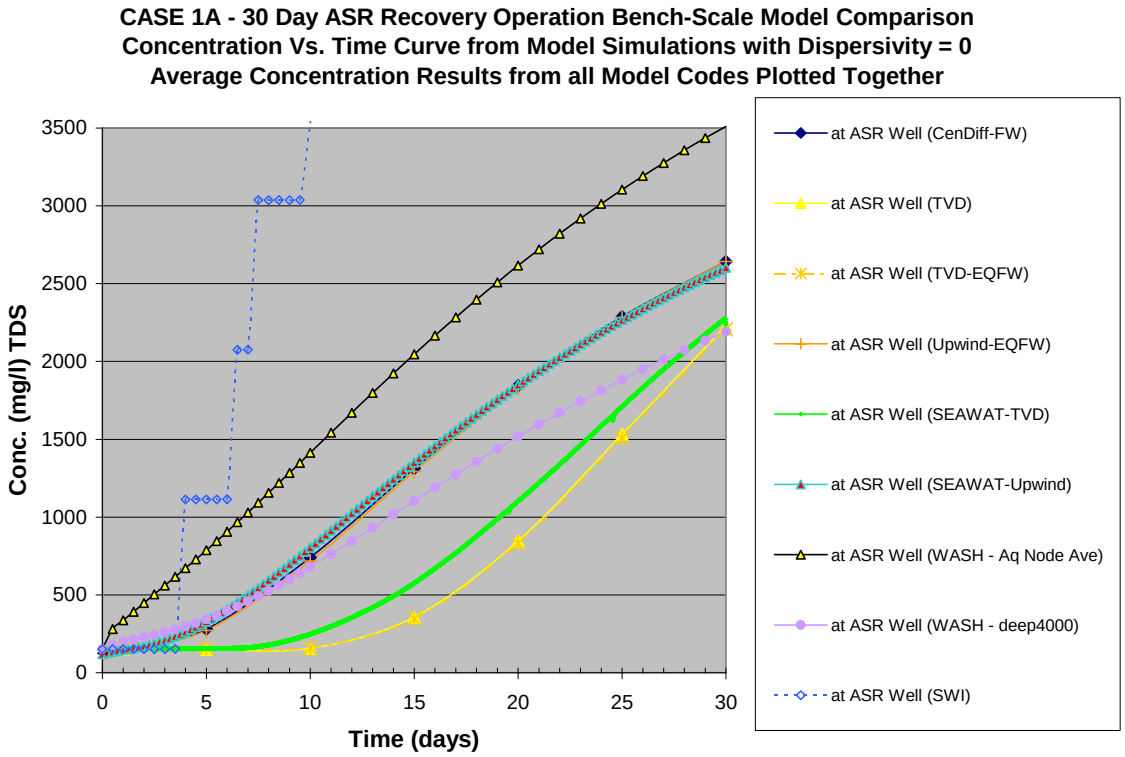
For Case 1A, comparisons were made at the ASR well and at different radii from the ASR well. Figure 5 depicts results from the different codes for concentrations versus time estimates during the 30-day ASR recovery period. It should be noted that the recovery curves represent average concentrations at the ASR well location.

For all of the ensuing figures, a naming convention is employed for each of the various model runs, model codes, and contaminant transport solution algorithms. The primary names are listed as follows:

- CenDiff-FW is a MODFLOW/MT3DMS simulation using the Central difference weighting algorithm
- TVD is a MODFLOW/MT3DMS simulation using the total variation diminishing scheme
- EQFW or FW are simulations using “equivalent freshwater heads” on the model boundaries rather than simulating true density-dependent flow
- SEAWAT-TVD are simulations using SEAWAT with the TVD scheme
- SEAWAT-Upwind are simulations using SEAWAT with the upwinded backward difference weighting algorithm
- WASH-Aq Node Ave are simulations using WASH123 and averaging the concentrations of the model aquifer nodes

- WASH-deep4000 are simulations using WASH123 and modifying the confining unit initial condition concentrations to mimic calculations performed by MT3DMS

Figure 5. Model simulation results for Case 1A at the ASR well.



In examining the simulation results at the ASR well, it is apparent that the model codes, along with the various contaminant transport algorithms, result in a wide variation of concentration versus time predictions. During a real ASR recovery event, the recovery would be ceased once the TDS concentration exceeded a threshold value of 500 mg/l. In reviewing the simulation results, the number of days of recovery before exceeding 500 mg/l can be readily observed.

For the MODFLOW/MT3DMS solutions, two general results are observed. First, solutions using the TVD algorithm (using either uncorrected heads or density corrected/EQFW heads) predict that 500 mg/l level would be exceeded after 17 days. Using the central-difference or upwinding algorithms result in exceedance after 7 days. Since a dispersivity value of zero was utilized for Case 1A, the main difference between the TVD solution and the other finite-difference solutions is suspected to result from truncation error or so-called “numerical dispersion”. This finding is consistent with previous work completed by Merritt (1986; 1993). Merritt found that the predicted amount of freshwater recovered from an ASR well is sensitive to the contaminant transport solution selected for the simulation. In addition, Merrit (1993) noted that the

estimate of freshwater recovered is somewhat sensitive to vertical model resolution and the algorithm utilized to simulate vertical flow and dispersion. For ASR simulations involving large concentrated injection and recovery rates, the apparent degree of dispersion would also be greatly dependent upon local flow velocities.

For the two SEAWAT solutions, a similar pattern emerged. The TVD solution predicted that the 500 mg/l water quality threshold would be exceeded after approximately 14 days, whereas the upwinded solution predicted exceedance after 7 days. Since SEAWAT is a finite-difference model with the same geometry as the MODFLOW/MT3DMS model, the differences between the two solutions are also caused by numerical error. Another interesting finding is that the comparable upwinded solutions between non-density model and the density-dependent SEAWAT model are almost identical, suggesting that the numerical dispersion issues mask the density related differences. When a similar comparison is completed for the constant-density TVD solution versus the density-dependent SEAWAT TVD solution, there is a notable difference of 3 less days of ASR recovery for the SEAWAT TVD solution probably due to buoyancy stratification effects. This finding reveals that density stratification during the 305 day ASR storage period does marginally affect the predicted results. It would be expected that longer storage periods would result in additional stratification effects that would further reduce the amount of freshwater that would be recovered.

The WASH123 results also show variation between two different model simulations. The first simulation (WASH – Aq node avg) predicts that the water quality threshold of 500 mg/l would be exceeded after 2.5 days. The second simulation (WASH- deep4000) predicts an exceedance of the threshold after approximately 8 days. The only difference between these solutions is the assignment of the starting concentrations within the Middle Floridan Confining Unit (MFCU). The first simulation includes an assignment of 35,000 for all nodes within the MFCU, while the second simulation includes an assignment of 4,000 mg/l for upper nodes and 35,000 mg/l for lower nodes. The second simulation is thought to be equivalent to the finite-difference runs since the starting concentration for those runs is assigned at the cell center rather than at the cell edge. Further review of the second simulation (WASH – deep4000) still reveals that the concentration versus time curve is generally between the finite-difference upwinded and TVD solutions. It is likely that the WASH123 results are also subject to numerical dispersion. Woods (2004) noted similar numerical dispersion problems with the finite-element model SUTRA (Voss and Provost, 2002). Future improvements to WASH123 will utilize the “local zooming and peak-valley capturing algorithm as outlined by Cheng et al. (1998). These improvements should further minimize numerical errors.

The SWI result shows major differences as compared to the other model simulation results. The SWI simulation predicts that the water quality threshold of 500 mg/l would be exceeded after 4 days. Also, the slope of the concentration versus time curve is much steeper than any other simulation result. Since the SWI code was originally designed for regional sea water intrusion issues, this result is not surprising. Since the SWI code was designed based upon an interface approach, it was not designed to simulate dispersion.

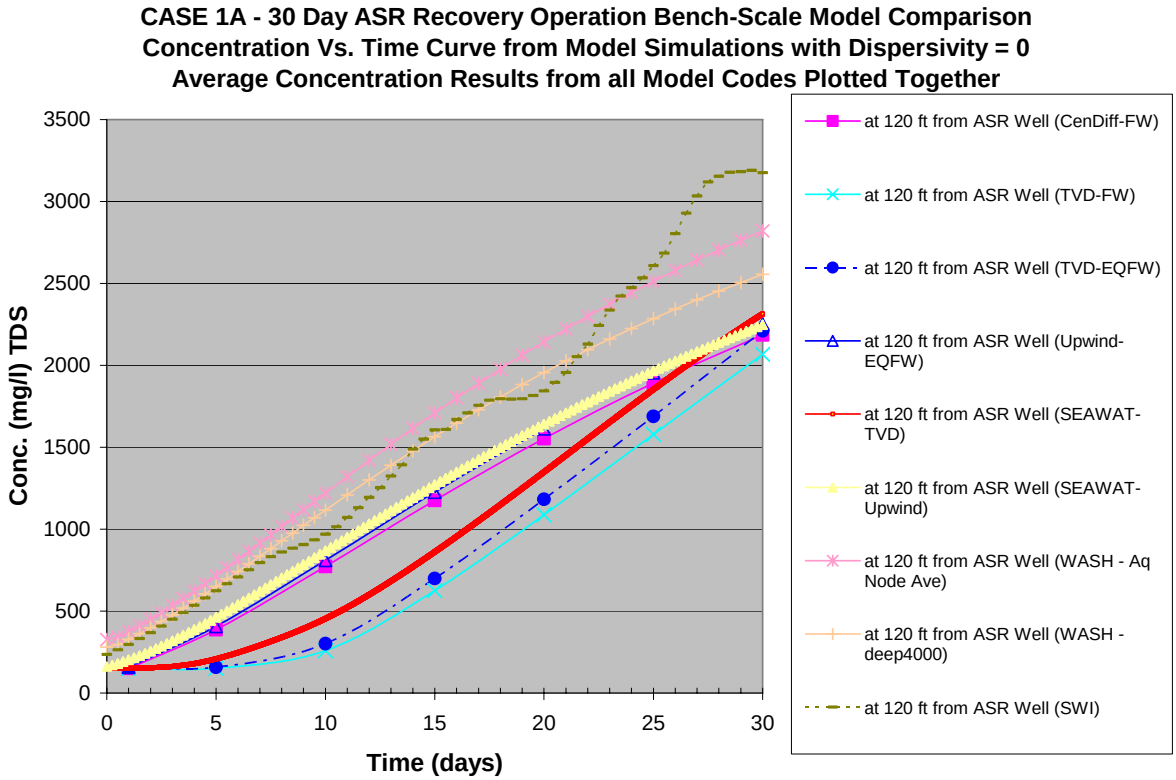
Therefore, it is unclear if the SWI results are the "most accurate" or if the Dupuit approach implemented in SWI is resulting in unrealistic concentration increases.

Since no known ASR analytical solutions were available, a full accuracy assessment of the Case 1A results is not possible. The results clearly do show that the four codes predict a wide range of concentration estimates. It is theorized that the code results would converge and be more similar if the following improvements were incorporated:

- Additional horizontal resolution around the ASR well
- Additional vertical resolution within the storage zone and below the storage zone
- Lower well pumping rates would reduce the steep vertical gradients at the ASR well minimizing errors associated with the velocity field

Similar data plots were produced for a theoretical monitoring well approximately 120 feet distant from the ASR well. Figure 6 displays the simulation results from the various model codes and contaminant transport solutions during the 30-day ASR recovery period. At this radius (near the edge of the freshwater bubble), the effects of buoyancy stratification are probably more pronounced such that the differences among the various codes is likely due to a combination of numerical dispersion and the degree of buoyancy stratification predicted by the code.

Figure 6. Model simulation results for Case 1A at monitoring well 120 feet away.



Generally, the simulation results can be subdivided into three groups. The TVD results from the MODFLOW/MT3DMS and SEAWAT models predict lower TDS concentrations over the first 15 days of ASR recovery as compared to the other model simulations. The WASH123 and the SWI model codes predict the highest TDS concentrations over the first 15 days of ASR recovery. The central-difference and upwinded solutions fall between the TVD and WASH123/SWI results. The "spread" of model results is less pronounced than at the ASR well as presented in figure 5. This also suggests that errors associated with the velocity field and the model resolution are larger at the pumping well location than 120 feet distant. Since dispersivities were assigned a value of zero, model stability was also an important issue. Some oscillations were seen in the results of all model codes with the exception of the WASH123 code and finite-difference upwinded solutions as discussed previously. Some of these are evident in the SWI results.

For Case 1B, comparisons were made at the ASR well and at different radii from the ASR well. Since Case 1B assigns a seawater TDS concentration in the ASR storage zone, more significant density effects were noted. Figure 7 depicts results from the different codes for concentrations versus time estimates during the entire 30-day ASR recovery period. Figure 8 depicts results from the different codes for concentrations versus time estimates during the entire 365-day ASR simulation period, including recharge for 30 days, storage for 305 days, and recovery for 30 days. It should be noted that the concentration curves represent average concentrations at the ASR well location for Figure 7, while discrete model layers are depicted in Figure 8.

Figure 7. Model simulation results at ASR well for Case 1B during ASR recovery period.

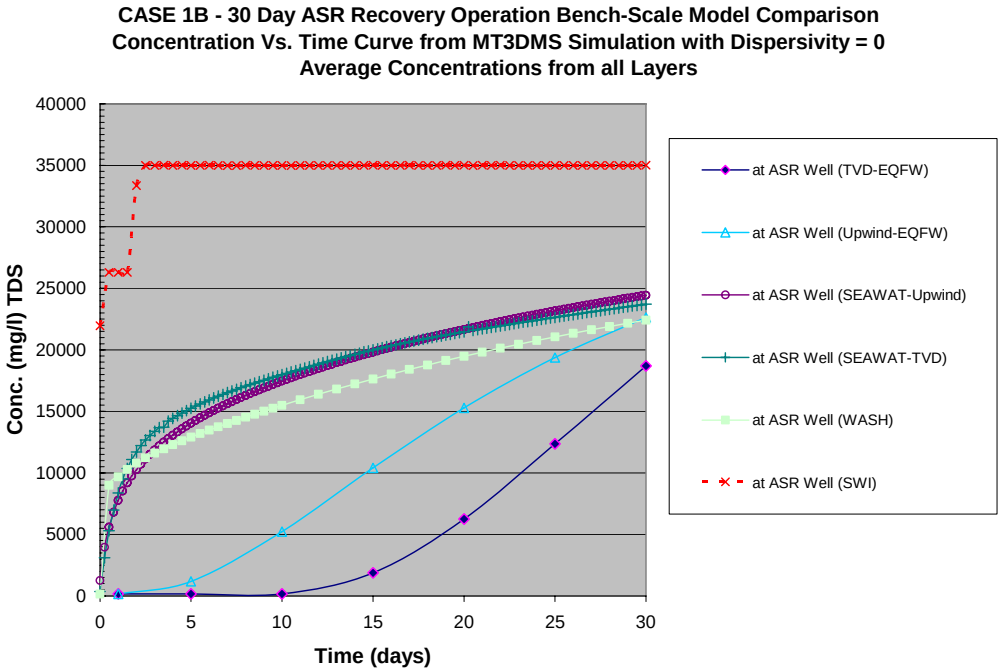


Figure 8. Model simulation results at ASR well for Case 1B during entire simulation period.

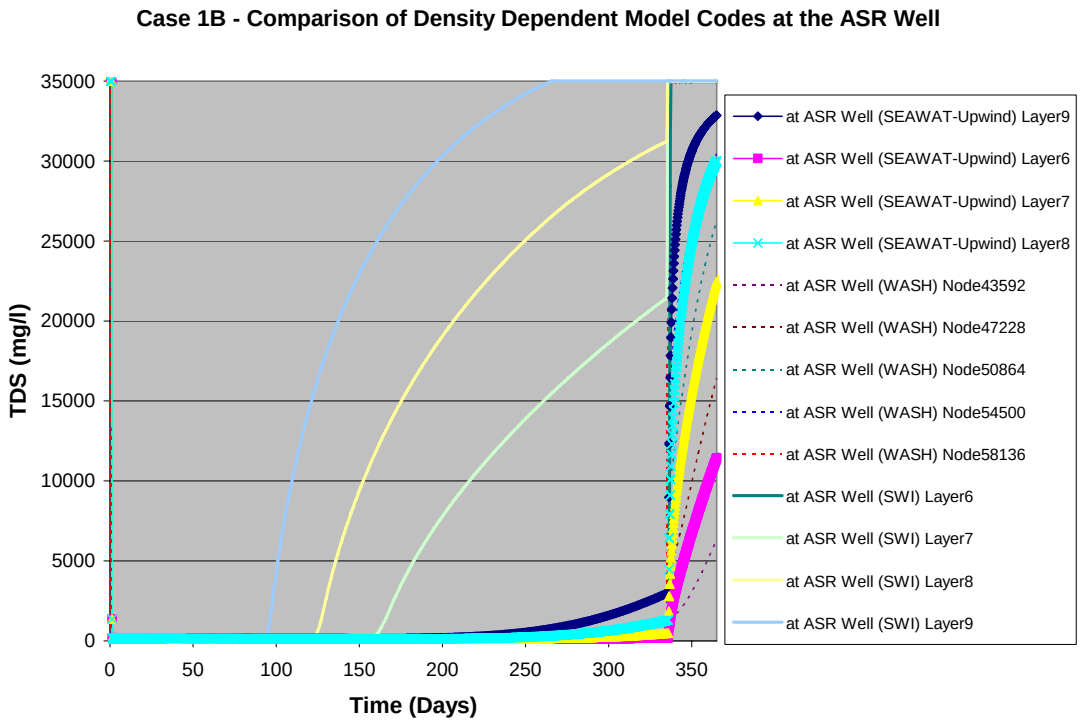

In reviewing Figure 7, it is evident that the results vary widely between the different codes. First, the non-density dependent simulations greatly underestimate the TDS concentration at the ASR well as compared to the other model codes. Both of the SEAWAT solutions and the WASH123 solution exhibit similar concentration versus time curves. The SWI results seem to overestimate the TDS concentrations at the ASR well location. The SWI code was originally designed for implementation at coastal boundaries, therefore the results may be misleading. Since the SWI code was not designed to model concentration changes around active pumping wells, it may not be the best tool for evaluating changes around the ASR well.

For Figure 8, only the density dependent capable model codes were investigated. Figure 8 clearly depicts large differences between the SEAWAT/WASH123 results versus the SWI results. Both SEAWAT and WASH123 predict moderate buoyancy stratification during the 305-day storage period as compared to the major buoyancy stratification predicted by SWI. In general, at the ASR well, the results predicted by SEAWAT and WASH123 are very similar. Both codes clearly demonstrate the capability to evaluate changes in water quality due to density stratification effects. Figure 9 depicts the results at a theoretical monitoring well located approximately 120 feet distant from the ASR well.

Figure 9. Model simulation results at 120 feet distant from the ASR well for Case 1B during entire simulation period.

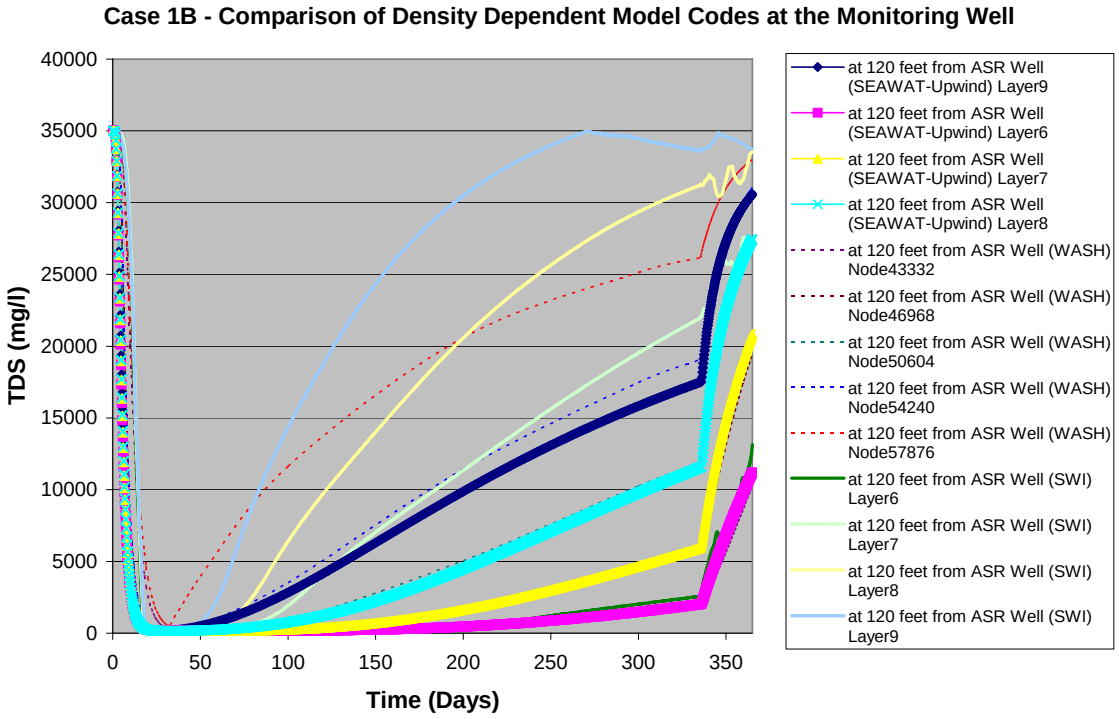

Figure 9 reveals that at the monitoring well located 120 feet from the ASR well, the SWI simulation predicts a higher degree of density stratification than the comparable SEAWAT TVD solution. The WASH123 results tend to fall in the middle of the SWI and SEAWAT results. During the 30-day recovery period, both the SEAWAT and WASH123 results exhibit similar shaped recovery curves as compared to the SWI simulation that appears to have some minor oscillations during the recovery duration. Figures 10 to 16 depict spatial concentration differences between the SEAWAT and WASH123 results for selected time steps during the one-year simulation period. The contour maps were developed from three sets of model output for the center of the aquifer storage zone. Each set of model output data was then contoured to a new two-dimensional mesh using an "inverse distance weighted" algorithm. The contouring resulted in minor oscillations in each dataset but did not inhibit the overall comparison of the results. The contour maps compare the spatial concentration differences at the middle of the ASR storage zone. The figures clearly show that both the finite-difference (upwinded or central difference) and WASH123 solutions are subject to moderate to high numerical dispersion and possibly more significant density stratification. WASH123 appears to have the highest numerical error with the upwinded solution exhibiting moderate to high error while the TVD solution had the smallest error. The SWI code was not included in this comparison since it does not have the capability to model hydrodynamic dispersion. It should also be noted that the finite-difference and WASH123 solutions are similar at day 365 as shown on Figures 15 and 16. The finite-difference and WASH123 results at day 365 both have a similar concentration gradient or

radius where seawater concentrations have been lowered at least 500 mg/l. The comparable radius for the TVD solution is much smaller. One notable difference is that the WASH123 solution displays more concentric contours, although curiously the circles are not centered on the ASR well, while the finite-difference results are heavily influenced by the grid resolution and bias. However, the WASH123 results also appear to be heavily influenced by mesh effects. As was mentioned previously, each of the models could have been improved through the incorporation of additional horizontal and vertical resolution around the ASR well.

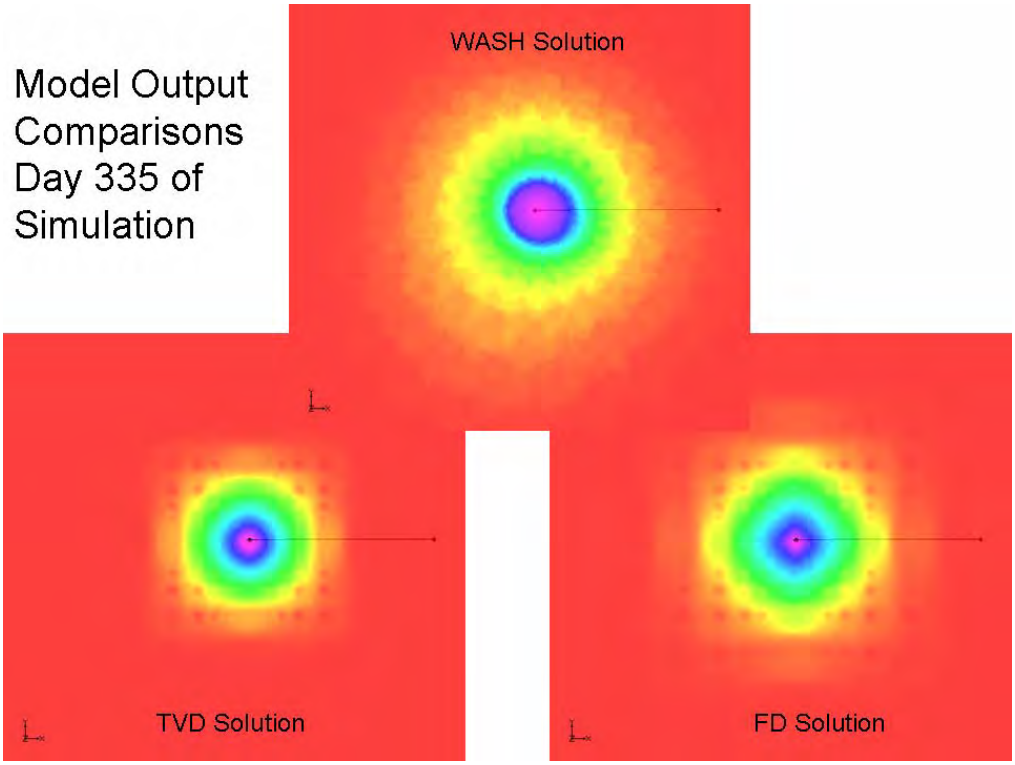

Figure 14. Comparison of simulation results for Day 350.

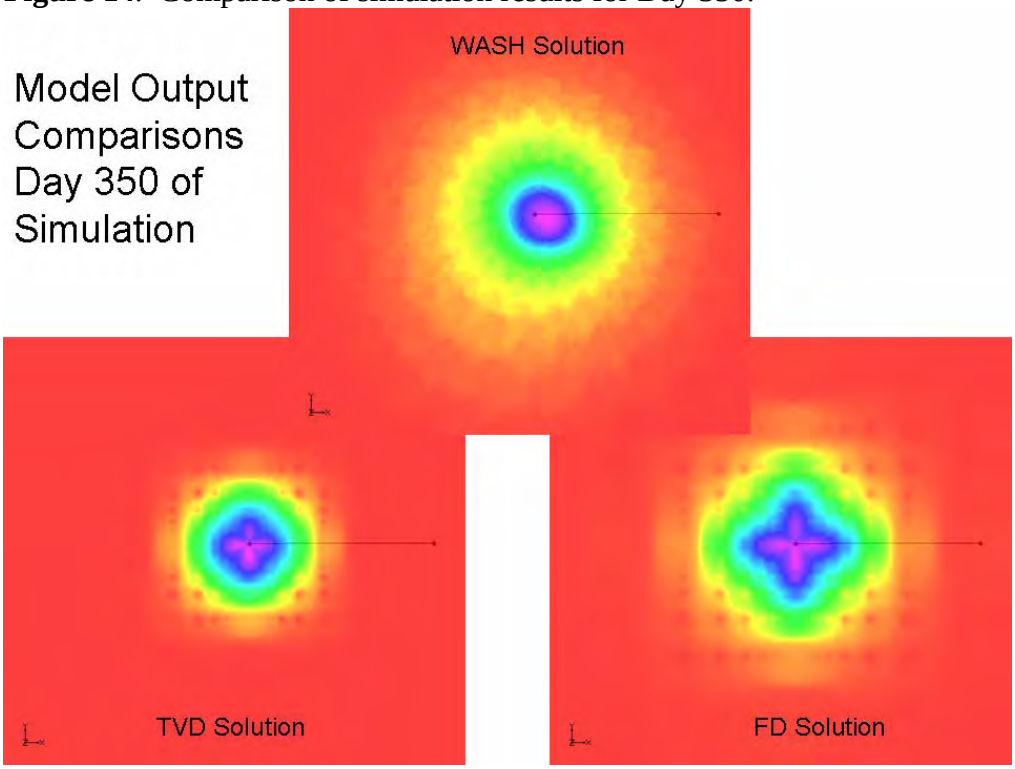

Figure 15. Comparison of simulation results for Day 365.

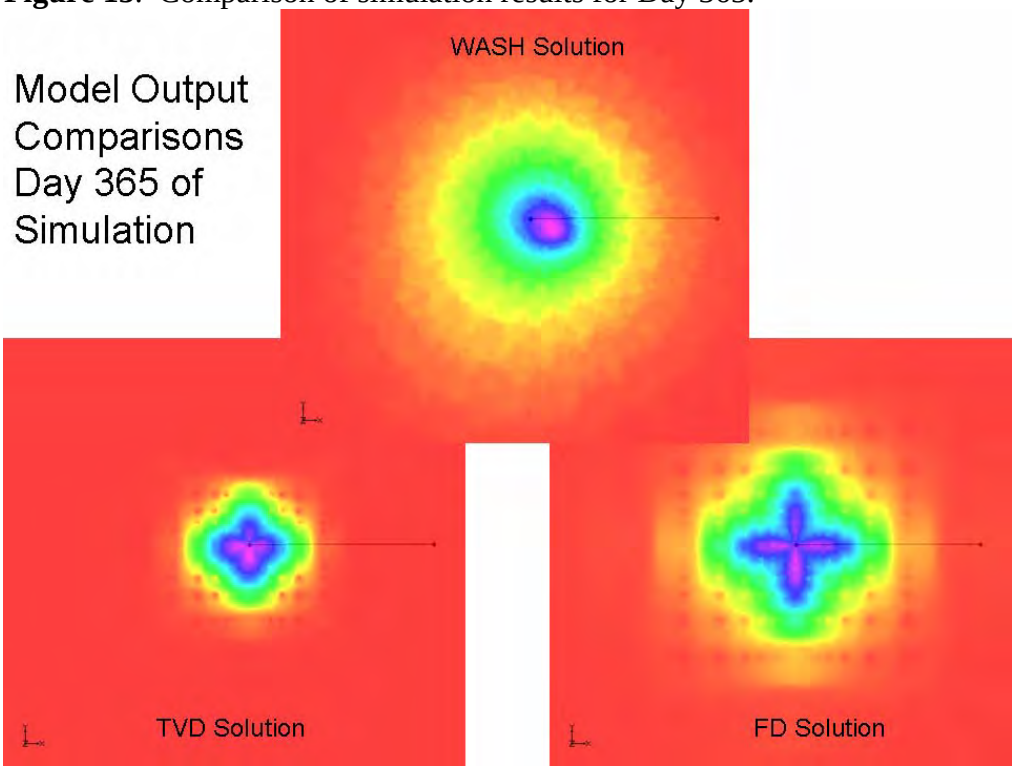

Figure 16. Comparison of simulation results for Day 365 with radius marker.

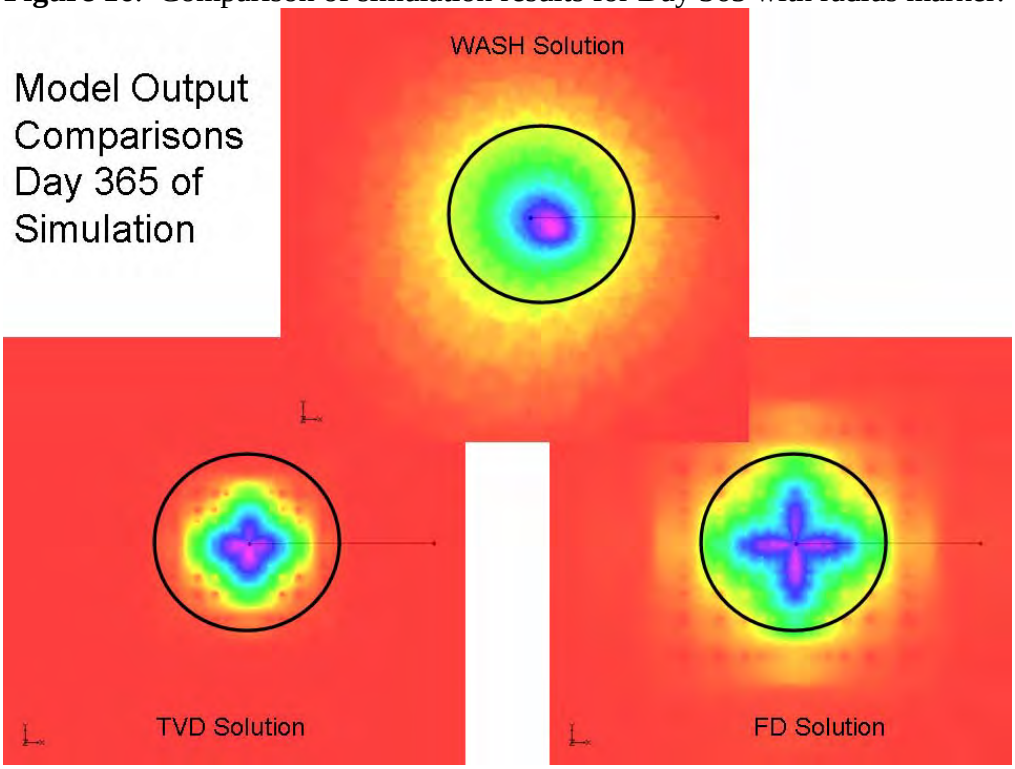
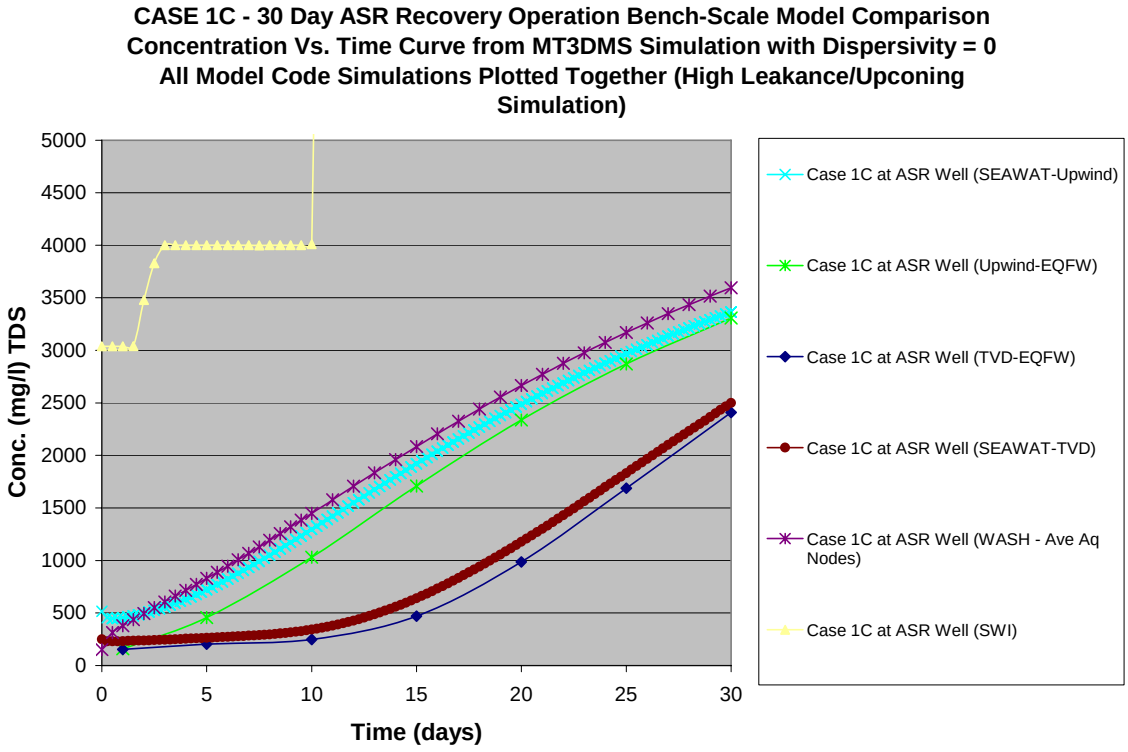


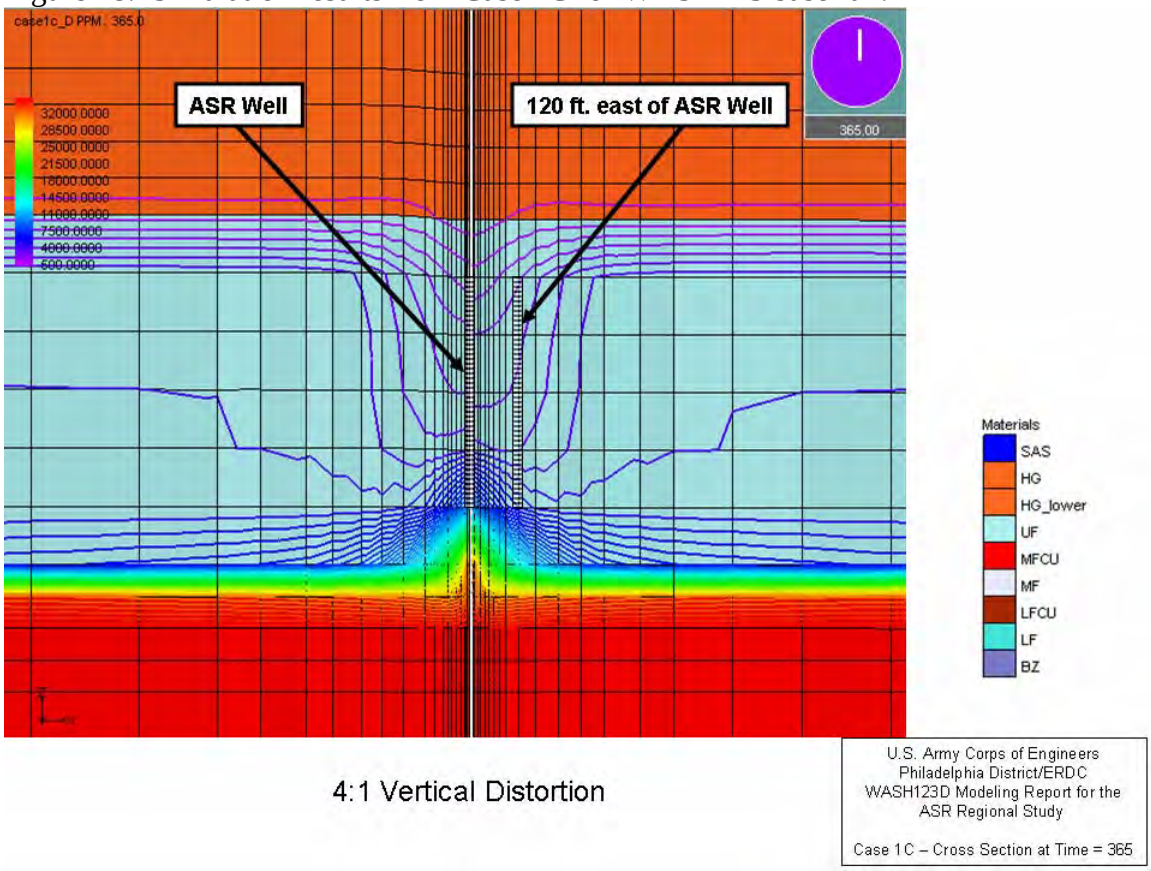
For Case 1C, the model simulation results were similar to those of Case 1A except that density-dependent upconing was encouraged to occur within the models due to assignment of much higher hydraulic conductivity within the MFCU as compared to the assignment for Case 1A. Figure 17 depicts the simulation results for the various model codes and contaminant transport solutions for Case 1C at the ASR well during the 30-day recovery period.

Figure 17. Simulation results for Case 1C at the ASR well during the recovery period.



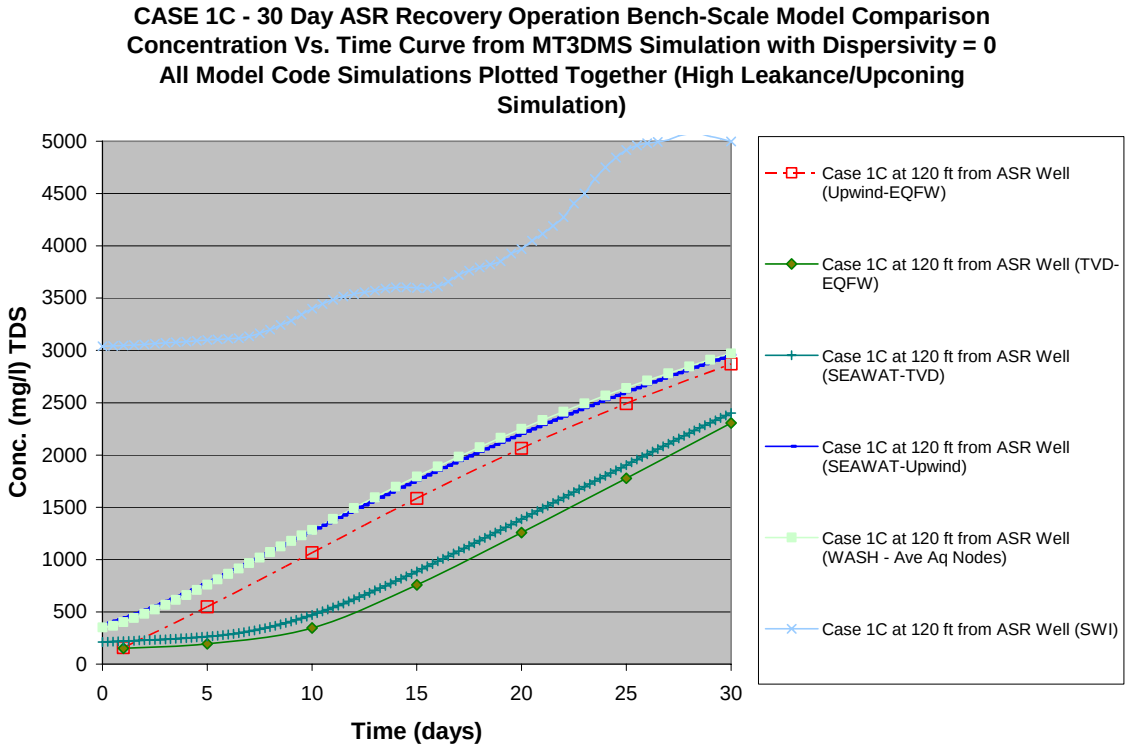
The results reveal three distinct groups of data. The SWI results clearly show predicted TDS concentrations that are considerably higher than the other codes. The TVD results from both the MODFLOW/MT3DMS and SEAWAT models predict the lowest TDS concentrations. The MODFLOW/MT3DMS and SEAWAT upwinded results and the WASH123 results fall between the TVD and the SWI results. It should be noted that the WASH123 results depict saltwater upconing more clearly than the other codes. The WASH123 results for Case 1C are shown on Figure 18.

Figure 18. Simulation results from Case 1C for WASH123 base run.



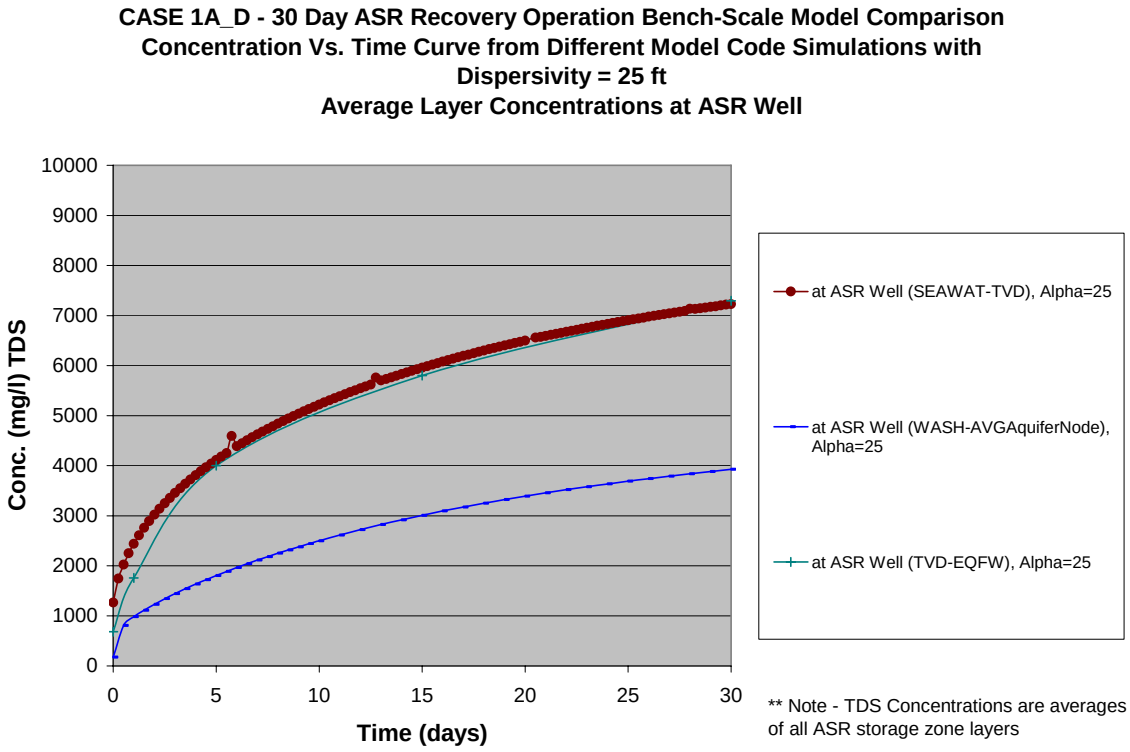
Although not completed for the study, an additional WASH123 run optimizing the boundary assignment of the MFCU (similar to WASH deep4000 for Case 1A) may have resulted in lower predicted TDS concentrations and less severe upconing. Figure 19 depicts similar model simulation comparisons for a theoretical monitoring well located 120 feet distant from the ASR well. The same three distinct data groups are visible.

Figure 19. Simulation results for Case 1C at 120 feet from the ASR well during the recovery period.



For Case 1D, the results were similar to Case 1A except that real dispersion was simulated through the assignment of 25 feet for the longitudinal dispersivity and transverse dispersivity. For Case 1D only the MODFLOW/MT3DMS, SEAWAT and WASH123 codes were compared since SWI does simulate hydrodynamic dispersion. Figure 19 depicts the results of the three comparisons. The MODFLOW/MT3DMS and SEAWAT results are very similar and predict higher TDS concentrations than the WASH123 simulation results. All three model codes predict TDS concentrations to quickly elapse the 500 mg/l regulatory limit following the long 305 day storage period. The MODFLOW/MT3DMS and SEAWAT results also predict concentrations at the ASR well in excess of 4,000 mg/l suggesting either upconing or significant numerical error.

Figure 19. Simulation results for Case 1D at the ASR well during the recovery period.



For Case 2A, the results for the SEAWAT, SWI, and WASH123 codes are all very similar. All three codes appear capable of handling any salt-water intrusion issues that may need to be simulated in the future as part of the ASR Regional Model.

Conclusions and Recommendations:

This benchscale study was developed to evaluate the potential for various model codes to provide answers to issues confronting the ASR Regional Study team. The benchscale study was developed and carried out by an interagency PDT. During the conduct of the study, problems and difficulties were encountered that limited the value of the study to address all goals outlined in the original plan. In general, the main problem was that the test models should have contained more horizontal and vertical model resolution to adequately simulate the cases selected. In addition, one or more benchmark problems with known solutions should have been thoroughly evaluated as part of this study to better ascertain the accuracy limitations of the various codes. An unfortunate consequence of the present work is that there really is no way to tell which code or solution mechanism provides the most accurate result. These shortcomings have been acknowledged and discussed in this report. However, even with the shortcomings identified, the study is valuable. The study also clearly indicated that the important issues

to be addressed for the ASR Regional Study represent three different scales of problem. Therefore, ultimately, three different model scales will be required to address them.

This benchscale study was useful in comparing four different model codes under consideration for use in development of a regional ASR model. The four codes tested represented a reasonable range of code options available and were selected based upon PDT members overall familiarity with the codes. Other codes such as SUTRA and FEFLOW were also considered but rejected. SUTRA has been used for past ASR simulation studies so that some of its advantages and disadvantages were already known. FEFLOW is a proprietary code from Europe that would have been difficult to procure for U.S. Government work efforts. Each code exhibited both strengths and weaknesses. All of the codes provide much of the model functionality desired for the ASR Regional Study team with the SEAWAT and WASH123 codes providing the best overall functionality. All of the codes were determined to be easy to moderately difficult to use, while all codes with the exception of SWI probably require workstation class computers to efficiently develop and calibrate a large regional model. Effective pre and post-processors can be utilized directly by all model codes with the exception of SWI.

A few notable lessons learned can be gleaned from the completed work efforts including the following:

- Where ASR wells with large injection or recovery rates are to be modeled, additional horizontal and vertical model resolution is necessary
- The combination of steep head gradients and sharp concentration fronts present very challenging model simulations
- Comparing code results to known published solutions is recommended even though no “ASR solutions” are currently available
- The initial goal to compare four identical models was a worthy one but ultimately difficult due to different stability requirements for the four codes

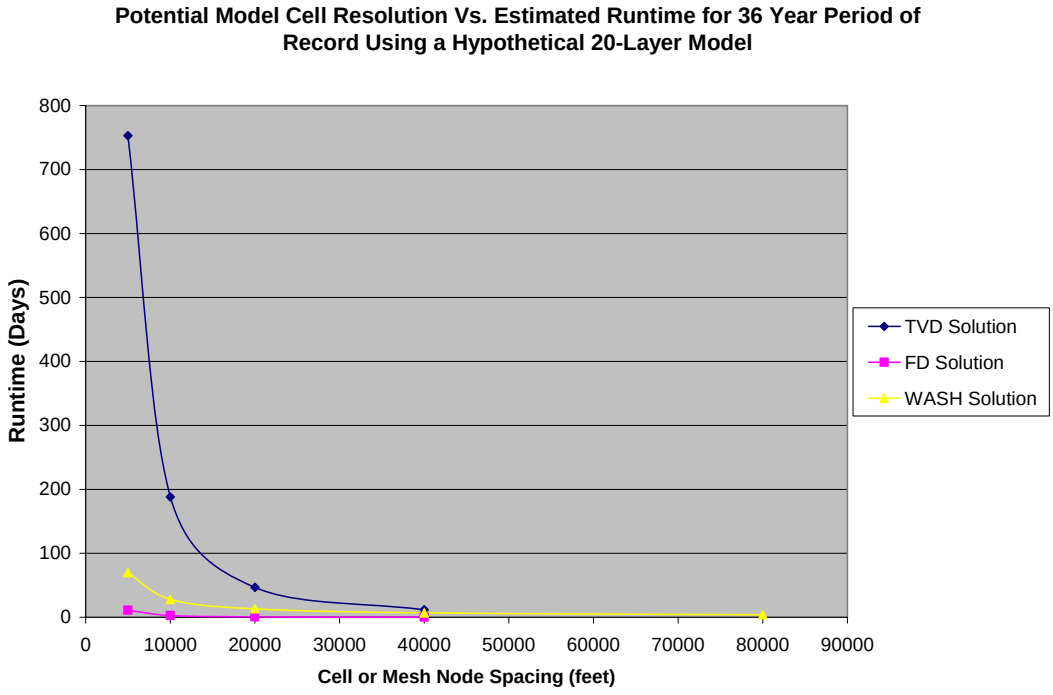
Overall the SWI code had the shortest run times while the SEAWAT (with TVD solution) had the longest run times. The SEAWAT (with upwinded finite-difference solution) and WASH123 fell in between. In general, based upon the results of the benchscale studies, the SEAWAT TVD code is approximately 7 times slower than the WASH123 code and the WASH123 code is approximately 10 times slower than the SEAWAT Upwind code. Due to geometry advantages inherent in finite-element codes, a model designed with WASH123 could have less calculation points than a comparable finite-difference code. Therefore, the run time difference between the SEAWAT Upwind and WASH123 would be reduced considerably. Based upon the results of the benchscale modeling, model run times were extrapolated for identical hypothetical models with 100,000 calculation points using either SEAWAT or WASH123. Run time estimates were calculated for 1 year transient simulations and 36 year transient simulations (similar to CERP modeling period). These are presented in Table 12. It should be noted that the predicted run-times for the SEAWAT TVD solution could be reduced if time step size could be increased. A code improvement of the TVD solution, allowing for larger step sizes, may be feasible in the future.

Table 12. Hypothetical Model Run Times for the ASR Regional Study.

Model Code	Projected Run Time for 1 Year Simulation (Days)	Projected Run Time for 36 Year Simulation (Days)
SEAWAT TVD	2.84	102
WASH123	0.41	14
SEAWAT Upwind	0.04	1.4

The SWI code is approximately twice as fast as the SEAWAT Upwind code but the SWI code does not have a capability to simulate hydrodynamic dispersion, a key ASR performance consideration for the CERP. The SWI code does appear useful for quick evaluations of possible salt-water intrusion episodes caused by ASR recovery. It may also be useful as a screening model tool. If the SWI code is eliminated from consideration, the WASH123 or SEAWAT codes would be the best candidates for use in the ASR Regional Model study. Based upon the results of the benchscale tests completed, a further analysis of potential run times for the ASR Regional Model were prepared assuming the domain would cover approximately 34,000 square miles and the model would contain 20 vertical layers with varying degree of horizontal resolution. Figure 20 depicts projected model run times for the SEAWAT code (TVD and Upwinded Finite Difference Solutions) and the WASH123 code. Also, it was assumed that the full CERP 36-year period of record would be run for each code. Scale up from the benchscale model domain size (County size) to the regional domain is generally straight forward using a simple domain size ratio and assuming additional vertical model resolution.

Figure 20. Estimated Model Run Times for the ASR Regional Model



The SEAWAT (with upwinded finite-difference solution) and WASH123 codes appear to be subjected to the highest amount of numerical dispersion of the codes considered. A portion of the numerical dispersion most likely could be eliminated through better model grid or mesh design allowing for additional resolution in the vertical direction. In addition, accuracy could be further improved for these codes through improved horizontal grid or mesh resolution. It appears that the concentration changes around the ASR well are focused within 250 feet of the ASR well. Therefore, it may be appropriate to maintain a constant horizontal grid or mesh resolution within that radius, increasing grid or mesh size at a reasonable bias beyond 250 feet.

All codes seem capable of simulating density-stratification as evidenced in Case 1B. The accuracy of the codes for this case is unknown however, since no known analytical solution is available to provide a comparison or check. Qualitatively, the SEAWAT (TVD solution) and the WASH123 results appear very similar to each other so it is surmised they probably have a similar accuracy for this case. For Case 1C, the WASH123 code revealed more clear density upconing as compared to the other codes. Since no analytical solution was available for comparison, it is unknown if the simulation results are more representative than the other codes tested.

For Case 1D, the MT3DMS and SEAWAT codes predicted much higher concentrations at the ASR wellhead than the WASH123 code. It is unclear why the differences are so large for this case. Again, the vertical grid resolution may have been insufficient to ensure the highest accuracies of the velocity field around the ASR well. Inaccuracies in the vertical velocity field may have resulted in more significant contaminant transport errors for the model codes. For Case 2A, all the codes tested produced reasonable results and seem capable of simulating cases of salt-water intrusion.

Weighing all of the factors and considering improvements that could be made to the model grid or mesh for future models, it appears that either the SEAWAT (Upwinded finite-different Solution) or the WASH123 codes would be appropriate to utilize for the ASR Regional Study model development effort. Both codes appear to solve the requisite flow and transport equations adequately as well as providing a back stop of published comparisons against density-dependent case studies. SEAWAT appears to be the most widely tested code of the two but recent efforts conducted at the ERDC aim to lessen the gap here. Each of the codes also have inherent disadvantages including long model run times due to small time-step requirements for contaminant transport models. One strategy that was considered valuable was the employment of both model codes to study the same ASR problems thus ensuring a higher degree of reliability in overall conclusions and future recommendations. Using both codes to “bracket” the most likely issues and solutions would go a long way towards better overall decision making for the ASR program. For smaller domain models, the SEAWAT (TVD Solution) code could be utilized to minimize numerical errors and provide the best estimate of ASR recovery efficiency. The SWI code should not be utilized unless hydrodynamic dispersion can be ignored for the particular problem under consideration.

In order to address the maximum number of ASR questions as rapidly as possible, it is recommended that two models be developed simultaneously for the ASR Regional Study. As discussed above, the two codes would enable the PDT to bracket the cogent issues related to potential ASR system impacts and expected benefits. The two codes would provide a much needed measure of decision making reliability. First, a coarse resolution regional model should be developed with horizontal model resolution of 5,000 to 10,000 feet. The coarse model would be developed using the SEAWAT upwinded code and would be utilized to evaluate system groundwater exchange/flows and the movement of the salt-water interface. This model would be calibrated using existing water level and water quality information within the study area along with contour maps showing the depth to the salt-water interface. Long-term simulations of the salt-water interface would be required to simulate current steady-state conditions and concentrations. Therefore, this model needs to run rapidly in order to complete the numerous simulations required. A key advantage of this approach would be the large number of sensitivity tests that could be completed. This would result in a more reliable model calibration of heads and concentrations at the Florida coastline.

Second, a variable resolution regional model should be developed with horizontal model resolution of 100 to 250 feet around the proposed ASR wells increasing to 10,000 feet in the far reaches of the study area. This model would be developed using the WASH123 code and would take advantage of the geometry advantages of a finite-element code such that the model mesh would have varying resolution across the model domain. In essence, finer resolution could be employed at the areas of interest while far-field areas would be modeled with coarse resolution. This model would build upon calibration results achieved for the SEAWAT model by calibrating against seasonal water levels and water quality as well as utilizing transient calibration at existing ASR and well sites where aquifer test or ASR cycle testing data is available. It is believed that at least ten to fifteen such sites would have the necessary data to support this more rigorous calibration effort.

Based upon the model domain of 34,000 square miles, an estimate was made of the number of computational points for each model versus resolution. The SEAWAT grid would be a minimum of 5,000 feet horizontal resolution while the WASH123 mesh would be the same coarse resolution at the model exterior but with 1,000 feet resolution around Lake Okeechobee (key area of interest for the CERP). Table 13 lists the number of computational points for a 1 layer model at different horizontal resolutions. Based upon the benchscale study, the PDT has determined that the regional model should be limited to less than 500,000 computational points to ensure more reasonable run times. In reviewing Table 13, it is important to note that at 5,000 feet of horizontal resolution, both model codes would be similar but WASH123 would have finer resolution around the Lake Okeechobee study area. As resolutions become coarser, SEAWAT clearly results in less computational time. In order to stay within the prescribed number of computational points, the overall ASR regional study model resolution should be limited to minimum of 7,500 to 10,000 feet.

Table 13. Model resolution vs. # of computational points for a one layer model

Horizontal Resolution (feet)	# Grid Points	# Mesh Nodes
5,000	37,704	34,443
10,000	9,426	13,935
20,000	2,356	6,207

Both models would be developed by the same team and would utilize all of the same model input data sets (e.g., water levels, starting conditions, hydrogeology, water quality, and boundary conditions) in order to maximize synergy between the two development efforts. Both models would be combined into a single modeling report for review by an external ITR team. Ultimately, these two models and a very fine-resolution model would represent a "family" of models that could help the ASR Regional PDT address all of the outstanding technical issues identified previously. In addition, this family of models would be utilized to optimize the final design of the entire CERP system of wells.

Abstract Aquifer Storage and Recovery (ASR) is the storage of fresh water in an aquifer via injection during times when water is available, and recovery of the water from the same aquifer via pumping during times when it is needed. ASR is expected to provide a cost-effective solution to many of the world's water management needs: storing water during times of flood or when water quality is good, and recovering it later during emergencies or times of water shortage, or when water quality from the source may be poor. ASR systems can usually meet water management needs at less than half the capital cost of other water supply alternatives. When compared to other alternatives that require construction of water treatment plants and surface reservoirs to meet increasing peak demands, potential cost savings have been anticipated. Besides, ASR has been recognized to have less impact on the environment, aquatic and terrestrial ecosystems. When water is stored deep underground in brackish aquifers, however, the mixing of the saline water that is originally in the brackish aquifer and the fresh water that is injected into the aquifer may degrade the water quality of the stored water and reduce the volume of the available fresh water in the following recovery periods of time. The mixing can be modeled by both the diffusion and the dispersion transport processes. Although both the diffusive and the dispersive fluxes are proportional to concentration gradient, the dispersion coefficients are highly dependent on the flow velocity, whereas the diffusion coefficients are independent of the flow velocity. Therefore in the evaluation of brackish aquifer storage recovery (BASR), whatever factor that would significantly affect the flow velocity in the brackish aquifer during both the injection and withdrawal periods should be accounted for in the associated evaluation models. In this paper, we will demonstrate how BASR can be modeled with the WASH123D numerical model that computes saline transport and density-dependent flow in a watershed system which can be conceptualized as a combination of 1D channel network, 2D overland regimes, and 3D subsurface media. A hypothetical example that includes various model parameters, *e.g.*, pumping rate, hydraulic conductivities, porosity, and

dispersivities will be employed to detail the model setup and conduct a sensitivity analysis.

INTRODUCTION

Aquifer Storage and Recovery (ASR) is one of the proposed alternatives recommended by the Comprehensive Everglades Restoration Plan (CERP). The goal of ASR in the South Florida Region is to help with water supply, storage, and distribution. The ASR Regional Study will include numerical groundwater models in order to evaluate the effectiveness of ASR. For this phase of the project, four box models (~ 40 miles x 40 miles x 2340 ft) were developed using the WASH123D finite element code. Each of the four "cases" is intended to evaluate modeling code performance under different hydraulic conditions. The following paper details the WASH123D model construction and summarizes the simulation results for one of the CERP box models.

WASH123D CODE

WASH123D is a finite element numerical model designed to simulate variably saturated, variable-density water flow and reactive chemical and sediment transport in watershed systems. It is capable of conceptualizing a watershed system as a combination of 1D river/stream, 2D overland, and 3D subsurface sub-domains. A modified Richards' equation is used to solve for 3D flow when density effect is taken into account. The equation is solved with the Galerkin finite element method. WASH123D uses the Lagrangian-Eulerian (LE) method to solve the transport equations. Particle tracking is used in the Lagrangian step to handle the advection term. Other terms (such as sources, sinks, diffusion, and dispersion) are calculated in the Eulerian step, where element matrices are assembled into a global matrix, and matrix solvers are used to solve for the spatial concentration distribution at the end of each time step. A predictor-corrector numerical technique, combined with an adaptive explicit-implicit numerical scheme, is employed to compute reactive transport efficiently and robustly. The use of this methodology allows the numerical stability of WASH123D not to be restricted by the Mesh Courant number. In addition, the Mesh Peclet number is restricted only by computational accuracy, not numerical stability. More detailed discussion on various types of numerical dispersion and how the LE method deals with these types of numerical dispersion are discussed in the referenced papers.

Since computational accuracy is dependent on the time step size used in the simulation, a sensitivity analysis was performed to evaluate the variations in the time-step size on model results. For this sensitivity analysis the time step of the injection and extraction cycles were varied between 0.05 and 5 days. The results of this analysis, presented in Figure A1, indicate that the change of the computational result becomes insignificant as the time step size is reduced to

below 0.5 days. Therefore, a time step size of 0.5 days was used during the injection and extraction cycles for all simulations in this study.

MESH DEVELOPMENT

WASH123D uses an unstructured three-dimensional (3D) finite element mesh to solve the flow and transport equations in variably-saturated media. Because flow and concentration gradients may be high in the vicinity of an ASR well, the vertical and horizontal resolution of the 3D mesh in the vicinity of the ASR well is important. Meshes that do not have sufficient resolution in the area of interest may not accurately simulate observed conditions in these high gradient areas. On the other hand, meshes that contain too much resolution will require more computational resources, resulting in extended simulation times. The mesh used for this study was based on conceptual geology developed by the Jacksonville District. The horizontal resolution of the mesh at the ASR well is 10 feet. The elements at the ASR well were deleted to allow Cauchy flux boundary conditions to be assigned directly to the interior faces of the mesh, representing the well screen. The mesh resolution expands to 5000 feet along the model perimeter. Vertical mesh resolution varied among the different conceptual geologic units. Increased resolution was used in the confining units directly above and below the ASR injection aquifer (Upper Floridian). This increased resolution allowed the WASH123D model to depict the large head and concentration gradient at the interfaces of these confining units. The final 3D mesh was composed of 112,716 nodes and 212,940 triangular-prism elements. Figures A2a and A2b illustrate the mesh resolution and conceptual geology used for the ASR simulations. The DoD Groundwater Modeling System (GMS) v.5.1 was used to generate the WASH123D mesh.

BOUNDARY CONDITIONS

Boundary conditions were assigned to the finite element model to simulate ASR pumping into the Upper Floridian aquifer. At the ASR well, Cauchy flux boundary conditions were used to simulate injection and extraction flow rates of 5 MGD. These boundary conditions were applied to the element faces representing the well screen within the Upper Floridian Unit (approximate elevation –1,014 to –1,171 ft). The saline concentration of the injected fluid was 150 mg/L. The saline concentration of the fluid at the ASR well during storage and extraction varies with depth and time depending on the relative saline concentration in the surrounding nodes, the extraction rate, and the mixing process in the ASR well. Dirichlet boundary conditions were used to assign the total head along the eastern and western model boundaries. WASH123D converts these assigned heads to equivalent fresh water heads based on the concentration and depth of each node. No-flow boundary conditions were used along the northern and southern model boundaries. Dirichlet boundary conditions were also used to assign the concentration along the model perimeter. Tables A1 and A2 show the

hydraulic and transport properties,respectively, for each geologic unit in the WASH123D model.

EVALUATION OF RESULTS

The WASH123D model simulated a 30-day injection period, followed by a 305-day storage period, and a 30-day recovery period. Prior to performing the transient simulation WASH123D calculates steady state initial hydraulic conditions based on the specified input parameters. The following discusses the results of the WASH123D model during each phase of the simulation.

Initial Condition

Since the WASH123D model is a coupled density dependent code, the initial hydraulic head boundary conditions were converted to equivalent freshwater heads based on the depth and saline concentration at each node. For this simulation, the nodes in the geologic units above the Upper Floridian aquifer were assigned a saline concentration of fresh water (150 mg/L), while the nodes in and below the Upper Floridian aquifer were assigned a saline concentration of seawater (35,000 mg/L). The specified boundary conditions result in a west to east hydraulic gradient. Figure A3a shows a cross sectional view of the concentration profile in the vicinity of the ASR well. The contours on this figure reflect the constant concentration profile used as the initial condition prior to pumping.

Injection Period

Once the initial steady state flow field is generated, the ASR pumping well injects fresh water into the Upper Floridian aquifer at 5 MGD for 30 days. During this injection cycle the hydraulic head at and immediately surrounding the ASR well increases substantially, nearly doubling in magnitude. Figure A3b shows a cross sectional view of the concentration profile in the vicinity of the ASR well at the end of the injection cycle. This figures show that the injected fresh water has displaced the ambient saline water forming a spheroid of lower concentration water in the vicinity of the ASR well. This lower concentration water permeates into the confining units above and below the Upper Floridian aquifer.

Storage Period

After the 30-day injection cycle, the ASR well is turned off for 305 days. During this storage period, the hydraulic conditions stabilize to near steady state conditions. Figure A3c shows a cross sectional view of the concentration profile in the vicinity of the ASR well at the end of the storage period. Although the concentration at the ASR well remains relatively constant, the effects of buoyancy stratification are noticeable. During the storage period, the density effect is the dominate factor in the flow fields simulated by WASH123D. Consequently, the concentrations at the nodes in the lower portion of the Upper Floridian aquifer increase substantially faster than the nodes at the top of the aquifer.

Extraction Period

After the storage period the ASR well extracts at 5 MGD for 30 days. During this extraction cycle the hydraulic head at and immediately surrounding the ASR well decreases substantially. Figure A3d shows a cross sectional view of the concentration profile in the vicinity of the ASR well at the end of the storage period. Up-coning of the higher concentration saline water below the ASR well was observed during extraction. It must be noted that the well screen of injection and extraction in the Upper Floridian aquifer covers the center four vertical elements, rather than all the six vertical elements in the aquifer. This setup allows the mesh to compute for convergent flow fields around the well at the interfaces of the Upper Floridian aquifer and the two aquitards above and below without using high resolution meshes and small time steps when the density effect is strong. Because of this, the salt concentration of nodes in the lower portion of the aquifer in the vicinity of the ASR well increase in concentration faster than the nodes above during the period of extraction due to both diffusion and up-coning.

FUTURE MODEL DEVELOPMENT

During the development of the WASH 123D model, meshes of various vertical and horizontal resolutions were tested. The WASH123D simulations became more computationally stable as the vertical resolution was increased in the geologic units above, below, and containing the ASR well. Additional studies are anticipated that evaluate the effect of various mesh resolutions on computational speed and accuracy.

In addition to the mesh sensitivity simulations, additional modifications to the WASH123D code are anticipated. One modification will be to the algorithm used to calculate the equivalent freshwater head in variable density flow systems. In simulations where higher density fluid is overlain by fluid of a lower density, the current algorithm tends to overestimate the equivalent freshwater head in the higher density solutions. Additional upgrades to address temperature variations on thermal transport will also be incorporated to the WASH123D code. These upgrades in conjunction with WASH123D's current ability to model variably saturated groundwater flow and surface/subsurface flow interactions will enhance WASH123D's ability to model the dynamic flow and transport issues inherent in the ASR program.

1.0 INTRODUCTION

The U.S. Army Corps of Engineers (USACE), Philadelphia District, has prepared this report for the USACE, Jacksonville District, and the South Florida Water Management District (SFWMD) in support of the Comprehensive Everglades Restoration Plan (CERP). Aquifer Storage and Recovery (ASR) is one of the proposed alternatives recommended by the CERP to help with water supply, storage, and distribution in South Florida. The CERP recommends approximately 333 ASR wells distributed over a large region with well field clusters proposed within the Floridan Aquifer System (FAS) near Lake Okeechobee, near the proposed C-43 reservoir in Hendry County, and at several locations along the Lower East Coast in Palm Beach and Broward Counties. The proposed plan, with an injection and recovery pumping rate of approximately 1.65 billion gallons per day, is larger than any currently operating ASR project. To evaluate the numerous design considerations and the variation in aquifer response on regional, sub-regional, and local scales, density-dependent numerical modeling of the FAS is required as discussed in the ASR Regional Study Project Management Plan developed in 2003.

The ASR Regional Study – Benchscale Modeling report (Brown et al, 2006) evaluated several density-dependent flow and transport modeling codes. Two codes were selected for use in the ASR Regional Modeling application: the finite element code, WASH123D (Yeh et al., 1998) and the finite difference code, SEAWAT (Langevin et al, 2003, and Guo and Langevin, 2002). The two models were selected as the best of those evaluated to address the maximum number of questions regarding the ASR Regional Study and to reduce technical uncertainties that might arise from the proposed CERP ASR plan. Some of the issues to be addressed by the two models include potential regional changes in aquifers heads, flows, and water quality, the potential for salt water intrusion caused by ASR pumping, regional impacts to wells completed in the FAS, and ASR design, siting, layout, and performance considerations. The WASH123D and SEAWAT models, under development simultaneously, encompass a peninsula-wide area of approximately 39,000 square miles extending from Polk County to Florida Bay (Figure 1).

The regional modeling effort was divided into 2 Phases because of its extent and complexity. The Phase I model is a coarse test bed for the more refined Phase II model. Specific goals of the Phase I and Phase II models are:

Phase I

- Identify model boundaries and test model boundary parameters
- Identify regional flow and salt migration pathways
- Identify the timing of salt water intrusion
- Evaluate model run times and model sensitivity to time step sizes
- Test hydraulic and transport parameter sensitivity
- Compare WASH123D and SEAWAT results

Phase II

- Identify areas of the Phase I model for refinement
- Incorporate regional-scale transient groundwater withdrawal

- Calibrate density-dependent flow and transport results to observed measurements in major geologic units
- Select sites and determine refinement locations to incorporate ASR well field clusters
- Evaluate proposed ASR project alternatives effects on aquifer heads, flows, and water quality; for pressure-induced changes; for increased potential for salt-water intrusion; and on withdrawals for existing well users

The focus of this report is the Phase I Regional Modeling. This Phase I effort includes regional conceptualization, estimates of hydraulic and transport parameters, density-dependent 3-D groundwater model construction, gross comparisons to head and concentration data, evaluation of flow and transport patterns, and sensitivity analyses to several model parameters. Each of these tasks and analyses provide a greater understanding of the flow and transport system that makes up the majority of the Florida subsurface. This increased understanding provides a platform on which to build in the additional complexities of the Phase II model.

2.0 PHASE I REGIONAL MODELING APPROACH AND ASSUMPTIONS

The primary objective of the Phase I model is to identify the parameters and issues that will be most important when building the more-detailed Phase II model. The Phase I model is a coarse resolution regional-scale model constructed based on several simplifying assumptions. The simplifying assumptions are intended to maintain the model ability to represent the regional flow and transport patterns while facilitating model construction and reducing model run times. This section introduces the most significant model assumptions. Model conceptual and construction details are presented in Sections 3 and 4.

For the Phase I modeling effort, it was assumed that porous media models adequately and accurately represent the system modeled for both flow and transport. The impact of lineament and/or fracture flow was not included in the Phase I model, but may be significant as discussed in Section 5.

The boundary used for the Phase I model was approximately twenty miles offshore to reduce the effects of boundary conditions on model results and to attempt to simplify boundary condition assignments. The horizontal model resolution was coarse to decrease the model run times and to allow long-term simulations to be investigated.

Geologic interpretations were based on previous ASR Regional Study reports discussed in Section 3. The model focuses on the FAS, the geologic units where the ASR wells are proposed. Geologic units that are shallower and deeper than the FAS are incorporated to the Phase I model with geologic information that is greatly simplified and functions only to provide flow and salinity interaction with the FAS. Unsaturated flow in the surface aquifers is omitted as it is not pertinent to the model objectives. Therefore the top of the model is assumed to be the water table surface rather than ground topography.

Pumping wells are omitted from the Phase I model. The coarse resolution of the model makes incorporating pumping wells difficult. Also, model parameter assignments can be simplified without the inclusion of pumping wells. The omission of pumping has a significant effect on the results; however, these "pre-development" results can provide an overall picture of flow and transport patterns.

Flow boundary conditions around the model perimeter are specified as constant heads that do not vary in time. This simplification was made to reduce the amount of data collection required for the Phase I model. The heads specified at the boundaries are considered as "pre-development" heads because there is no pumping in the model. Pre-development boundary heads were assembled based on pre-development head contours generated by USGS (Bush and Johnston, 1988) and by selecting the highest consistent values at selected wells from online databases. Although the boundary heads were based on available data, some interpretation was required for boundaries that either did not have adequate water level data or that did not intersect the ocean, where head values are known. As discussed later in this report, the heads assigned to these boundaries were extensively tested until reasonable regional flow patterns were developed. The head data in the surface aquifer were utilized to specify the model surface head boundary instead of estimating recharge based on precipitation and evapo-transpiration. This assumption is reasonable since only the surface aquifer flow interaction with the Floridan aquifers is necessary to meet the ASR model objectives. No flow is assumed to enter or exit the model from the bottom.

Boundary conditions for salt concentrations also were set around the perimeter of the model. Water quality data from SFWMD and online databases were used to estimate the salt concentration around the boundary. Much less water quality data were available than head data so considerable interpolation and extrapolation was necessary to determine the boundary concentrations. Due to this uncertainty, sensitivities were performed on the type of boundary condition used, fixed or variable, as well as on concentrations specified. These sensitivities were completed for both the aquifer perimeter and model bottom. The concentration boundary conditions on the model surface were fixed as fresh water over land and seawater over the ocean. These estimates of boundary concentrations are sufficient to generate and test transport patterns for this investigation. Further discussion of these sensitivity analyses is presented in Sections 5 and 6.

The effect of heat transfer was not considered for the Phase I model and is not currently within the scope of the ASR Regional Study effort. Heat transfer may be important as a primary mechanism for salt intrusion based on the convectional cell theory (Kohout 1965). The convectional cell theory states that salt water upwells from deep geologic units based on the geothermal reduction of water density. For the Phase I model, it is assumed that the temperature variation does not have a significant impact on the water density. Although heat transfer is not considered, limited temperature effects within the deepest model aquifer are examined as part of the sensitivity analyses (Section 5).

Variable density models must be run under transient conditions to allow the system to equilibrate over time and because solute transport calculations always are performed under transient conditions. The duration of the simulations was dictated by recent

groundwater age research as discussed in Section 3.4 and 4.4. Steady state runs were done first to provide initial conditions for the transient simulations to help the solution converge on an answer more quickly. Once steady state results compared reasonably with monitoring data, long-term transient simulations were completed. The transient results were used as a basis for several sensitivity tests.

The Phase I modeling was performed using both WASH123D and SEAWAT codes. The model parameters used to produce results comparable with monitoring well data were determined using the WASH123D model runs. Subsequently, the WASH123D model configuration and parameters were used, with conversion to the proper format, to complete a comparable model run in SEAWAT. The differences in the results from the two codes are compared and evaluated. In addition, sensitivities were performed for both models to evaluate the effects of several parameters. This approach helped evaluate the sensitivity of each model to variations in input data, as well as similarities and differences between the two codes.

3.0 CONCEPTUAL MODEL

A conceptual model was developed for the system to identify all known hydrologic and hydrogeologic factors that influence flow and transport. The factors include sources/sinks, the boundary of the model domain, and stratigraphy. The conceptual model provides an understanding of observed groundwater flow directions and transport pathways and helps determine the dimensions and important features of the numerical model.

A wealth of geologic and hydrogeologic data exists across the region. As part of previous ASR Regional Study tasks, certain information was collected and evaluated for use in the Phase I model. Reese and Richardson (2004) compiled The Draft-Final Report – Task 3.0 Define Preliminary Hydrogeologic Framework, (referred to herein as the Preliminary Hydrogeologic Framework), which presents an evaluation of regionally significant works and new data to generate a consistent hydrostratigraphic and hydrogeologic visualization of the Florida peninsula subsurface from Orlando to Key West. A further assessment of geologic and hydrogeologic data is presented by CH2MHill (2006) in Groundwater Numerical Model Development Support and Data Collection Report, (referred to herein as the Data Collection Report). The Data Collection Report provides a review of the Preliminary Hydrogeologic Framework together with geologic and hydrogeologic data used for eight existing numerical models of various scales and resolutions across the peninsula (Figure 2). Also included in the Data Collection Report is a dispersion research study that gathered and tabulated dispersion data from technical reports of similar geologic environments around the world. Additional information for the Phase I conceptual model was collected from other sources listed in the References section and from online databases including SFWMD's DBHYDRO, USGS's South Florida Information Access (SOFIA), and the National Park Service's South Florida Natural Resources Center (SFNRC).

All geographic information associated with geologic and hydrogeologic data was converted to the following coordinates:

- Horizontal geographic data – Florida East State Plane 1983 (FESP 83)
- Vertical geographic data – National Geodetic Vertical Datum 1929 (NGVD)

3.1 CONCEPTUAL GEOLOGIC FRAMEWORK

The conceptual geology is based predominantly on the findings documented in the Preliminary Hydrogeologic Framework. For that report, key wells were reviewed to correlate major aquifers and confining units of the FAS. Figure 3, taken from Table 1 of the Preliminary Hydrogeologic Framework, shows the resulting Regional Study schematic cross section representing the geologic units that are defined for the numerical models. The Preliminary Hydrogeologic Framework also defined hydrostratigraphic surfaces for the geologic units and hydraulic parameters for the FAS units. Hydrostratigraphic surfaces define the depth and thickness of the geologic units over the study area. (Figure 4). Hydraulic parameters were generated for the Upper Floridan (UF), Middle Floridan (MF), Lower Floridan (LF), Upper Middle Confining Unit (MC1), Lower Middle Confining Unit (MC2), and the Lower Confining Unit (LC) (Figures 5, 6, 7, 8, 9 and 10, respectively). The transmissivity of the Boulder Zone (BZ) was estimated to be on the order of 10^6 to 10^7 ft^2/d. Details regarding the correlation of the geologic units and the definition of the hydrostratigraphic surfaces and hydrogeologic parameters for the FAS can be found in the Preliminary Hydrogeologic Framework.

The Preliminary Hydrogeologic Framework defines the hydrostratigraphic surface between the Intermediate Confining Unit/Intermediate Aquifer System (IC/IA) and the Surficial Aquifer System (SAS) but does not define hydraulic parameters for those units. These two units are both complex systems of alternating aquifers and confining units. Part of the conceptualization of the IC/IA and SAS is to greatly simplify these units because they are not the focus of this modeling effort. The primary function of these two units in the Regional Model is to permit water to enter the FAS, where the ASR wells are proposed.

Hydraulic parameters for the IC/IA were composited from information in the Data Collection Report. All of the eight numerical models reviewed for the Data Collection report provide ranges and distributions of hydraulic parameters for portions of the IC/IA. The IC is represented as a thick semi-confining and confining unit that retards flow between the SAS and IA or between the SAS and UF, where the IA is not present. The IA is found only in west-central and southwest Florida. The lateral extent of the IA is shown in Randazzo and Jones (1997), Figure 6.23.

The hydraulic conductivities for the SAS were based on a figure generated by SFWMD (Figure 11). The lateral extent of the SAS is shown in Randazzo and Jones (1997), Figure 6.6. In the northwest corner of the model area, the SAS pinches out and the IC/IA is present at the surface. For this Phase I model, this simplified SAS layer acts primarily as a boundary condition providing the driving flow into and out of the FAS.

3.2 DISCHARGE AND RECHARGE

Discharge from the system is mainly to the Atlantic Ocean or Gulf of Mexico and also to surface water features, such as rivers, lakes, streams, canals. Although the numerous agricultural and municipal pumping wells are a significant discharge from the system, no pumping is included in the Phase I model. Without pumping, all heads generated by the Phase I model are considered to be "predevelopment heads". Regional pumping information, including locations, open hole depths, and transient pumping rates, will be assembled and assessed for model input to the Phase II model.

Recharge to the system is mainly attributed to infiltration to ground water from precipitation. Infiltration can be difficult to quantify, especially over such a large region, as it depends on obtaining transient precipitation gage information and estimating evapo-transpiration rates and land-use information. Correctly quantifying infiltration would facilitate computing correct heads within the SAS that make up the driving head through the IC/IA to the FAS. Because the SAS heads are important mainly as a surface boundary condition, the head data in the SAS was set based on observations rather than estimating several parameters to compute head data in the SAS layer. This simplifying assumption facilitates model construction and should not have an adverse effect on the computed results in the FAS, the primary area of concern for the Regional Study.

Head data from SAS monitoring wells was gathered and used to specify the heads over the surface of the model domain. SAS monitoring well head data was gathered from a number of sources, including online databases, a depth-to-water grid from the Florida Geological Survey (FGS), Reese and Cunningham (2000), and model results from Sepulveda, 2002. Not all SAS monitoring well head data available in online databases were used. SAS wells that form well clusters with wells screened in lower geologic units were favored. Additional SAS wells were selected to obtain an adequate coverage over the model area. Also notable is that transient data sets available for SAS monitoring wells were condensed into a constant head value that represents the highest consistent value over the period of record. The highest consistent value for the period of record of each well was chosen as a representation of the predevelopment condition for the Phase I model. The highest consistent value for the SAS was selected from all the aquifers present in a particular region, including artesian aquifers that exist in the SAS. As a result, some of the SAS heads selected are actually above ground surface, such as those beneath the Caloosahatchee River Basin west of Lake Okeechobee.

Figure 12 shows the surface head distribution and values over the peninsula. The FGS depth-to-water grid data is not shown in the figure because the data density is too large for clarity. The FGS data compares favorably with the data shown in Figure 12 except where artesian values were selected.

Figure 12 shows the highest head values and the area of most significant recharge are in the Polk County area with values as high as 175 ft NGVD. Much lower heads are found across the large area south of Lake Okeechobee, where head values range from 0 to 20 feet NGVD.

3.3 ANALYSIS OF MONITORING WELL DATA

Visualization of regional groundwater elevation and water quality data provides an understanding of groundwater flow patterns and the location and movement of the salt water concentrations over time. The visualization was performed using the Department of Defense's Groundwater Modeling System (GMS) version 6.0. Head monitoring data for numerous wells across South Florida is contained within online databases, but not all wells were used. Wells clusters were chosen to see the relative changes in different geologic units, and additional wells were selected to allow for adequate coverage across the unit. From the transient head data set available at a particular well, only the highest consistent value was chosen to represent predevelopment conditions. These datasets were also used to compare with the computed results of the Phase I model.

Figure 13 shows the predevelopment head distribution and values for the UF as collected from selected wells in online databases, model results from Sepulveda (2002), and from Development of a Density-Dependent Saltwater Intrusion Model for the Lower East Coast Project Area, prepared by HydroGeoLogic, Inc., April 2006. Also shown in the figure are contours of UF predevelopment heads generated by USGS (Bush and Johnston, 1988). This data gives the overall flow pattern of UF predevelopment heads. The primary inflow to the UF is in the Polk County area. Groundwater flows radially from the high point in Polk County toward the eastern and western coasts and to the south from the central ridge of higher heads.

Figure 14 shows that less head information was evaluated in the MF. The data were collected from online databases and HydroGeoLogic, Inc., April 2006. Generally the MF heads seem similar to the UF heads with the highest heads in the Polk County area. Lower heads are found in all directions surrounding the highest head in Polk County.

Head information for the LF was gathered from HydroGeoLogic, Inc., April 2006, from online databases and from Hydrogeology and Water-Quality Characteristics of the Lower Floridan Aquifer in East-Central Florida (O'Reilly et al., 2002) as shown in Figure 15. These head values are generally lower than the UF and MF heads. Much lower heads in the LF are found in the southern counties. In the northern counties, especially Polk County, the heads are somewhat lower but more similar to those observed in the UF and MF. A similar pattern appears to exist for each of the units with the highest heads in central part of the Florida peninsula and lower heads to the south.

Similar visualizations were performed for selected water quality data. For this study, total dissolved solids (TDS) are used as a measure of salinity. Seawater salinity is assumed if TDS values are 35,000 mg/l or larger (Parker et al, 1955). An overall depiction of the water quality pattern in South Florida is shown in Figure 16 which shows elevation contours where the TDS concentrations are 10,000 mg/l as developed by SFWMD. Fresh-to-brackish groundwater is present at greater depths below Polk County than at the coasts. There is a secondary area of fresh-to-brackish groundwater south of Lake Okeechobee. Visualizations of water quality data in the UF, MF and LF taken from online databases and HydroGeoLogic, Inc., April 2006 (Figures 17, 18 and 19), show that the majority of the UF has TDS values lower than 5,000 mg/l while MF concentrations

are slightly higher and LF concentrations are much higher. These values are generally consistent with the elevation of 10,000 mg/l TDS data depicted in Figure 16. However, in some areas on the west coast, the selected data evaluated for Phase I shows fresher water at greater depths than shown in Figure 16. Judgment was used in determining the value used for model input.

3.4 GROUNDWATER AGE ANALYSIS

To better understand the timing of water flow through the FAS, additional investigations related to groundwater age data for the UF and MF were reviewed. These investigations included Kaufmann and Bennett (2005) and Mirecki (unpublished) (Figures 20 and 21). The contours in these figures indicate the age of groundwater in "years before present" and were computed based on the Pearson correction method. The general trend shows that the groundwater age is younger near Polk County where rainfall infiltration is believed to occur and along the central portion of the peninsula extending southward just west of Lake Okeechobee. Groundwater becomes increasingly older as it moves to the south and as it moves east and west of the central peninsula ridge. An area near the east coast indicates some mixing with ocean water because the groundwater ages are younger than those upgradient. Also, the MF groundwater ages are younger than the UF groundwater ages indicating that groundwater moves faster in the MF. The maximum age of groundwater in both aquifers is about 35,000 years.

3.5 CONCEPTUAL MODEL SUMMARY

The final conceptual model for Phase I was formed with the information and data gathered, and provided the basis upon which the numerical models were developed. Recharge through infiltration to the SAS provides driving heads that supply water to the FAS through the IC/IA. The primary area of recharge to the FAS appears to be in the Polk County area where flow infiltrates through the confining units to recharge the UF, MF and the LF. This statement is supported by the fact that the highest observed heads for the UF, MF and LF monitoring wells compiled for this study occur in Polk County and lower salinity is found in the deeper units in the Polk County area. Based on the data used for the Phase I model, flow appears to move through the aquifers in all directions from Polk County. In the UF, fresh-to-brackish water exists through much of the aquifer until it reaches an outcrop to ocean water on the east coast where some mixing occurs. The MF has similar heads and slightly higher concentrations compared to the UF. In the MF, a salinity mixing zone is also present on the east coast. Water flow is expected to move faster through the MF as hydraulic conductivities are larger and groundwater ages are younger than the UF. The LF appears to be influenced in the north by recharge from the Polk County region with water elevations that are much higher than those observed in the south. The southern LF water levels and salt concentrations are more consistent with ocean water. Mixing is expected in areas of the LF where the less-saline infiltrated water mixes with the ocean water. Discharge from the system is mainly to the Atlantic Ocean or Gulf of Mexico and also to surface water features.

The conceptual model was translated into the two numerical models, but the process is an iterative one. Numerical model results will be used to refine and revise the conceptual model with an updated understanding of flow and salt transport processes for Phase II.

4.0 MODEL CONSTRUCTION

Two density-dependent flow and transport codes, WASH123D and SEAWAT, were used in the Phase I modeling. The following sections chronicle model development from mesh/grid development to model input selection. Mesh/grid development and model input was completed for both models using GMS, version 6.0.

4.1 MODEL CODES

The WASH123D model code (Yeh et al., 2003), compiled in September 2006, was one of the codes used for model construction. WASH123D is an unstructured finite element code that simulates variable-density flow and reactive chemical and sediment transport in 1-D channel networks, 2-D overland regimes and 3-D subsurface media. For the Phase I model, the capability of computing density-dependent coupled subsurface flow and transport using WASH123D was utilized. With WASH123D, the variably saturated, density-dependent water flow is described by the modified Richards' equation and solved with the Galerkin finite element method. The Lagrangian-Eulerian (LE) method is employed to solve the subsurface transport equation, where particle tracking is used in the Lagragian step to handle the advection term, and the other terms (such as sources, sinks, diffusion, and dispersion) are calculated in the Eulerian step to determine the spatial concentration distribution at the end of each time step. The use of this methodology allows the numerical stability of WASH123D not to be restricted by the Mesh Courant number. In addition, the Mesh Peclet number is restricted only by computational accuracy, not numerical stability. Therefore, a sensitivity to time step sizing was performed to ensure the numerical accuracy was adequate for the scale and stated goals of the Phase I modeling effort. More detailed discussion on various types of numerical dispersion and how the LE method deals with these types of numerical dispersion are found elsewhere. (Cheng et al., 1996; Cheng et al., 1998; Yeh et al., 2006).

The SEAWAT model code (Langevin, et al, 2003, and Guo and Langevin, 2002) also was chosen for the Phase I modeling effort. SEAWAT is a finite difference code that simulates variable-density flow in three dimensions by combining a version of MODFLOW–2000 (Harbaugh et al, 2000) and MT3DMS (Zheng and Wang, 1999) in a single program to solve the coupled flow and solute transport equations necessary to model variable-density flow. MODFLOW—2000 is used to solve the flow part of the variable-density flow equations and MT3DMS is used to solve the solute transport equations. SEAWAT runs in one of four simulation modes: Constant-density flow without solute transport; constant-density flow with solute transport; variable-density flow without solute transport; and variable-density flow with solute transport. SEAWAT uses a finite difference approximation for the variable-density form of Darcy's law for groundwater flow and simulates dispersive transport using Fick's law. The program contains several methods for solving the solute transport equation including an implicit finite difference method with either upwinded or central-in-space weighting, the method of characteristics, and a third order total-variation-diminishing (TVD) scheme. For the Phase I study, SEAWAT modeling was performed with the variable-density flow with solute transport mode to simulate the system.

4.2 THREE DIMENSIONAL MESH/GRID DEVELOPMENT

The 3-D nature of the study area must be considered during mesh/grid development. As such, the 3-D mesh/grid must balance accurate depiction of topography, geology, and groundwater sources/sinks with model goals and computational resources.

Horizontally, the ideal model boundary alignment would be around the Florida peninsula boundary, where all the geologic units outcrop to the ocean (Figure 22). This would ensure that boundary effects in the interior of the model would be limited because boundary condition assignments would be greatly simplified: all of the boundary heads in each geologic unit would be equal to sea level and all of the boundary concentrations 100% salt water. However, since the Florida peninsula extends 150 miles westward into the Gulf of Mexico, modeling the entire peninsula was not feasible within the scope of this study. The model boundary chosen for the Phase I model generally follows a path just north of Polk County and extends around the peninsula approximately 20 miles seaward from the coast (Figure 23). The northern boundary was chosen to ensure that the entire recharge area, the driving force of the model, was incorporated. The remainder of the model boundary was selected a distance offshore to reduce boundary effects, but close enough to the coast to maintain a model size that would not result in unreasonable computation times and to have some information on which to base the head and concentration boundary condition assignments. The model encompasses an area of approximately 39,000 square miles.

Vertically, the mesh/grid was based on the geologic interpretations discussed in the Conceptual Geologic Framework section of this report. The 3-D mesh/grid represents geology between the low water table and the Sub-Floridan Confining Unit. The top of the model is the low water table rather than the land surface. The low water table was generated by selecting the lowest value from the transient data set of SAS monitoring well heads in online databases and interpolating over the model area. Low water table was chosen for the top of model to eliminate computations within the unsaturated zone. Computations within the unsaturated zone are not needed to reach the model goals and would slow model run times. From the low water table, the model extends down to a constant elevation of approximately -3250 feet NGVD. Figure 24 shows a cross section of the geologic units as classified in the 3-D mesh and grid. The cross section shows the distribution of the model's 23 layers of nodes for the WASH123D model and 22 layers of cells for the SEAWAT model. Each geologic unit is represented by a number of layers depending on its importance to the model goals. The SAS is only represented by 1 layer because variation in the SAS is not expected to impact the ASR plan objectives. The UF and MF are each represented by three layers of elements as the results within these layers will affect several ASR plan decisions. Between the LC and BZ is a transition layer that represents a combination of non-continuous permeable layers and confining units. This transition layer also allows for a transition of hydraulic parameters between the low magnitude values assigned for the LC and the extremely high values for the BZ. The cross section also shows that the shallower layers, SAS and IC/IA, are very thin in the recharge area in the northern part of the model and become thicker toward the south. Additional horizontal resolution in the recharge area, an area with large flow gradients, may be necessary for stability because the vertical resolution is fine.

The WASH123D mesh and the SEAWAT grid were developed in GMS using triangular irregular network (TIN) surfaces based on the hydrostratigraphic surfaces from the Preliminary Hydrogeologic Framework. The same TIN surfaces were used to create the mesh and the grid. For both models, a relatively coarse resolution is used for the Phase I study to allow the long-term simulations to run quickly to test many model parameters. Figure 25 shows the resolution and horizontal extent of the mesh and grid.

The WASH123D mesh used element sizes of approximately 25,000 feet along the model perimeter and no additional refinement within the model boundary. The mesh is comprised of 49,151 nodes and 90,376 elements.

The SEAWAT grid is comprised of 41 cells in the x-direction, 56 cells in the y-direction and 22 vertical layers. The model contains 50,512 cells and 55,062 nodes with a cell size of 25,000 feet by 25,000 feet across the entire model domain. The grid developed for the SEAWAT model is oriented along the major direction of flow, 18 degrees southeast, according to the predevelopment flow patterns in the region. The SEAWAT grid is created with the Layer-Property Flow (LPF) package, a MODFLOW package that allows for dipping beds.

4.3 MODEL INPUT PARAMETERS

WASH123D and SEAWAT groundwater flow and transport models are made up of three basic input file types: a 3-D mesh or grid, head and concentration boundary conditions, and initial total head and concentration files. For WASH123D, the 3-D mesh is comprised of unstructured prismatic elements that represent the low water table and geology of the study area. Computational nodes are located at the corner of each element. WASH123D solves for flow and transport parameters, such as head, velocity, and concentration at each node. For SEAWAT, a 3-D grid comprised of cells represents the study area low water table and geology. Computational points for the grid are cell-entered and represent the point at which flow and transport parameters are calculated. For both codes, model boundary conditions are used by the model to define flow and transport parameters within the system that are known with a reasonable degree of certainty. Boundary conditions are generally defined for parameters such as heads along the ocean or lakes and known concentrations such as salinity within the ocean. The initial total head conditions and initial salt concentrations must be defined at every node or grid cell within the model. The initial condition files are used as a starting point in the iterative solution process. The important considerations for each of these input files are described in the following sub-sections.

Both WASH123D and SEAWAT support the input of head data to the model as observed heads rather than equivalent freshwater heads. Equivalent freshwater head is the head of a column of water if the entire column's density is that of fresh water. Observed head is subject to the effects of the variation in density of the water column. During a simulation, the observed heads are applied as boundary conditions and converted to equivalent freshwater heads for the numerical model computations. Both model codes use the equivalent freshwater heads to compute the flow fields and velocities. Once the

head results are computed, the WASH123D code outputs both equivalent freshwater heads and observed heads, and the SEAWAT code outputs observed heads.

4.3.1 TRANSMISSIVITY AND HYDRAULIC CONDUCTIVITY

The transmissivity (T) and hydraulic conductivity (K) are both measures of the capability of an aquifer to transmit water where T is the product of K and the saturated thickness of the aquifer. Because WASH123D utilizes K rather than T as an input parameter, K values were estimated from each aquifer unit using the range of T values from the sources cited in the Conceptual Model. The saturated thickness of the aquifers was estimated from the distance between the hydrostratigraphic surfaces. For the aquifers, it is assumed that the vertical hydraulic conductivity (Kv) is 10 times less than the horizontal hydraulic conductivity (Kh).

For the confining units, MC1, MC2, and LC, Kv values published in the Preliminary Hydrogeologic Framework were input to the model. For the ICU, leakance and Kv values published in the Data Collection Report were used to estimate Kv. Values for Kh are assumed to be 2 times the Kv values.

Figures 26 through 37 present the Kh values and their distribution within each model geologic unit for the WASH123D mesh and SEAWAT grid. Kh values of 1.0 ft/d or less within an aquifer represents an area where the aquifer is not believed to be present based on the Preliminary Hydrogeologic Framework. In the case of the SAS, the IC outcrops to the surface in northwest corner of the model domain so the IC hydraulic conductivities are used within the upper layer of the model. Any element that was found to be completely within the ocean when compared to the bathymetry was assigned with an ocean material type (Figure 38) and a high hydraulic conductivity of 10,000 ft/d. Where the ocean abuts a confining unit hydraulic conductivity, a buffer hydraulic conductivity of 100 ft/d was defined to make the simulation more computationally stable.

4.3.2 STORAGE TERMS

Transient simulations require storage parameters to make the transient calculations. For WASH123D, the storage coefficient is made up of several terms including the porosity, moisture content and modified compressibility of the soil matrix for each geologic unit and the modified compressibility of water. For SEAWAT, the specific yield or specific storage for each geologic unit is defined. The values for the storage terms were obtained from the ASR Benchscale Modeling study (Brown et al, 2006).

4.3.3 WATER TABLE HEAD (RECHARGE)

To simplify the model input, recharge based on precipitation is not used. A specified constant head is assigned to the top of the model that represents the predevelopment water table, created as described in Section 3.2. This provides a constant source of water and the driving force of the model. Figure 39 shows the heads assigned to the SAS layer of the mesh and grid.

4.3.4 PERIMETER BOUNDARY CONDITIONS

The head boundary condition values are specified along the entire model perimeter for

each aquifer. The head data depicted in Figures 12, 13, 14, and 15 are used to help define the specified heads. Along the northern model boundary, the data coverage is good for the SAS and UF; however assumptions are required for the MF, LF, and BZ head boundaries. For the remainder of the model boundary, the head is known for the SAS, i.e. sea level, but the heads for the UF, MF, LF and BZ must be estimated. The UF specified heads are extrapolated from the predevelopment head contours generated by SFWMD in areas beyond the data shown in Figure 13. The MF specified heads along the entire model perimeter are assumed to be equal to the UF specified heads. The LF specified head boundary values are extrapolated from the data shown in Figure 15 along the northern boundary and are assumed to be 0.0 feet on the remainder of the boundary. Specified heads in the BZ are assumed to be 0.0 feet. For aquifer elements on the boundary that are completely within the ocean, a head value of 0.0 feet is assigned. Because many assumptions were made in assigning the specified boundary heads, these values were varied until they compared favorable with the head data. The distribution of assigned observed heads is shown in Figure 40. Figure 41 shows the same view after the observed heads are converted to equivalent freshwater heads.

Boundary conditions for salt concentration were assigned around the entire model perimeter using a variable concentration condition. A variable concentration is equal to the concentration specified in the input file if the direction of flow is into the model. If the direction of flow is out of the model, the concentration on the boundary is computed by the model. For both WASH123D and SEAWAT codes, salinity values along the SAS perimeter boundary are known and are specified as fresh water along the land boundary in the north and 100% salt water along the ocean boundary. Concentrations are also assigned for the SAS on the model top with fresh water specified over land and salt water specified over the ocean. For the UF, an extrapolation of concentrations shown in Figure 17 is used to assign the variable boundary concentrations. Boundary concentrations in the MF are assumed to be the same as for the UF. Figures 16 and 19 are used to help define variable boundary concentrations in the LF. The BZ boundaries are assumed to be fully salt water except for a small area along the northern boundary which is less than 10,000 mg/l based on Figure 16. For aquifer elements that are completely within the ocean, a 100% salinity value of 35,000 mg/l is assigned. Salt concentrations are specified as 35,000 mg/l on the model bottom. The distribution of assigned salt boundary concentrations is shown in Figure 42.

4.3.5 DISPERSIVITY

Dispersion refers to the spreading of salt, or any solute, caused by variations in fluid velocity about the mean velocity. Dispersion is taken into account in the model by defining the longitudinal and transverse dispersivity coefficients that represent mixing. As part of the Data Collection Report, a database of dispersion data for sandstone and carbonate aquifers around the world was created. Few of the values are based on physical test data and most values are based on estimates or groundwater model calibrations. Longitudinal dispersivities range from 0.002 feet to 13,100 feet. Transverse dispersivities are between 1% and 100% of the longitudinal values. Dispersivities are found to be scale-dependent, i.e. for large models, like the Phase I model, the dispersivities are typically higher than for well tracer tests. An analysis of the data

indicates that dispersivity is more of a model calibration parameter rather than a property of an aquifer. While the dispersivity values do depend on the nature of the aquifer materials, they also depend on the size of the flow field and model discretization. A range of dispersivity values were tested for use in the Phase I model as discussed in the sensitivity analyses. A value of 2.5 feet was chosen for use in all the geologic units while a value of 25.0 feet was used for elements within the ocean. For simplicity, the longitudinal and transverse coefficients used are equal. Further study of dispersivity will be performed for the Phase II model including calibration to field values as discussed in Section 8.0.

4.3.6 UNSATURATED PARAMETERS

Because the top of the model is the water table, no unsaturated zones occur within the model. Although they are not used, the WASH123D model requires unsaturated parameters in order to run, so simplified curves were adopted. For SEAWAT rewetting of the cells was allowed in the model, however, none of the cells went dry, so rewetting was not needed.

4.3.7 INITIAL CONDITIONS HEADS

The initial condition potentiometric heads were specified at every computational point in the model. The initial condition is used as a starting point in the iterative solution process. A constant total head was specified as elevation for the steady state model simulation. The resulting heads from the steady state simulation are used to begin the transient simulation. Initial head assumptions have no impact on final results because the convergence criteria used for the steady state results is very small, $1x10^{-6}$ feet.

4.3.8 INITIAL CONDITIONS CONCENTRATIONS

The initial condition salinity concentrations were specified at every computational point in the model based on the visualizations of monitoring well data in aquifers in Section 3.3. In addition, it is assumed that the SAS is 100% salt water in the ocean and 100% fresh water over land. The BZ is 100% salt water except under a small portion of the Polk County recharge area where Figure 16 shows that a value of 10,000 mg/l extends into the BZ. The salt concentrations in the confining units were interpolated based on the aquifer values. The initial condition is used as a starting point in the solution process. The distribution of initial concentrations is shown in the fence diagram in Figure 43 for the WASH123D model, but applies to SEAWAT as well.

4.4 SIMULATION DURATION SELECTION

Because the mesh and grid are coarse and simulations can run fairly quickly, geologic time-scale simulations are possible. Initial simulations were performed starting from 120,000 years ago, the last time that the peninsula was partially inundated by ocean water, and marching through time to the present. Initial concentrations for the simulations were 100% salinity throughout the entire model with fresh water infiltrating through the Polk County recharge area. These simulations were very unstable due to sharp salt fronts moving through the thin vertical elements in that area of the model. A shorter duration model with more variation in initial concentrations was chosen.

As shown in the groundwater age data for the UF and MF in Figures 20 and 21, the oldest groundwater within the aquifers is about 35,000 years old. A total simulation time of 35,000 years was estimated to provide enough time for groundwater to move completely through the system. The boundary heads and concentrations set as described throughout Sections 3 and 4 do not vary over the 35,000 years. The assumption is that the boundaries are in equilibrium over the course of the simulation time.

A time step of 10 years was used. This is the largest time step tested that provided results as accurate as any smaller time step. Time step sensitivities are presented in Sections 5 and 6.

5.0 WASH123D PHASE 1 MODEL RESULTS

The Phase I Regional WASH123D model was developed to meet specific objectives associated with the ASR Regional Study. Few density-dependent models of this size have been completed so the main goal of the Phase I model is to construct a test to determine what problems need to be addressed to build a successful Phase II model. Using the Phase I model, several parameters were tested including code computation parameters, site-specific flow and transport parameters, and code and platform run times. The model results provide insight into how the WASH123D model represents the behavior of the FAS, the impacts of changes in specific model parameters on that behavior, potential missing elements from the conceptual model, and the importance of collecting and understanding all available existing data for formulation of the Phase II model.

When viewing the model results, it is essential to remember that many significant factors are excluded from the Phase I model. The most notable omission is that of pumping stresses. Without pumping, the resulting heads are higher than measured monitoring well heads, the hydraulic conductivity values may not be reliable values and do not have as great an impact on the model results, and computed transport patterns may have a lesser variation. It is not advised that pumping be added to the Phase I model as it exists. The resolution of the Phase I model is not sufficient to capture the behavior of pumping stresses for any pump, let alone the numerous pumping wells that will need to be incorporated to completely assess pumping effects in the FAS.

Another important caveat regarding the Phase I model is related to the model time period. Although the model time period extends over 35,000 years, the model is not necessarily representative of the Florida subsurface changes over that period. Over the last 35,000 years, sea level has varied by 100 feet or more. Wet and dry rainfall periods have impacted the surface heads and recharge. Hydraulic conductivities have varied due to dissolution and diagenesis. The model boundary conditions have not been fixed in time as assumed in the model and salt concentrations 35,000 year ago did not have the pattern used as the initial conditions. This type of data is sparsely, if at all, available. These assumptions and simplifications were used to determine model behavior over a long time period rather than to reconstruct an accurate history of flow and transport in the Florida peninsula.

5.1 WASH123D COARSE MODEL RESULTS

To assess the WASH123D coarse model results, model input parameters were varied within a reasonable range in order to match simulated output to observed conditions within some acceptable error criteria. This comparison was completed for both steady-state or transient conditions. Steady-state model simulations provide a snap-shot of the hydraulic conditions in a stable aquifer system. Steady-state simulations were performed and results compared to observed data to improve model input parameters without waiting for longer transient simulations to complete. However, a transient comparison is a more reliable means of ensuring that a large scale regional model is accurately responding to a variety of stresses. Once model input parameters were relatively close to observed values, transient comparisons were performed. Comparisons of the computed head data were made to the UF predevelopment head contours shown in Figure 13 and to selected monitoring well head data in the IAS, UF, MF, and LF. Comparison to the elevation of 10,000 mg/l TDS map is used to compare salt transport patterns. More important than the actual comparisons of the computed values and monitoring data, this analysis is concerned with reproducing observed flow and transport patterns to generate starting parameters for the Phase II model. This section presents separate results for heads, velocities, and transport leading to a summary of how these results represent the entire system.

Because the monitoring head data are affected by pumping, the best comparison to the simulated heads is the UF predevelopment head contours (Bush and Johnston, 1988). Figure 44 shows the comparison for the steady state condition. Generally the contours agree with the highest heads in the Polk County area and the lowest heads at the coasts. The highest computed head is approximately 115 feet. The highest predevelopment head contour, 120 feet, is in the same area. Agreement between the computed and predevelopment head contours is very good down to the 70-foot contour. There is also fair agreement between the computed and predevelopment contours from the 40-foot contour down to the 10-foot contour. Between the 40-foot and 70-foot contours, the computed heads are much lower than the predevelopment heads. The predevelopment head contours show much higher head values into the southern part of the state.

Comparing the UF predevelopment heads to the UF computed heads after 35,000 years shows that the computed heads in the southern part of the state continue to decrease over time (Figure 45). The heads in the northern half of the model stay nearly the same as those shown in the steady state conditions with some increase in the 50-foot contour toward the west coast. A cross section showing flow vectors through the northern part of the model shows water entering the model in the Polk County area and moving down through the geologic units toward the coasts (Figure 46). Conversely, the flow vectors in a cross section (Figure 47) just south Lake Okeechobee shows that water in the central part of the UF moves vertically upward from the lower aquifers. The flow vectors show this pattern of upward movement throughout the southern part of the state.

In order to see the spatial variation of heads based on monitoring well data, computed water elevations were contoured along with calibration targets. The calibration targets show the location of each monitoring well water level and the relative error between

computed and monitoring well heads. Each target is color coded. Green means that the computed head is within 10 foot of the observed head, yellow means that the computed head is within 15 feet of the monitoring well head, and red means that the computed head is more than 15 feet different than the monitoring well head. If the target is colored above its centerline, the computed head is greater than the monitoring well head. If the target is colored below its centerline, the computed head is less than the monitoring well head.

Figures 48, 49, 50 and 51 show the computed heads and velocity vectors for the four major aquifer units under steady state conditions. In all of the aquifers, the highest computed heads are located in the Polk County and Highlands County areas with computed head values decreasing and the velocity vector pointing out toward the east and west coasts. The calibration targets comparing the computed heads to monitoring well heads are also shown in the figures.

For the IA, most of the wells show green calibration targets meaning the computed heads are within 10 feet of the monitoring wells heads. A few of the computed values are too high. Some of these discrepancies are due to small variations that cannot be reproduced with the coarse mesh resolution. For example, on the Sarasota and Charlotte County border there are two monitoring wells near each other where the heads differ by 13 feet. It is not possible to match both of these values with coarse resolution of this model. Other discrepancies between the computed and monitoring well heads result from the omission of pumping effects. At ROMP-49 near Tampa, the head at the well is largely affected by pumping (Figure 52) so it would be difficult to simulate the heads in this well with the Phase I model. In fact, because the Phase I model does not include pumping, the computed head values are expected to be higher than the monitoring well head values. Velocity vectors within the IA show flow from the Polk and Highlands County areas to the Gulf of Mexico. Outside the limits of the IA, the vectors point more vertically upward or downward transferring flow through the IC toward either the SAS or UF.

The computed head results compared to the monitoring data in the UF and MF show similar patterns to each other. In the Polk County area, where flow enters the two aquifers, the computed head values are generally higher than the monitoring data results. In the southern half of the state, the computed values are lower than the monitoring data results. The plots also show that the velocities are higher in the Polk County area for the UF and MF than in other areas of those aquifers. In the south, the velocities are low, except in the area along the east coast where the proximity to the ocean allows mixing of salt water with the brackish water in the aquifers.

The computed head contours for the LF match reasonably with several monitoring data points in the southern portion of the model; however velocity vectors for the LF appear to show chaotic patterns. To understand these patterns and some of the results in the UF and MF, it is necessary to review the initial salt concentrations and changes to those concentrations over time. Transport of salt is the mechanism that acts to change the model heads over time through solution of the variable density flow equations. Without salt transport, there is no transient stress in the model. Consequently the heads in the IA unit, which is close to the surface and mostly present in the northern part of the model

where water is freshest, do not vary greatly over the course of 35,000 years. Figures 53, 54, and 55 depict the change in salt concentrations from steady state conditions (Time 0.0 years) to the end of the 35,000 year simulation for the UF, MF, and LF, respectively. In the northern part of the model, salt concentrations in the UF and MF change very little since these areas start as fresh water and are constantly recharged by fresh water. In the southern part of the model, salt concentrations increase significantly in the UF and MF as flow from the coast and lower geologic units carry the salt upward and inward from the model boundary through time. The LF starts with concentrations that are much higher than the aquifers above it. In the Polk County area, the LF becomes fresher over time as fresh water infiltrates downward from the UF and MF. Salt concentrations in the LF start high in the south and remain high during the simulation as salt migrates with the upward flow from the bottom of the model.

Another view of the change in concentrations over time is shown in Figure 56. The left and right sides of the figure show elevation contours where salinity concentrations are 10,000 mg/l at time 0.0 years and time 35,000 years, respectively. At time 0.0 years, the elevation contours appear very similar to those shown in Figure 16 in the northern portion of the model, where fresher water is deepest. In the southwest at time 0.0 years, 10,000 mg/l salt concentrations are deeper in Figure 56 than in Figure 16 because the model initial conditions are based on monitoring well data used for Phase I that show that fresher water is located at greater depths. As time progresses to 35,000 years, the area where fresher water is deepest shrinks and moves from Polk County to just northwest of Lake Okeechobee. Also, the depth to fresher water decreases significantly in the south half of the model, especially on the southwest coast where the elevation of 10,000 mg/l TDS changes from -1,800 feet to -600 feet.

To summarize these results, water entering the model in the Polk County area moves downward to provide a source of fresh water to all of the aquifers. The highest heads and lowest salt concentrations occur in this area in all the aquifers. From Polk County, water moves out in all directions. As the water moves south, there is a point in the vicinity of Lake Okeechobee where the heads within the SAS are not high enough to maintain a downward gradient. In this area and south, the gradients of all of the confining units are upward. Freshwater in the UF moves to the surface. Saltier water from below and from the continental shelf on the east infiltrates the MF and UF and acts to reduce the heads in these units over time. As the heads in these units decrease in the southern part of the model, the gradient between the higher heads in the north and lowering heads in the south increases, resulting in a southern shift in the area where fresher water is deepest. The LF is an area where significant mixing takes place between fresher water infiltrating from above and the high salinity water that exists across most of the unit. The chaotic flow patterns seen in the LF are indicative of this mixing.

Numerous model simulations have been conducted to determine if the model is an accurate representation of the flow system or if something is missing in the conceptual model that leads to the significant increase in saltwater in the south. When salt concentrations are low, the southern part of the model is dominated by the boundary conditions. Looking at the UF steady state head results, Figure 48, the computed boundary heads all compare favorably with the monitoring well heads. The boundary

condition values could be revised to match these boundary wells more closely. However, during the transient simulation when salt water begins to enter the UF, the heads decrease significantly across the entire southern portion of the model. Based on data presented in the Conceptual Model section, these heads in the UF and MF are higher than the computed results at the end of the simulation and likewise the actual salt concentrations are lower.

The main problem is to identify the mechanism to allow more freshwater into the south part of the UF and MF aquifers. Freshwater can only come from the surface or from the upgradient Polk County area. Unless there is a shallow artesian aquifer south of Lake Okeechobee that has higher heads than the UF, the gradient will be upward preventing any surface freshwater from entering the UF. While artesian SAS aquifers do exist and have heads higher than the UF heads in some locations (i.e. beneath the Caloosahatchee River Basin), in areas further south their heads are not higher than the UF heads. If the hydraulic conductivity in the UF or MF is higher than that selected in the conceptual model, it is possible that more freshwater will travel to the south. Trials of several hydraulic conductivities in these aquifers improve the model results only slightly. If the hydraulic conductivity of the MC2 confining unit is lower or the IC is tighter, it is possible that more freshwater will travel to the south part of the UF and MF aquifers. Trials of several hydraulic conductivities in these confining units also showed only small improvements in the model results. Decreasing the hydraulic conductivity in the MC2 also acts to reduce the amount of water that enters the UF and MF because the gradient is upward. The hydraulic conductivity of the IC in the south is very small even in the conceptual model and reductions do not cause significant model changes. Another potential mechanism for freshwater flow south of Lake Okeechobee is preferential flowpaths or fractures. The USGS predevelopment head contours and the monitoring data indicate that the higher heads observed in the UF fall along a fairly narrow axis along the center of the peninsula. It is possible that a preferential pathway exists that leads flow from north to south along that axis. In fact, a recent unpublished study by the USACE, Jacksonville District identifies several northeast trending surface lineaments on the northwest side of Lake Okeechobee. Surface lineaments indicate possible fractures or fault zones which could act as conduits for groundwater flow.

Other possible explanations for the discrepancy in model results and observed values are related to model construction and assumptions. Many of the model parameters are dependent on mesh resolution. It is possible that with the more refined mesh that will be used for Phase II, some of the discrepancies in the results will be resolved. Also, a major assumption in conceptualizing the Phase I model is that the boundary conditions do not change over time and that the initial salt conditions, which represent salt conditions today, are representative of salt conditions 35,000 years ago. Over the last 35,000 years, there have been several major changes that are not coded into the model including changes in sea level which lead to changes in head and salt levels, changes in precipitation amounts, and changes to hydraulic conductivity in the geologic units due to dissolution and diagenesis.

A complete explanation of the salt migration processes over 35,000 years may be beyond the scope of the ASR Regional Model effort. To meet the Regional Study goals, the

Phase II model has to adequately capture the migration patterns over the calibration and validation periods and over the selected duration of the predictive simulations. For the calibration and validation periods, the simulation duration will be approximately 1 year. For the predictive simulations, the duration will be on the order of 1 to 50 years. Using the Phase I model run times as a guide, a simulation with a 5-day time step and a duration of 50 years shows a salt concentration change of less than 1 percent inland from the boundaries in the FAS. It may be that for the Phase II model runs, regional salt migration will not have a significant impact on the computed results relating to the specific ASR-related goals for the study.

5.2 WASH123D SENSITIVITY ANALYSIS RESULTS

Sensitivity analyses were performed to determine how changes in input values affected the model results compared to the base run results described in Section 5.1. Several parameters were varied as part of the Phase I model to determine what variables have the greatest impact. Those parameters include hydraulic conductivity, initial concentrations, concentration boundary conditions, dispersivity, time step size and temperature effects on boundary conditions in the BZ. The sensitivity analysis duration was chosen at 10,000 years to provide enough simulation time for significant changes in results to be observed without unnecessarily extending run times. The results of the Phase I sensitivity analysis provide some basis for how Phase II model parameters will behave however, most of these parameters are heavily dependent on mesh resolution. Additional sensitivity analyses will be performed as part of the Phase II modeling.

5.2.1 HYDRAULIC CONDUCTIVITY – AQUIFERS

Hydraulic conductivity was varied in all of the aquifers in the model by doubling and halving the values used for the base run. Head and concentration results compared in the Upper Floridan are typical of the results shown in the Middle and Lower Floridan. The base run head and concentration results at time 10,000 years across the model are shown in Figure 57 for the UF. Figure 58 presents the head and contour results for the UF for doubling the hydraulic conductivities in all the aquifers. When the aquifer K values are doubled, the resulting heads in the UF are lower than the base run along the central ridge of the peninsula. Between the central ridge and the coasts, the UF head values are higher than the base run head values except near the area where the UF abuts the ocean. The largest head differences are in the Polk County area with a maximum of approximately 6 feet. The concentrations decrease across the model when the aquifer K values are doubled except near the east coast where the UF abuts the ocean. In other words, in the Polk County region, fresh water enters the aquifer and the higher K values allow the fresh water to move quickly through the region resulting in lower heads and concentrations. The higher conductivities also allow fresh water to move more quickly out from the central ridge extending the area of fresher water and lowering concentrations. The increase in heads between the central ridge and the coast for the higher K run is a combination of the decrease in concentrations and the milder gradient between the lower maximum heads in Polk County and the constant boundary conditions. Near the ocean, the higher hydraulic conductivities allow salt intrusion to occur more quickly increasing the concentrations and decreasing the heads. Figure 59 shows the UF head and concentration results when the aquifer hydraulic conductivities are halved compared to

the base run. With the aquifer conductivities halved, the results are the opposite of doubling the conductivities.

Neither doubling nor halving the hydraulic conductivities in the aquifers has a significant impact on the flow or concentration patterns for the Phase I model.

5.2.2 HYDRAULIC CONDUCTIVITY – CONFINING UNITS

Hydraulic conductivity was varied in all the confining units in the model by doubling and halving the values used for the base run. Head and concentration results compared in the Upper Floridan are typical of the results shown in the Middle and Lower Floridan. The base run head and concentration results at time 10,000 years across the model are shown in Figure 57 for the UF. Figure 60 presents the head and contour results for the UF for doubling the hydraulic conductivities in all the confining units. When the confining units are more permeable, the resulting UF heads are higher than the base run along the central ridge of the peninsula because more fresh water is able to infiltrate from the surface. The UF heads are lower near the coasts and in the southern part of the peninsula when the confining units are more permeable compared to the base run due to saltwater intrusion from the coasts and from deeper units. Figure 61 shows the UF head and salt concentration results when the confining unit hydraulic conductivities are half as permeable. The results of halving the confining unit hydraulic conductivities are the opposite of doubling the conductivities.

Doubling the K values in the confining units has a larger impact on the model results than halving the confining unit K values, especially in the southern part of the model. For example, at the location where Dade, Broward and Collier Counties meet, the head value is 6 feet lower when the confining unit K values are doubled than the head values for the base run. When the K values are halved, the UF head at that location is only approximately 2 feet higher than the UF head for the base run. This result is directly related to the upward direction of the velocity vectors in the southern part of the model. When the confining units are more permeable, more salt water upwells to shallow aquifers. When the confining units are less permeable, the upwelling occurs but at a slower rate.

5.2.3 INITIAL CONCENTRATIONS

Initial concentrations were increased and decreased by 25% compared to the base run. The minimum and maximum concentrations were maintained at 0 mg/l and 35,000 mg/l, respectively. Head and concentration results compared in the Upper Floridan are typical of the results shown in the Middle and Lower Floridan. The base run head and concentration results at time 10,000 years across the model are shown in Figure 57 for the UF. Figures 62 and 63 show the heads and concentrations within the UF after 10,000 years when the initial concentrations are increased and decreased by 25%, respectively. The UF heads and concentrations along the central ridge of the model after 10,000 years are almost exactly the same for the three different initial conditions as shown in Figures 57, 62, and 63. The UF initial concentrations in the base run are very low in that area so varying them by +- 25% does not change the values significantly. In addition, fresh water enters the model in that area keeping the concentrations low. Beyond the central

ridge area, the UF heads are lower and concentration are higher where the initial concentrations were increased by 25% and the UF heads are higher and concentrations are lower where the initial concentrations were decreased by 25% compared to the base run. Note that the concentrations at 10,000 years are significantly impacted by the initial concentrations. When the concentrations start higher they remain higher for the duration of the simulation and vice versa.

5.2.4 CONCENTRATION BOUNDARY CONDITIONS

For the base run, the boundary salt concentrations are assigned as a variable boundary condition. This boundary condition allows the concentrations to be calculated by the model when the flow direction is out of the model. When the flow direction is into the model, the concentrations are defined based on a specified concentration that varies within each aquifer. A sensitivity analysis was performed to observe the results if the salt concentrations on the boundary were held constant using the observed data for each aquifer. The resulting heads and concentrations for the UF and LF are not very different compared to the base run. Generally, the UF heads are slightly lower and the LF heads are slightly higher than the base run. The opposite is true for the salt concentrations. In the MF, the head results can vary up to 5 feet. Also, the MF salt concentrations near the boundary increase as a result of salt intrusion from below. This creates a strange pattern where the concentration on the boundary is fixed at a lower value but just inside the boundary the concentrations are 20,000 mg/l higher (Figure 64). Therefore, it appears that the specified concentration boundary conditions do not provide an accurate picture of flow and transport patterns. Although the variable concentration boundary condition appears to provide the model more freedom to compute accurate flow and transport patterns, some oscillation occurs on the boundary which may result in propagation of error through the model. This is discussed further in Section 7.0.

5.2.5 DISPERSIVITY

Several values of dispersivity, 0.0, 25.0 and 250.0 feet, were tested and the results were compared to the base run results. The dispersivity of the base run is 2.5 feet for all materials except the ocean and the ocean buffer material types where dispersivities of 25.0 feet and 10 feet, respectively, were used. The dispersivities of the ocean and ocean buffer materials for the base run were the lower limits used for those material types in the sensitivity runs. As dispersivity increases, the rate of mixing of higher salinity water with lower salinity water increases. Through the upper part of the model, from the surface down to the MF, the salt concentrations are initially low, so a higher dispersivity acts to increase the concentrations and lower the heads in those areas over time. In some areas of the LF and deeper units where salt concentrations are initially high, large dispersivities cause a salt concentration reduction and an increase in head.

A further investigation was completed to determine the impact of dispersivity variation on head and concentration at specific wells within the UF. ROMP-45 is located in Polk County where water enters the UF from the surface geologic units. ENP-100 is located in Dade County where water enters the UF from the deeper geologic units. Locations for both wells are shown in Figure 57. Figure 65 shows the head and concentrations results over time for dispersivities of 0.0, 2.5, 25.0, and 250.0 feet. Note that for a dispersivity

of 0.0 feet, the code was unable to converge after 4,000 years as small instabilities can not be smoothed out without any mixing coefficient. At ROMP-45, the resulting concentrations vary through time from the initial concentration until a particular time when the concentration becomes constant until the end of the run. For a dispersivity of 250.0 feet, the concentration increases to a constant value of almost 6,000 mg/l. This result is unlikely to be correct since ROMP-45 is within the Polk County area where concentrations are expected to be low. The results from the runs with dispersivity values of 2.5 feet and 25.0 feet seem more reasonable as the concentrations are less than 1,000 mg/l. The same pattern is true for the head results at ROMP-45 where the heads for a dispersivity of 250.0 feet are much less than the values for both 2.5 feet and 25.0 feet. Also notable at ROMP-45 is that the heads decrease initially and then increase until approximately 4,000 years when a constant value is reached. This dip in the graph indicates an initial period of instability until the model reaches an equilibrium. In the case where dispersivity is 250.0 feet, the instability is so large that the long-term results are impacted.

In the southern part of the model at ENP-100 (Figure 65), the salt concentrations for the variety of dispersivities increase through the simulation as salt water intrusion occurs from the east coast and from the deeper geologic units. No constant value is reached as the salt continues to increase, and therefore the heads decrease, through time. The largest magnitude of increase in salt concentrations and decrease in head is shown for the dispersivity of 250.0 feet. The smallest changes in concentration and head are shown for dispersivities of 0.0 and 2.5 feet.

Based on these results, it is reasonable to remove a dispersivity of 250.0 feet from consideration as it results in too much mixing. However, it is difficult to determine which is better between a value in the magnitude of 2.5 or 25.0 feet. For the Phase I base run, a dispersivity of 2.5 feet was chosen in an attempt to limit the mixing and salt intrusion in the southern part of the model. For the Phase II model, additional sensitivity analysis will be completed to provide more insight in selection of this parameter. In Phase II, the spatial and temporal discretizations of the model will be more refined which will have a significant impact on dispersivity. In addition, whereas the Phase I model has a constant dispersivity across all the geologic units, the Phase II model will take account potential variation of dispersivity through and between geologic units. Calibration of the Phase II dispersivities will be dependent on data, where it's available, as discussed in Section 8.0.

5.2.6 TIME STEP SIZE

Several time steps were evaluated to determine the largest time step (i.e. shortest run time) that provides accurate results. These values include 0.2 year, 1 year, 5 years, 10 years and 100 years. Plots were created depicting the head and concentration variation over time at two specific wells within the UF (Figure 66). Locations for the two wells are shown in Figure 57. ROMP-45 is located in Polk County where water enters the UF from the surface geologic units. ENP-100 is located in Dade County where water enters the UF from the deeper geologic units. At ROMP-45, the heads are almost identical for each of the simulations tested except for the 100 year time step. Even for the 100-year

time step, the resulting heads are only approximately 0.5 foot higher than the head results using the other time steps. The concentration results at ROMP-45 using the different time steps are all very similar and decrease to a constant value of almost 0.0 mg/l at 5,000 years. Note that only 1,000 years are plotted in Figure 66 for ROMP-45 so the variation between the simulations is visible. At ENP-100, the head values decrease and concentrations increase throughout the simulation time for all the different time steps evaluated. The 100-year time step yields results that have the largest deviation from the results of the other time step simulations. The 100-year time step results are only plotted out to 3,000 years on Figure 66 because the simulation failed to converge due to boundary instabilities. The 0.2-year time step results are only plotted out to 1,000 years for the same reason.

Based on the results of this sensitivity, the 10-year time step was selected as the most computational efficient time step size because it provides the shortest run time and results that are very similar to those produced by the smaller time steps.

5.2.7 LIMITED TEMPERATURE EFFECTS IN THE BOULDER ZONE

The effect of temperature variation in the Boulder Zone was coded into the head boundary condition of the model for that geologic unit to observe any impact it may have on the aquifers above. Figure 67 shows the head used for the BZ boundary that incorporates the temperature effect on density added to the assumed head for the BZ boundary condition of 0.0 feet around the perimeter of the model. Note that heat transfer, temperature effects on salt concentrations on the boundary of the BZ, and temperature effects on head and salt concentrations within the model boundary and on other geologic units are not considered. Revising the boundary heads in the BZ does have an effect on the heads in the geologic units above the BZ as shown in Figure 68. The figure shows two maps of change in heads resulting from the revised BZ boundary condition as compared to the base run for Time 0.0 years. The impact on the heads in the overlying units is largest at Time 0.0 years and decreases as the model simulation proceeds. The left map shows the head change in the UF and MF layers where the magnitude varies from -1.0 foot on the southeast coast to 5.0 feet on the southwest coast. The map on the right shows the head change in the LF where the magnitude varies from -2.0 feet on the southeast coast to 18 feet beyond the southwest coast.

These results show that the temperature effects can have a significant impact on the computed model results. Consideration should be given to including temperature effects in the Phase II model boundary conditions or the possibility of including full heat transfer computations, if feasible.

5.3 WASH123D SALTWATER INTRUSION RESULTS

Where the model boundary extends to the Atlantic Ocean, it is possible to observe how the model behaves due to the effects of saltwater intrusion. Figure 69 shows the salt fronts at three time steps over the 35,000 year simulation at a cross section through the mixing zone. Comparing the three snap shots reveals the salt fronts in the UF, MF and LF moving westward from the coast. For the UF, the concentrations increase from a range up to 3,500 mg/l to a range up to 10,500 mg/l with the 10,500 mg/l contour moving

westward by approximately 30 miles over 35,000 years. In the MF, the concentrations increase from a range up to 7,000 mg/l to a range up to 14,000 mg/l with the 14,000 mg/l contour moving westward by more than 40 miles over 35,000 years. The concentrations in the LF increase from a range up to 28,000 mg/l to up to 31,500 mg/l and the 31,500 mg/l contours moves westward by approximately 15 miles. Even at the coarse resolution of the Phase I mesh, the wedge shape of the salt water front in each aquifer is clearly visible with the denser, saltier water extending further westward along the bottom of the aquifer and the less dense, less salty water extending further eastward along the top of the aquifer. This demonstrates that WASH123D is capturing the processes that occur in the saltwater intrusion mixing zone which will be important for the Phase II model.

6.0 SEAWAT PHASE I MODEL RESULTS

As stated previously, the Phase I modeling effort included the construction of a fully density-dependent SEAWAT model. This model had essentially the same grid resolution and utilized the same hydraulic parameters developed for the Phase I WASH123D model. The purpose of this SEAWAT model was to provide a comparison of the WASH123D model results, identify similarities and differences in the flow and concentration fields computed by the two models, and help identify issues to be addressed in the Phase II modeling effort.

Using the Phase I SEAWAT model, several parameters were tested including code computation parameters, site-specific flow and transport parameters, and code and platform run times. The model results provide insight into how the SEAWAT model represents the behavior of the FAS, the impacts of changes in specific model parameters on that behavior, potential missing elements from the conceptual model, and the importance of collecting and understanding all available existing data for formulation of the Phase II model.

Since the SEAWAT model was constructed in a manner consistent with the WASH123D model, this SEAWAT model will have the same abilities and limitations discussed for the WASH123D model. Another potential limitation of the Phase I model is the relatively coarse vertical discretization. The model contains 22 vertical layers. The UF and the MF are represented by three layers each; the LF has two model layers. Guo and Langevin (2002) discuss the importance of grid resolution for variable density flow models in particular vertical resolution. In areas of complex flow patterns and high concentration gradients, additional vertical discretization often is needed to adequately represent the flow system. These authors have found that vertical grid resolution often needs to be much finer than horizontal resolution and recommend up to 10 model layers per aquifer. The grid will be refined in Phase II of the ASR modeling study.

6.1 COMPARISON OF WASH123D AND SEAWAT RESULTS

The SEAWAT model was run as a base case to 35,000 years with two stress periods starting with a steady state stress period for one day. Those steady state results were used as the starting point for the transient stress period. Most parameters were kept the same between the WASH123D and SEAWAT models; however, minor variations were required due to the inherent differences between the model codes. The SEAWAT model

was not compared to monitoring well data to determine input parameters, but rather used the input parameters generated from the WASH123D results for the same period. When the results of the WASH123D and SEAWAT models were compared, several interesting similarities and differences were observed.

The steady state results computed for both the SEAWAT and WASH123D models were similar. Figures 70, 71, 72, 73 and 74 show the computed heads in both models for the SAS, UF, MF, LF, and BZ, respectively. The computed SEAWAT heads are shown as dashed lines while the computed WASH123D heads are shown as solid lines. Although some minor discrepancies exist, the regional steady state flow patterns simulated for both models are reasonably consistent.

The results of the transient simulations revealed that several differences exist between the WASH123D and SEAWAT model results. The magnitude of these differences increased with time. One of the most notable differences occurs in the BZ in the Polk County area. Figure 75 shows that after 35,000 years the WASH123D simulation computes heads in Polk County of between 30 and 40 feet, while SEAWAT computes higher heads of approximately 60 to 70 feet in the same area. The differences in heads between the two models are directly related to the way in which salt concentrations are computed in each model. In both models the salt concentrations in the northern portion of the BZ start at 10,000 mg/L TDS. However, in the WASH123D model, the concentration quickly increases to a fully saline concentration of 35,000 mg/L TDS. Conversely, the concentrations computed in the SEAWAT model gradually decrease during the simulation to a concentration of less than 100 mg/L TDS at 35,000 years. Figure 76 shows a cross sectional view of the concentration distribution in each model after 35,000 years. The primary reason for this discrepancy is due to differences in the boundary conditions applied to the bottom of each model. In the WASH123D model, the BZ is represented by one element layer with computational nodes above and below this layer. The conceptual model for the BZ assumed that the bottom of the BZ is a no-flow boundary with a constant saline concentration. As such, a constant salt concentration boundary condition of 35,000 mg/L was applied to the bottom layer of nodes in the WASH123D model. In the SEAWAT model, one element/cell was again used to simulate the BZ. However, since the computations are cell centered in SEAWAT, a constant concentration boundary condition could not be reasonably applied without overly constraining the salt transport in the bottom layer of the model. Instead a variable boundary condition was applied that allowed the model to compute the concentration in the BZ based on the flow and concentration of the surrounding cells, unless flow was into the model from the boundary. Along the model boundary, if the flow was into the model, the assigned salt concentration of the fluid entering the model was assumed to be 35,000 mg/L TDS. After comparing the computed results in both models, the WASH123D model was modified to simulate a variable boundary condition similar to that used in the SEAWAT model. Figure 77 shows the computed heads in the BZ at 20,000 years in the SEAWAT model and the revised WASH123D model. This figure illustrates that once the WASH123D boundary condition was revised to a variable concentration type boundary, the computed results are similar in WASH123D and SEAWAT. Figure 78 shows that this revision also improved the correlation between the two models in the Polk County area in the LF.

In addition to the differences noted in the heads of the BZ and LF, the heads in the southern portion of the UF and MF (Figures 79 and 80, respectively) appear to be lower in the SEAWAT model. This again is a direct result of the salt migration patterns. In these areas of lower head, the SEAWAT model computed higher salt concentrations than those in the WASH123D model. Figure 81 shows a cross section view of the concentration distribution in each model after 35,000 years. These differences in computed salt migration may be caused by the resolution of the mesh and grid used in the models and how each model calculates hydraulic conductivity for a particular element or cell. Figure 82 shows a simplified representation of the way in which vertical hydraulic conductivities are treated in each model. For the numerical computations, WASH123D determines the inter-nodal conductivity based on the conductivity assigned to each of the elements in the model. This inter-nodal conductivity is used in the matrix equations to resolve the flow fields and corresponding heads at each finite element node. SEAWAT treats the conductivity slightly differently. The vertical conductivity between each cell is described as the equivalent conductance between the cells, when a fully three dimensional approach is used. This difference in the treatment of vertical hydraulic conductivity is compounded by the configuration of the finite element computational nodes and the finite difference computational cells. As shown in Figure 82, the finite element nodes are not located at the same horizontal and vertical location as the center of the finite difference cells. Some of the issues with vertical conductance may be resolved by adding increased vertical discretization in the Phase II SEAWAT model.

The differences in computational methodologies and treatment of hydraulic parameters between WASH12D and SEAWAT may require actual calibration to observed heads and salt concentrations for both models in Phase II of the project. The WASH123D model parameters were determined as discussed in previous sections of this report; however, the SEAWAT model used hydraulic and transport parameters from the WASH123D model and the best parameters for the SEAWAT model were not developed independently. Hydraulic parameters used to calibrate the finite difference based model may be slightly different than those required to calibrate the finite element model. A detailed examination of this phenomenon was not within the scope of the Phase I ASR work.

6.2 SEAWAT SENSITIVITY ANALYSIS RESULTS

In addition to the comparisons between the SEAWAT and WASH123D results, several sensitivity analyses were performed on the SEAWAT simulation. These sensitivity analyses varied parameters such as time step size, flow and transport solvers, dispersivity and initial salt concentrations. The results of these sensitivity simulations were then compared to the base run described in the previous section. As discussed for the WASH123D model, the results of the Phase I sensitivity analysis provide some basis for how Phase II model parameters will behave. However, since most of these parameters are heavily dependent on mesh resolution, additional sensitivity analyses will be performed as part of the Phase II modeling.

6.2.1 TIME STEP SIZE

Time step size sensitivity SEAWAT model runs were made using the Strongly Implicit

Procedure (SIP) flow solver and the implicit finite-difference solver with upwinded weighting to solve the solute transport equations. This transport solver allows the user to select the length of the transport time step, however long transport time steps with this method can lead to problems with numerical dispersion that can result in sharp concentration fronts and large concentration gradients.

Model simulations using a 0.1 year, 1 year, 10 years and 100 years time step sizes were evaluated to determine the largest time step (i.e. shortest run time) that provides accurate results. Plots showing head and concentration variation over time at two specific wells within the UF (ROMP-45 and ENP-100) are shown in Figure 83. At both wells, the base run time step size of 10 years, shows oscillations in the computed heads for the first 100 year period. These oscillations are substantially greater in the ROMP-45 well. After this first 100 year period, the computed heads using the 10 year time step are in relatively synchronous agreement with the heads computed using the 0.1 and 1 year time step sizes. Results at both wells also show noticeable deviations in the computed heads when the time step size is increased to 100 years.

6.2.2 SOLVER

SEAWAT uses one set of solvers for the flow portion of the variable density flow equation and another set of solvers for the solute transport portion of the equations. Osiensky and Williams (1996) discuss the accuracies and problems associated with different flow solvers. The solvers that had the best results were the Strongly Implicit Procedure (SIP) and Preconditioned Conjugate-Gradient (PCG2) solvers. The main flow solver used for the Phase I modeling was the SIP solver, although the base run was tested with the PCG solver as a test of solver sensitivity. An advantage of the PCG2 solver is that one of its convergence criteria depends on the water budget, so errors related to water budget are reduced. In addition to the PCG2 solver, a sensitivity simulation was also performed using the Geometric Multigrid Solver (GMG), based on recommendations from the USGS. The computed heads using each of these flow solvers at groundwater wells, ENP-100 and ROMP-45, are shown in Figure 84. The heads computed using each of these flow solvers are reasonably correlated. All SEAWAT runs had solutions that converged, except where noted, and mass balance errors that were less than 1.0%.

In addition to flow solvers, different numerical methods and corresponding solvers exist to solve the advection-dispersion-reaction equations. Details of the transport solvers are described by Zheng and Wang, 1999. One solution method is the Eulerian approach which uses a fixed grid, in this case a finite difference grid, to solve the transport equation. The Eulerian approach is better in advection-dominated groundwater systems, but may be subject to numerical dispersion and/or artificial oscillation in the results. Two options within the Eulerian approach finite difference solution are available to calculate advection; upwinded weighting and central-in-space weighting. Upwinded weighting can result in fewer oscillations, but numerical dispersion can be increased because upwinding provides only a first order solution. Central-in-space weighting solves the advection term with an accuracy to the second order and problems related to numerical dispersion are minimized. However, if the transport in the system is advection-dominated, this scheme can cause excessive oscillation in the model results. Because of this oscillation issue,

Phase I simulations using the central-in-space weighting methodology were very unstable and consequently are not evaluated as part of this sensitivity analysis. The standard finite difference method is somewhat limited in systems that are advection-dominated, however, when the grid Peclet number is smaller than four (Zheng and Bennett, 1995), this method is thought to be reasonably accurate. Another advantage of the finite difference method is faster run times.

Another class of transport solution techniques for advection are the total-variation-diminishing (TVD) methods. MT3DMS contains a third-order TVD solver with a universal flux limiter called the third-order ULTIMATE scheme (Zheng and Wang, 1999). This scheme conserves mass, has little numerical dispersion, and is fairly free of numerical oscillation. TVD solutions are generally more accurate for advection-dominated flow, but have much longer run times than the finite difference methods.

The SEAWAT model for Phase I was run initially with the finite-difference solution for the transport equations with upwinded weighting. Sensitivity runs were made to test the central-in-space weighting, and also the third-order TVD solver. The TVD runs were slow in comparison to the standard finite difference solver simulations. The TVD solver selects the best time step that meets convergence criteria. For SEAWAT runs with the TVD solver, the Courant number was specified to be 0.75. For these SEAWAT TVD runs, the time step size was on the order of 0.2 days. By comparison, the upwinded simulations used time step sizes of 10 years. This resulted in significantly longer model run times for the TVD simulations, as shown in Section 8.2 of this report. The computed heads for each of the transport solver simulations at the ENP-100 and ROMP-45 groundwater wells are shown in Figure 84. This figure shows that although more oscillation occurred in the finite difference solver simulations, the results of the TVD solver are higher than those computed using the upwinded methodology. This slightly higher head in the UF, is the result of slower vertical salt migration in the TVD solution. However, it is important to note that because of the extended run times for the TVD solution, only 1,000 years of each simulation is shown on Figure 84. Since the ASR injection and extraction is expected to be advection-dominant, the computed differences between the two transport solvers are expected to be significant once pumping stresses are incorporated into the model. Additional methodologies for increasing the speed of the simulations using the TVD solver are being examined. The goal of this effort is to be able to decrease the run time of the TVD simulations, without compromising numerical accuracy in the Phase II modeling effort.

6.2.3 DISPERSIVITY

The dispersivity sensitivity analysis performed for the SEAWAT simulation was similar to that performed for WASH123D. The baseline SEAWAT simulation used a dispersivity value of 2.5 feet for longitudinal and transverse dispersivity for the aquifer and confining unit materials, which was the same as used in the baseline WASH123D simulation. The ocean and the ocean buffer used dispersivities of 25.0 feet and 10 feet, respectively. For the SEAWAT sensitivity analysis, dispersivity values of 0.0, 25.0 and 250.0 feet were simulated and compared to the base run. The dispersivities of the ocean and ocean buffer materials for the base run were the lower limits used for those materials in the sensitivity runs.

As seen in the WASH123D dispersivity sensitivity analysis, increases in dispersivity generally resulted in higher concentrations with time. This increase in concentration resulted in a corresponding decrease in heads, especially in the southern portion of the model. An example of this can be seen in the vicinity of ENP-100. Figure 85 shows the head and concentration profiles for the dispersivity simulations at ENP-100 and ROMP-45. The charts for ENP-100 show an increase in concentration and decrease in head as dispersivity is increased. This indicates that as dispersivity increases, the rate of mixing of higher salinity water with lower salinity water also increases.

A similar trend, but with a smaller magnitude, is observed in the Polk County area. In this area of the model, the concentration generally drops with time. However, increases in dispersivity tend to keep the concentrations higher for a slightly longer period of time. This results in slightly lower computed heads in the high dispersivity simulations, as shown ROMP-45 charts in Figure 85. Since dispersivity is scale dependent parameter, further evaluations of its affect on computed heads will be performed for the more refined Phase II model.

7.0 SOURCES OF ERROR

Many potential sources of error exist for the Phase I model. For such a large model, it is impossible not to condense available data and make several simplifying assumptions. In addition, the Phase I model is a test bed model so some simplifications are built-in to the conceptual model with the knowledge that more details will be incorporated and more data will be available for Phase II.

Model Resolution

The horizontal distance between computational points for the WASH123D and SEAWAT models is 5 miles. The vertical distance between computational points varies, with some computational points only a few feet from each other as found in the northern part of the SAS and others up to 500 feet apart as found in parts of the MC2. This resolution contributes to several potential sources of error. The surface heads are set as fixed boundary conditions across the top of the model. Because the computation points are 5 miles apart, the driving head of the model is very dependent on the interpolation of the data applied to the surface. For example, if the computational points fall on either side of the central ridge through Polk and Highlands Counties, the highest value of head that forces water into the top of the model may be missed therefore underestimating the head in geologic units below. Also the location where the majority of water enters the model from the top is the same area where the model elements are very thin vertically compared to their large horizontal scale. Large gradients occurring through these horizontally coarse and large aspect ratio elements/cells may result in increased instabilities which can propagate through the model. Generally, the large distances between the computational points leads to the inability to resolve small variations that may be important to fully understand the flow and transport results.

Boundary heads and salt concentrations

An exhaustive data search was not completed for the Phase I model. Particular data that was considered representative was selected for use in determining head and concentration boundary conditions. No attempt was made to collect data to vary the head and

concentration boundaries through time. This strategy was implemented in order to shorten the time needed for data collection and model construction so that boundary conditions and other parameters could be tested. Additional data collection for Phase II will provide more information on which to base boundary conditions, allow transient boundary condition assignments, and therefore reduce the error associated with estimating the boundary values.

It will not be possible to completely eliminate the error regarding the boundary conditions. One problem is the availability of data for use along the boundaries. For the UF, a large number of monitoring wells exist to provide head and water quality data over time. In the LF and BZ, this is not the case and some estimation will still be required and potential errors will exist. In addition, because the model boundaries are set 20 miles into the ocean, the head and concentration boundary conditions for the UF, MF, and LF are extrapolated from the selected data at the Florida coast. This extrapolation introduces uncertainties that are a potential source of error for the model. This is especially true in the southern portion of the model where boundary conditions have a greater impact on the head and concentration results. As discussed in Section 8.2, the Phase II model boundary may be moved inland along the western coast of Florida to minimize the amount of extrapolation necessary to generate the boundary condition values.

The model boundaries were set out from the coast to reduce boundary effects in the areas of the proposed ASR wells. Because a variable concentration boundary condition is used, oscillations of concentrations and heads are possible due to minor changes in flow direction at computational points on the model boundary. If the direction of flow varies over consecutive time steps such that flow is into the model for one time step but out of the model for the next time step, then the salt concentration is computed differently for the two time steps. Also, when heads are specified, it is the effective freshwater head that is specified rather than the observed head. Therefore a change in concentration over two consecutive time steps results in a change in observed heads when the constant equivalent freshwater head is converted to observed head. Figure 86 shows a graph of head and salt concentration computed using the WASH123D model over the simulation duration for a node on the boundary in the MF. The observed head specified at the node is 35 feet and the concentration is variable with a value of 5,200 mg/l specified when flow is moving into the model. The observed head oscillates around the specified value of 35 feet and the salt concentration oscillates around the model computed value of approximately 11,000 mg/l. The southern boundary of the MF is the model location where the oscillations are the most pronounced. A plan view of the south boundary of the MF (Figure 87) shows that the oscillating head and concentrations do not propagate to the interior of the model and so do not have a critical impact on the results. However, for this reason, it is appropriate to maintain the model boundaries far away from the areas of interest.

More investigation of this boundary oscillation issue will be conducted for the Phase II model. For the Phase II model, maintaining the boundaries at 20 miles offshore with a finer spatial discretization may result in too many model computational points. With a finer spatial and temporal discretization and shorter simulation duration that will be used for Phase II, the oscillations observed in the Phase I model may not occur.

Pumping

As mentioned several times through this report, pumping is not included in the Phase I model which constitutes a significant source of error for the head and concentration results and the determination of other parameters such as hydraulic conductivity. Pumping was excluded to shorten the data collection and model set-up time and because the model resolution was not sufficient to support pumping. Pumping will be included in the Phase II model and will also be considered a source of error for that model. Errors associated with the availability and accuracy of transient pumping data and the likelihood that several pumps will need to be combined on a computational point will result in sources of error for Phase II.

Dispersivity

For this study, the value of dispersivity used in the model is an estimate. From the sensitivity results, it appears that the value is in the range of 1 to 50 feet, however no site specific data has been reviewed at this time. Site specific data will be reviewed in conjunction with the Phase II model (Section 8.2) to attempt to obtain values that are more representative. However, because dispersivity is difficult to measure and depends on mesh/grid resolution as well as geologic material, some variation in this parameter will remain to be a potential source of error for Phase II.

Time Step and Duration

The use of such a large time step, 10 years, creates some error in the model results. However the time step sensitivity plots indicate that this error is small enough to be acceptable for this Phase I test model. Use of smaller time steps does produce less instability on the boundaries. For Phase II, a much smaller time step will be required because the spatial resolution will be refined. A time step sensitivity will also be performed for all Phase II models.

The Phase I model duration is 35,000 years. Data is not available for this time period to determine the accuracy of the initial condition concentrations or to understand how the head and concentration values have varied over that period. The Phase I model is not an accurate representation of actual changes in head and concentration over 35,000 years as discussed in Section 5.0. For the Phase II model calibration, simulation durations will not exceed 1 years which will allow for a better comparison of model result variation with variation observed in monitoring wells.

Despite all the assumptions and potential sources of error, the model fulfills its intended purpose. That is, to test several parameters to determine their relative importance to the numerical model, to determine starting parameters for the Phase II model, and to identify some of the problems that may develop during the Phase II model.

8.0 PHASE I SUMMARY AND PHASE II RECOMMENDATIONS

A regional groundwater model was developed for southern Florida using both the WASH123D and SEAWAT density-dependent codes. This coarse-resolution model was developed to test model boundaries, hydraulic and transport parameters and run times; to generate preliminary flow and transport results to compare against monitoring well data;

and to compare the WASH123D and SEAWAT results as Phase I of the ASR Regional Modeling Study. Lessons learned in the Phase I study will be incorporated into the development of the more-detailed Phase II regional model.

8.1 PHASE I MODEL SUMMARY

The Phase I model conceptualization was completed using information from existing ASR Regional Study task reports and limited review of existing monitoring well data. Based on the information, the primary area of freshwater recharge for the FAS is the highland ridge area of Polk County. In this area, groundwater elevations are highest and salt concentrations lowest in all of the Floridan aquifers. As groundwater moves out in all directions from this area towards the locations where the geologic units outcrop to the ocean, heads decrease and salinity increases. Groundwater in the UF is fresh-to-brackish through most of the unit with an increase in salinity near the southeast coast adjacent to the ocean. The MF has slightly higher salt concentration and the LF has significantly higher salt concentrations.

Using WASH123D and SEAWAT, the Phase I model was constructed to include the Surficial Aquifer System, the Intermediate Aquifer System, the Floridan Aquifer System and the Boulder Zone but the focus of the model is the Floridan Aquifer System. Three vertical layers of elements were used to define the most important units for the ASR study, the UF and MF, with most of the other units represented with two or less vertical layers. The horizontal model boundaries were defined just north of the recharge area and 20 mile beyond the coast with 5 miles between computational points. The model was run for 35,000 years assuming that the oldest age of groundwater found in recent groundwater age research is the length of time for water to traverse the system. The major assumptions used in construction of the Phase I model are:

- Coarse resolution is able to resolve flow and transport behavior
- No pumping stresses
- Top of the model is the water table (no unsaturated zones)
- Bottom of the model is a no-flow boundary
- Recharge from precipitation is represented using fixed surface heads generated from existing surface aquifer monitoring well data
- Head boundary conditions do not vary over time
- Dispersivity is constant throughout the model for all materials
- No temperature effects on groundwater density

The results of the model replicate flow and transport behavior in the Polk County recharge area. Model heads are highest and salt concentrations are lowest in that area for all the aquifers. Model heads are too low and salt concentrations too high compared to monitoring well data in the southern part of the model. In that area, the direction of flow is vertically upward so salt intrudes from the model bottom as well as the ocean in the southeast resulting in an over-estimation of the salinity. The timing of this upward salt migration is faster in the SEAWAT simulations than in the WASH123D simulations. This results in significantly lower computed heads in the UF and MF in the SEAWAT model at the end of the 35,000 year simulation. Despite varying several parameters including surface heads, hydraulic conductivities, and boundary heads and

concentrations, the mechanism for allowing more fresh water into the southern part of the model is unclear. It is possible that the mechanism is missing from the conceptual model, such as a preferential flowpath or lineament/fracture zone, or that the Phase I model construction assumptions limit the ability to reproduce the long-term flow and transport patterns. Additional work will be completed for the Phase II model to determine if higher spatial and temporal resolution and a shorter transient duration exhibit similar results.

Sensitivity analysis results show that the Phase I model is very sensitive to the concentration boundary condition method selected and the effect of temperature on density. The trials for confining unit hydraulic conductivity, initial concentration conditions and dispersivity show the model is somewhat sensitive to those parameters. The smallest effects were demonstrated by changes in aquifer hydraulic conductivity. These results provide some basis for how Phase II model parameters will behave however, most of these parameters are heavily dependent on mesh resolution. Additional sensitivity analyses will be required for the Phase II model.

8.2 RECOMMENDATIONS FOR PHASE II

Construction and execution of the Phase I model provide valuable information to aid in the approach and construction of the Phase II model. The Phase II model will consist of several parts. First, a comprehensive data review will be completed to ensure that all available head, concentration, and groundwater withdrawal data is incorporated. Phase II model construction will accompany the data review since the model construction will depend heavily on data availability and data requirements. Once the Phase II model is constructed, a flow only calibration will be performed. For the flow-only transient calibration, concentration values and transport parameters will be held constant. Flow parameters will be adjusted until the computed heads reasonably match observed data. Once a satisfactory flow-only calibration is obtained, full transient calibrations, with variable flow and concentration data, will be completed. In conjunction with the regional model, smaller scale transient stress-test “inset” models will be developed in the vicinity of operational ASR wells. Data collected during the on-going operations or cycle testing will be used to facilitate the calibration of transport parameters for the regional model. Regional model calibration data will encompass flow and water quality data in approximately 200 monitoring wells in multiple geologic units. Regional model calibration will be performed where computed and observed data are correlated over a duration of approximately 1 year. Flow and water quality data for a different 1-year time period, representing a different hydraulic condition (e.g. drier or wetter year), will be used for model validation. The goal of this effort is a fully-calibrated Phase II Regional Model. The calibrated Phase II model will ultimately be used in the evaluation of proposed ASR project alternatives.

During the data review and model construction portion of Phase II, several decisions will be required. The location of the model boundary is a trade-off between keeping the boundary conditions as far away from the areas of interest as possible and limiting the number of computational points required. The areas of interest for this modeling study are the proposed locations of the ASR wells. Most of the ASR wells are proposed near Lake Okeechobee and on the east coast (e.g. Hillsborough and Palm Beach County).

Only one proposed ASR location, near proposed reservoir C-43, is a west of Lake Okeechobee. It is located approximately 40 miles away from the western coast so moving the model boundary closer to the western coast should not impact it. It is recommended that the model boundary on the west and south side of the state be moved in to the Florida coastline as shown in Figure 88. In addition to reducing the amount of model computational points, moving the model boundary to the western coast has the benefit of eliminating uncertainties associated with extrapolating head and concentration boundary condition values along a portion of the model perimeter. As discussed in Section 7.0, testing will be required to determine if potential oscillations on the boundary will limit how close to the coast the boundary can be moved.

Once the model boundary is defined, the resolution will be selected. The Phase II model resolution will depend on how many calibration wells are chosen, how many pumping wells are incorporated for the time period selected, the potential for combining several pumping wells in the model and how the proposed ASR locations are simulated. This selection is critical because the number of computational points selected will dictate the model run times. The Phase I model contains approximately 50,000 computational points for both WASH123D and SEAWAT. To run 50,000 points with a 10-year time step for 35,000 years takes approximately 110 hours for WASH123D, 3.25 hours for SEAWAT (upwinded) and 1,247 hours (estimated) for SEAWAT (TVD). For Phase II, the mesh size will increase by approximately 10-fold yielding 500,000 computational points. Because the mesh resolution will be finer, the time step size will be smaller. Even though, more computations will be made at more frequent intervals, the run times are still expected to be reasonable because the total simulation duration will decrease to approximately 1 year for the separate calibration and validation runs. Table 1 shows the estimated run times for a 1 year simulation for a 500,000 node discretization with a 0.5-day, 1-day and 5-day time step size, assuming a direct relationship between the variables. This estimate indicates that run times should be reasonable as long as the mesh resolution does not increase beyond 500,000 computational points. Note that the additional model stresses resulting from incorporating pumping into the Phase II model could alter these calculations.

Table 1. Phase II Run Time Estimate

WASH123D			
Nodes	Time step	Duration (yrs)	Run time (hrs)
Phase I – 50,000	10 year	35,000	110
Phase II – 500,000	5 day	1	23
Phase II – 500,000	1 day	1	115
Phase II – 500,000	0.5 day	1	230

Table 1. Phase II Run Time Estimate (cont'd)

SEAWAT			
Cells	Time step	Duration (yrs)	Run time (hrs)
Phase I (upwinded) – 50,000	10 year	35,000	3.25
Phase II (upwinded) – 500,000	5 day	1	0.7
Phase II (upwinded) – 500,000	1 day	1	3.4
Phase II (upwinded) – 500,000	0.5 day	1	6.8
Phase I (TVD) – 50,000	10 year	35,000	1,247 (est.)
Phase II (TVD)– 500,000	5 day	1	260
Phase II (TVD) – 500,000	1 day	1	1,300
Phase II (TVD) – 500,000	0.5 day	1	2,600

Another model construction decision that will impact the resolution and run time is the vertical discretization. Near the ASR wells, complex flow patterns and high concentration gradients will exist that may not be adequately resolved with the three layers defined in both the UF and MF for Phase I. ASR wells will be located in the both UF and MF so these layers will require additional vertical discretization.

Additional vertical discretization may also be necessary in the confining units. As part of Phase II, several test models will be constructed to further examine the differences between WASH123D and SEAWAT noted in Section 6.1. Mesh/grid resolution issues, differences in treatment of vertical hydraulic conductivity and the configuration of the finite element computational nodes and the finite difference computational cells may affect the computed rate of vertical salt migration. A better understanding of these differences is required to ensure that the proper vertical salt migration is simulated in both the SEAWAT and WASH123D models.

Boundary heads will be set in all aquifers for Phase II based on transient data collected for the stress periods selected. The head and salt concentration within the surface aquifer will also be set based on transient data collected for the stress period. Variable concentration boundary conditions will be used in both models for the salinity boundaries in all aquifers. When the flow direction on the boundary is into the model, the concentration will be based on transient data collected for the stress period selected. When the flow direction is out of the model, the concentration will be model-computed.

For the flow-only calibration, a good concentration initial condition dataset will be selected based on available data. The initial condition concentrations will be smoothed by running the model for a few time steps and using the resulting concentration variation as the initial conditions for the calibration runs. This method should reduce any sharp fronts or "blockiness" in the concentration initial condition from data interpolation.

Based on the results of the sensitivity to temperature effects for Phase I, it is also recommended that temperature be included in some capacity in the Phase II model. At a minimum, the boundary head for the BZ should incorporate temperature effects. Additional Phase II sensitivity runs may determine whether temperature effects should be coded to other head boundaries or if full heat transfer computations are warranted.

Estimated Boulder Zone Head [Ft NGVD] as a result of temperature induced density differential.

Assumptions:

- Constant TDS = 37,500 ppm
- In the absence of temperature effect, BZ head would be zero.
- Specific Weight at Standard Temperature (4 °C) = 64.07 lb/ft^3. {Baxter-Wallace Equation}.
- Reference Depth = Estimated top of the Boulder Zone.

Executive Summary

The primary objective of the Comprehensive Everglades Restoration Plan (CERP) is the "restoration, preservation, and protection of the South Florida Ecosystem while providing for other water-related needs of the region, including water supply and flood protection (WRDA, 2000)." Aquifer Storage and Recovery (ASR) is one of the alternatives proposed by the CERP to provide long-term storage of excess water, resulting in a more stable water supply in South Florida. The CERP recommends the construction of 333 ASR wells completed in the Floridan Aquifer System (FAS) and distributed over a large region surrounding Lake Okeechobee. This report is the third in a series of four documents describing the multi-phased groundwater modeling approach undertaken to evaluate the proposed CERP ASR system. The four documents are:

- ASR Regional Study – Benchscale Modeling (Brown, et al, 2006). This report evaluated several model code options and concluded with the selection of WASH123D and SEAWAT as the best-suited to the ASR regional evaluation.

- Draft ASR Regional Study Phase I – Groundwater Modeling (NAP, 2006). This report described the first phase of the model development, including identification of boundaries and regional flow and salt migration pathways; evaluation of model run times and sensitivity to timestep sizes; testing of boundary parameters and the sensitivity of hydraulic and transport parameters; and a comparison of results from WASH123D and SEAWAT.

- Final Groundwater Model Calibration Report, Aquifer Storage and Recovery Regional Modeling Study (this report). This document presents the model setup, boundary condition development and calibration for the regional model, which will be the basis of the model evaluation of the CERP ASR plan. It further analyzes the sensitivity of the regional model to a number of parameters and discusses possible sources of error to the regional model.

- A final report will describe the evaluation of the CERP ASR plan against performance objectives such as rock fracture potential, impacts to nearby wells, recovery efficiency and the effects of ASR on salt water intrusion. This evaluation will be performed by running the calibrated, regional model with the addition of the ASR wells as described in the D13R scenario of the SFWMM model (SFWMD and USACE, 1999) and by the use of inset models, with higher grid resolution, centered on the locations of the Kissimmee ASR Pilot Site and the Hillsboro ASR Pilot Site.

This calibration report begins with a review of the modeling codes selected for the model in the Benchscale Report (Brown, et al, 2006), the development of the computational grids as presented in the Phase I Study (NAP, 2006) and the conceptual model, much of which was presented in Reese and Richardson, 2004 and Reese and Richardson, 2008. Other sections of the report describe data analyses and model setup. The boundary conditions and initial conditions for the model were based, wherever possible, on available site data. In areas of sparse data, both were necessarily estimated using available research and local knowledge as described in this report.

The most important groundwater flow parameters (principally hydraulic conductivity and specific storage) were set during the calibration process. Calibration proceeded by varying these input parameters and noting their effects on the model output. Parameters were changed until the model results most closely matched field measurements. A combination of hand calibration and automated calibration (PEST) was employed to minimize the time required while still allowing the introduction of engineering judgment in the manipulation of input parameter values. The model was calibrated to two separate periods: October 2003 through December 2004 for calibration, and October 1993 through July 1994 for validation.

The final calibration is sufficient for the purpose of the regional model, which is to determine on a coarse, regional scale, the impact of the CERP ASR program on the groundwater system in South Florida. Chapter 4 of the report presents details of the calibration and describes the quality of calibration both qualitatively and quantitatively.

Uncertainty in the regional pumping is considered to be the most important source of error in the model. It is recommended that future efforts be directed at collecting better quality data on the rates of extraction at private wells.

The report finishes with a description of a number of sensitivity runs, which were made to test the importance of some of the most uncertain model parameters. The sensitivity analyses determined that most of the transport parameters (porosity, diffusion and dispersion) are relatively insensitive. Also insensitive on a regional scale are the advection solution method, timestep size and specified head boundary conditions.

The Interagency Modeling Center (IMC) has reviewed this study and their comments on the draft report are listed in Appendix G with responses from the modeling team. While the modeling team addressed most of their comments with additional analyses or text, there are some differences of opinion between the two groups. The IMC comments on the final report and the modeler responses are provided in Appendix H and illustrate the two sides of each issue.

The recommendations for the future of the regional modeling study are that the calibrated SEAWAT model be used for evaluation of the regional impacts of the CERP ASR program. SEAWAT should also be used in the development of a pair of local-scale models, which will be highly resolved and capable of evaluating more local effects of small groups of ASR wells, such as recovery efficiency and well-to-well interaction. It is also recommended that the production simulations be performed in a probabilistic manner (e.g. Monte Carlo method) to provide for a quantification of uncertainties inherent in the model and the data.

1.0 Introduction

The U.S. Army Corps of Engineers (USACE), Philadelphia District (NAP), has prepared this report for the USACE, Jacksonville District (SAJ), and the South Florida Water Management District (SFWMD) in support of the Comprehensive Everglades Restoration Plan (CERP). This report documents Phase II of the regional groundwater modeling calibration effort and is the third in a series of four documents describing the multi-phased modeling approach undertaken to evaluate the proposed CERP Aquifer Storage and Recovery (ASR) system. The previous two modeling documents include the "ASR Regional Study – Benchscale Modeling Report" (Brown et al, 2006) and the "Draft ASR Regional Study Phase I - Groundwater Modeling" (NAP, 2006). The final document in the series will summarize the local scale model development and evaluation of various CERP ASR alternatives using the regional model. In addition to these modeling reports, an evaluation of the effects of various hydrogeologic theories on groundwater flow in South Florida was presented in the conference paper "Using Density-Dependent Numerical Models to Evaluate Regional Groundwater Flow Patterns in South Florida" (Bittner et al, 2008). This study was also preceded and is supported by "Groundwater Numerical Model Development Support and Data Collection Report" (CH2MHill, 2005). This report reviews the hydrogeologic framework and a number of previous modeling projects within the current model domain.

ASR is one of the alternatives proposed by the CERP to provide fresh water storage in South Florida. The CERP recommends the installation of 333 ASR wells open in the Floridan Aquifer System (FAS) and distributed over a large region with well field clusters near Lake Okeechobee, along the Caloosahatchee River, and at several locations along existing canals in the Lower East Coast Region (Palm Beach and Broward Counties). Figure 1.1 shows the study area and Figure 1.2 shows the approximate location of the proposed ASR well clusters envisioned in the CERP. The proposed plan, with total injection and recovery pumping rates of approximately 1.65 billion gallons per day, is larger than any currently operating ASR project. To evaluate the numerous design considerations and the variation in aquifer response on regional, sub-regional, and local scales, density-dependent numerical modeling of the FAS is required as discussed in the ASR Regional Study Project Management Plan developed in 2003.

The focus of this report is the Phase II Regional Model calibration. This Phase II effort builds on the findings of the Benchscale and Phase I modeling efforts and includes refinements to the regional conceptualization of the FAS. In addition, the modeling was supported by an extensive data collection effort performed by SAJ to compile and evaluate all pumping, water level, and salinity data available for the model domain. SAJ provided a description of the data collection effort and their report is included as Appendix A to this document. The following sections of this report describe how the available data was incorporated into the regional models and the model calibration process.

1.1 Acknowledgements

This report is part of a study prepared for and in cooperation with the SAJ and SFWMD. Thanks are given to the USACE Engineering Research and Development Center (ERDC) and the United States Geological Survey (USGS) for their cooperation, modeling code development assistance, and technical guidance during this study. Thanks are also given to South West Florida Water Management District

(SWFWMD), St. Johns River Water Management District (SJRWMD), the Florida Department of Environmental Protection (FDEP) and the Florida Department of Health (DOH) for their assistance in the data collection effort. Special thanks are given to the IMC for their cooperation in the review of the various phases of this study.

2.0 Regional Modeling Approach

The first and most important step in the modeling process is to define clear, achievable goals and objectives for each stage of the process based on the desired end results. Both the modeling team and the end user must keep the end goal in mind and have a clear understanding of the capabilities and limitations of the model.

The primary objective of the Phase II ASR modeling effort is to evaluate the impacts of the proposed CERP ASR wells on the hydrogeologic conditions in the FAS. This evaluation will be performed by using both regional and local scale models. Each scale of model will be used to address different project objectives. The current report pertains to development and calibration of the regional scale models, which will provide planning level information to address large-scale issues, such as the regional effect of the ASR well clusters on salt water intrusion, water levels, groundwater flow patterns, groundwater quality, and the potential for rock fracturing. This scale of modeling is *not* appropriate for evaluating local issues, such as well-to-well interaction within an ASR well cluster or ASR well recovery efficiency. These issues will be addressed as part of the next report with local scale models that have significantly finer mesh/grid resolution.

Data gaps and constraints on time, resources and budgets necessitate the use of simplifying assumptions in the construction of models. Efforts were made to ensure that assumptions had little or no impact on the primary objectives and goals of the modeling project. Those assumptions which might have impacted the objectives were tested using sensitivity analyses. Table 2.1 is a detailed list of the assumptions made in the development of the regional model. Each assumption is listed with a section of the report where the basis for the assumption, sensitivity analysis or explanation is provided.

2.1 Concept of Equivalent Freshwater Head

Because of the close hydraulic relationship between the aquifers in South Florida and the Atlantic Ocean and Gulf of Mexico, there are significant variations in the salinity of the groundwater. Except for small areas in the north part of the model domain, deep aquifers are highly saline due to their close interaction with the ocean. Some areas have been measured with salinity values higher than ocean water due to mineral build up. Surface aquifers are fed more by rainfall, resulting in generally low salinity.

Total Dissolved Solids (TDS) was used as a proxy for salinity in the ASR regional model and the two terms are used interchangeably in this report. TDS data was normalized by dividing each measured value by 35,000 mg/L, a commonly accepted TDS value for seawater. This results in a unitless value of approximately 1.0 for seawater and 0.0 for freshwater.

Comments from reviewers early in the modeling process indicated that temperature variations might also play a significant role in flow conditions in the model. Deeper aquifers are generally warmer near the west coast, likely due to geothermal effects, and cooler on the east coast, similar to ocean waters at depth.

Variations in both temperature and salinity of the groundwater cause variations in density. In addition, due to the significant depths in the model, pressure variations can also impact density. The density in the model is calculated to vary from about 62.2 lb/ft^3 to about 64.2 lb/ft^3. Temperature does not have as great an effect on water density as salinity, but it is included in the model and treated as another constituent concentration. Pressure has the least impact of the three variables controlling density.

Both SEAWAT and WASH123D require the user to enter head boundary conditions and initial conditions as observed head based on local density, or the water level measured in a well. The models then use the temperature and salinity to calculate the *equivalent freshwater head*, which takes into account TDS, temperature, and pressure to determine the potential energy at a given location. The flow equations are solved based on equivalent freshwater heads and then the solutions are converted back to observed heads for viewing and analysis. The governing equations used by SEAWAT and WASH123D are described in more detail in Section 2.2.

Because model results are reported as observed heads, the solutions sometimes appear to show unusual flow patterns. When there are significant differences in salinity, groundwater flow may appear to be moving "uphill." Since the equivalent freshwater head is actually the potential energy of the water at a given point, fluid flow would be expected to occur from locations of high equivalent freshwater head to locations of lower equivalent freshwater head. If the salinity is markedly different between two points, high observed heads may not correspond to high equivalent freshwater heads.

Equivalent freshwater head is calculated from observed head by first calculating the observed density from the TDS, temperature, and pressure, using Equation 2.1:

$$\rho = \rho_f + m_{tds}\left(TDS - TDS_{ref}\right) + m_{tmp}\left(TMP - TMP_{ref}\right) + m_p(P - P_{ref}) \qquad \text{Equation 2.1}$$

where:

ρ	=	Observed density
ρ_f	=	Density of water at the reference TDS and temperature
m_{tds}	=	Slope of the assumed linear relationship between density and TDS
TDS	=	Total dissolved solids in the water (proxy for salinity) normalized by dividing by 35,000 mg/L
TDS_{ref}	=	Reference TDS, normalized by dividing by 35,000
m_{tmp}	=	Slope of the assumed linear relationship between density and temperature
TMP	=	Temperature in the water (°C)
TMP_{ref}	=	Reference temperature
m_p	=	Slope of the assumed linear relationship between density and pressure
P	=	Pressure of the water calculated in terms of head
P_{ref}	=	Reference pressure calculated in terms of head

Once the observed density has been calculated, the equivalent freshwater head can be directly calculated by using Equation 2.2 (Guo and Langevin, 2002):

$$h_f = \left(\frac{\rho}{\rho_f}\right)h - \left(\frac{\rho - \rho_f}{\rho_f}\right)Z \qquad \text{Equation 2.2}$$

where:

h_f = Equivalent freshwater head
h = Observed head
Z = Elevation of point (using NGVD29 as a datum)

Table 2.2 lists the physical constants used in the flow equations.

2.2 Modeling Codes

The Benchscale and Phase I modeling efforts concluded that both the SEAWAT (finite-difference solution) and the WASH123D (finite-element solution) modeling codes would be used for the Phase II regional model. Since each code has inherent advantages and disadvantages, the use of both codes ensures a higher degree of reliability in the overall calibration, conclusions, and future recommendations.

2.2.1 SEAWAT

The SEAWAT (version 4) model (Langevin, et al, 2008, Langevin, et al, 2003, Guo and Langevin, 2002, Guo and Bennett, 1998) was chosen as one of the codes for the Phase II modeling effort. SEAWAT is a finite difference code that simulates variable-density flow in three dimensions by combining the flow equations in MODFLOW–2000 (Harbaugh et al, 2000) with the solute transport equations in MT3DMS (Zheng and Wang, 1999) into a single program coupling the flow and solute transport solutions.

SEAWAT uses a finite difference approximation for Equation 2.3, the governing equation for variable-density flow in terms of freshwater head and Equation 2.4, the governing equation for fate and transport of a contaminant in a three-dimensional, transient groundwater flow system (Guo and Langevin, 2002). (The reaction term has been removed from Equation 2.4 since the chemical reaction package was not used in this model.)

$$\frac{\partial}{\partial\alpha}\left[\rho K_{f\alpha}\left(\frac{\partial h_f}{\partial\alpha}+\frac{\rho-\rho_f}{\rho_f}\frac{\partial Z}{\partial\alpha}\right)\right]+\frac{\partial}{\partial\beta}\left[\rho K_{f\beta}\left(\frac{\partial h_f}{\partial\beta}+\frac{\rho-\rho_f}{\rho_f}\frac{\partial Z}{\partial\beta}\right)\right]$$
$$+\frac{\partial}{\partial\gamma}\left[\rho K_{f\gamma}\left(\frac{\partial h_f}{\partial\gamma}+\frac{\rho-\rho_f}{\rho_f}\frac{\partial Z}{\partial\gamma}\right)\right]=\rho S_f\frac{\partial h_f}{\partial t}+\theta\frac{\partial\rho}{\partial C}\frac{\partial C}{\partial t}-\rho_s q_s \qquad \text{Equation 2.3}$$

Where:

α,β,γ = Orthogonal coordinate axes, aligned with the principal directions of permeability
K_f = Equivalent freshwater hydraulic conductivity
S_f = Equivalent freshwater specific storage

t = Time
ϑ = Effective porosity
C = Solute concentration
ρ_s = Fluid density source or sink water
q_s = Volumetric flow rate of sources and sinks per unit volume of aquifer

$$\frac{\partial C}{\partial t} = \nabla \cdot (D \cdot \nabla C) - \nabla \cdot (vC) - \frac{q_s}{\theta} C_s \qquad \text{Equation 2.4}$$

Where
D = Hydrodynamic dispersion coefficient
v = Fluid velocity
q_s = Source/sink volumetric flow rate per unit volume of aquifer
C_S = Solute concentration of water entering from sources or sinks

The program contains several methods for solving the solute transport equation including an implicit finite difference method with either upwinded or central-in-space weighting, the method of characteristics, and a third order total-variation-diminishing (TVD) scheme. All simulations performed for Phase II model calibration and validation used the finite-difference upwinded solver; however, a final validation simulation was performed using the more robust TVD solver to confirm that any numerical dispersion in this solver was within acceptable tolerances. (See Section 5.1)

2.2.2 WASH123D

The October 2009 compile of WASH123D (Yeh et al., 2003) was also used to evaluate the regional effects of the proposed ASR wells. WASH123D is a finite element code that simulates variable-density flow and reactive chemical and sediment transport in 1-D channel networks, 2-D overland regimes and 3-D subsurface media on an unstructured mesh. For the Phase II model, only the 3-D subsurface variable-density flow options were enabled. With WASH123D, the variably saturated, density-dependent groundwater flow is described by the modified Richards' equation (Equation 2.5 and 2.6) and solved with the Galerkin finite element method.

$$\frac{\rho}{\rho_f} F \frac{\partial ph}{\partial t} = \nabla \cdot \left[\mathbf{K} \cdot \left(\nabla ph + \frac{\rho}{\rho_o} \nabla Z \right) \right] + \frac{\rho_s}{\rho_f} q_s \qquad \text{Equation 2.5}$$

Where:
ph = Referenced pressure head
$\mathbf{K}$ = Hydraulic conductivity tensor
F = Water capacity (see Equation 2.6)

$$F = a' \frac{\theta_e}{n_e} + \beta' \theta_e + n_e \frac{dS}{dh} \qquad \text{Equation 2.6}$$

Where:

α'	=	Modified compressibility of the medium
θ_e	=	Effective moisture content
n_e	=	Effective porosity
B'	=	Modified compressibility of water
S	=	Degree of saturation

The Lagrangian-Eulerian (LE) method is employed to solve the subsurface transport equation (Equation 2.4), where particle tracking is used in the Lagragian step to handle the advection term, and the other terms (such as sources, sinks, diffusion, and dispersion) are calculated in the Eulerian step to determine the spatial concentration distribution at the end of each timestep. The use of this methodology provides numerical stability without a Courant number restriction. In addition, the mesh's Peclet number is limited only by computational accuracy, not numerical stability. A sensitivity analysis of timestep sizing was performed to ensure the numerical accuracy was adequate for the scale and stated goals of the Phase II modeling effort (see Appendix F). More detailed discussion on various types of numerical dispersion and how the LE method deals with these types of numerical dispersion are found elsewhere. (Cheng et al., 1996; Cheng et al., 1998; Yeh et al., 2006).

2.3 Model Extent and Spatial Discretization

Both WASH123D and SEAWAT report numerical solutions to partial differential equations governing flow and transport at a set of discrete points. SEAWAT arranges these points as the centers of cube-shaped cells arranged in rows, columns and layers of a structured grid. WASH123D solves its equations at nodes on an unstructured 3-D mesh made up of prism-shaped elements. In each case, the grid or mesh was built to cover the area of interest (the proposed locations of the 333 CERP ASR wells) both horizontally and vertically. The sides of the grid or mesh were placed to coincide with convenient locations for assigning boundary conditions. Both the grid cells and mesh nodes were arranged in layers corresponding to the geologic layering of south Florida.

The Phase II model boundaries were established based on conclusions from the Benchscale and Phase I modeling efforts. The side boundaries of the model were generally established along geologic outcrops to the ocean or aligned near observation wells with available data during the calibration and validation periods. Figure 2.1 shows the horizontal extent of the model domain, which covers just over 23,000 square miles of the Floridan peninsula. The eastern boundary of the top model layer is located along the coast of the Atlantic Ocean. Subterranean geologic units extend eastward to their outcrop on the ocean floor, resulting in an additional 7,000 square miles of the model located offshore beneath the Atlantic Ocean. The northern model boundary for all geologic units cuts across the Florida peninsula, through Orlando and slightly to the south of Lake Apopka. The western model boundary closely follows the gulf coast of Florida, beginning at the model's northwest corner, just west of Tampa. South of Sanibel Island, the model boundary moves inland, crossing the Everglades to intersect the eastern boundary at the south end of Biscayne Bay. (All place names from this section are labeled on Figure 1.1.)

The computational grid/mesh resolution was selected to balance the purpose of the model with the constraints of time and computer resources. Higher resolution on the grid or mesh can provide greater accuracy and detail, but can also tax project budgets and computer resources due to the additional time required to compute the solution. The model purpose, as described in the introduction to Section 2.0, is to reasonably replicate the regional groundwater flow fields and effects of the proposed ASR well clusters.

Figure 2.1 shows the horizontal resolution of the WASH123D computational mesh and the SEAWAT computational grid. The smallest resolution (1,000 ft. in the WASH123D mesh and 2,000 ft. for the SEAWAT grid) is found at the proposed ASR well cluster locations where accuracy and detail are necessary. In the WASH123D, even finer resolution (100 ft.) is incorporated at the Kissimmee and Hillsboro ASR pilot sites to facilitate future local scale model construction. The size of both the grid cells and the mesh elements increases to 10,000 ft along the model boundary.

Vertically, the models extend from near the ground surface to the bottom of the confined Boulder Zone (BZ) member of the Lower Floridan (LF1) aquifer. Although the top layer of the SEAWAT grid is set to coincide with the Surficial Aquifer System (SAS), no calculations were made in this layer. To achieve the same effect in the WASH123D model, the top of the mesh is set at the bottom of the Surficial Aquifer system. This is explained in more detail in Appendix C. Although the depth of the model varies, the topographic high is near elevation 250 ft NGVD29 and the deepest point in the model is about -3,600 ft. NGVD29.

As shown in Figure 2.2, the models include five confined aquifers and four confining units. The SEAWAT grid also includes the Surficial Aquifer System (SAS), although no calculations are made here. The colors in Figures 2.3 and 2.4 are used to illustrate the arrangement of broadly-defined hydrogeologic material layers used in the model. Heterogeneity within the model layers was incorporated using zonal modifications to hydrogeologic properties of each geologic unit, or pilot point interpolation of hydrogeologic properties to individual cells of the model.

The 3-D grid contains 22 vertical cell layers and the 3-D mesh is made up of 23 vertical element layers. Figure 2.3 shows the geologic units associated with each layer in the SEAWAT model, while Figure 2.4 shows the geologic units associated with each layer in the WASH123D model. The 3-D mesh for this model is comprised of 391,228 nodes and 740,637 elements. The 3-D grid for this model is comprised of 1,092,256 cells, 823,038 of which are active. (The organized arrangement of the grid cells requires a rectangular shape to the grid. The desired shape of the model is incorporated by inactivating unnecessary cells.) Additional details concerning the model set up are discussed in Section 3.

Due to the dipping nature of the geologic layers some concerns were raised about the model resolution and aspect ratio and their possible contribution to model instability and inaccuracy. To respond to these concerns, a sensitivity analysis was performed to evaluate how the model discretization would affect the computed results of the regional models. The results of this analysis indicated that the errors resulting from model discretization were within the model's error tolerance for the majority of the model domain, including the area of interest for the proposed CERP ASR wells. Grid resolution was shown to

have a more significant effect in a small area in the northwest portion of the model near Tampa (where the geologic units thin significantly). However, since this area is north of the Polk County recharge area and does not appear to be influenced by the proposed ASR wells, the inaccuracies introduced by model resolution issues were considered acceptable for the scale and purpose of this modeling effort. Appendix B provides additional details on this sensitivity analysis.

2.4 Model Time Discretization

The calibration period selected for the transient calibration of the regional model was October 31, 2003 through December 31, 2004. The SEAWAT model was set up with 15 stress periods – one for each month of the period. Most boundary conditions and source/sink options in SEAWAT require constant values during each stress period. Thus, for head data, the average measured head during each month was applied to the entire month. For pumping data, the total pumped volume was divided by the number of days in the month and applied as a constant flux during the entire month. This simplification can result in some differences between observed and calculated data, but was necessary due to the paucity of reliable pumping data available at many locations in the model domain. Although the WASH123D model does not use stress periods, the same monthly averages were used to allow for direct comparisons between the two models and to minimize additional data collection.

The validation period of August 1993 through July 1994 was originally selected to be consistent with the calibration period of the USGS model by Sepulveda (2002). Analysis of the head data indicated that October 1993 was a better starting point for the model since the heads were generally relatively constant during the period leading up to October 1993. The validation period was, therefore, shortened to October 1993 through July 1994. The same process of assigning month-long stress periods to the model period was followed as explained above.

In each case, the first stress period was one day long and was solved as a steady state model to provide a starting condition for the rest of the modeled time periods. Timesteps (times at which the model computed and reported a solution) for both the flow and transport models were spaced evenly through the remaining stress periods. Each month was given 6 equally-sized timesteps, except for February 2004 and 1994, which only had 5 timesteps. Depending on the length of the month, this provided timesteps that were approximately 5 days long. Head results at the observation points are available at each timestep (approximately every 5 days). Head results on the grid as a whole were output about every 10 days to save on file sizes.

For the SEAWAT model, acceptable Courant numbers require a timestep about 8 hours long on average because of some of the thin cells located in the northwest section of the model. The approximately 5-day timesteps used for the calibration simulations were selected to provide a faster run time during calibration. At the end of calibration, additional model runs were made using a model-selected timestep to ensure accuracy of the final result (see Section 5.1). These final simulations used the TVD solution scheme, which used timestep sizes that were less than 1 day.

Additional details on the testing used to select the regional model time discretization are given in Appendix B.

2.5 Model Datum

Numerous data sources were compiled to generate the model input parameters, boundary conditions, and calibration/validation data sets. All data sets were converted to a common horizontal and vertical datum. The horizontal datum used for this model is feet North American Datum 1983 (NAD83), State Plane Florida East. The vertical datum used is feet North Geodetic Vertical Datum 1929 (NGVD29). Any data in a different coordinate system was converted using the coordinate conversion software, Corpscon, version 6.0 (December 2004 release), developed by the Topographic Engineering Center (TEC) of the U.S. Army Corps of Engineers.

All elevation data presented in this report are in NGVD29. Water levels (head) are presented as total head elevation, also in NGVD29.

3.0 Conceptual Model

Prior to construction of any numerical groundwater model, it is important to properly conceptualize the flow system in question. A conceptual model is a detailed description of the groundwater flow system to be modeled and should identify the hydrologic and hydrogeologic conditions and all important features and drivers of the groundwater system, including sources, sinks, boundary conditions, geophysical features that convey water or interrupt flow, recharge, site stratigraphy, material properties, etc. The conceptual model is generally developed through extensive literature research and data analysis. Most of the conceptualization for the Phase II ASR Regional Model had already been completed during the earlier phases of the project and is presented in previous reports (Brown et al, 2006 and NAP, 2006). However, additional conceptualizations were required for parameters that affect the density of the groundwater: temperature and salinity (represented by Total Dissolved Solids [TDS]). These analyses are presented in Appendix E.

The conceptual model should start with the basic components that are expected to have the greatest effect on groundwater flow. The preliminary conceptual model can be used to construct the model grid or mesh and develop the required simulations. Complexity can then be added to the conceptual and computational models as model outputs are compared to known conditions at the site and as the understanding of the flow system is refined. This often is an iterative process where interim numerical model results are used to help direct the research process and improve the conceptual model.

When evaluating the results of the WASH123D and SEAWAT models, it is important that the reader have an adequate understanding of the conceptual model so that potential model limitations are fully understood. The following subsections provide a brief description of the features included in the Phase II conceptual model and detail how these features were incorporated into the WASH123D and SEAWAT numerical models.

3.1 Topography

The topographic data was provided by SAJ and included bathymetric data for the offshore portion of the models. This data was a compilation of the SFTOPO-RC5 Topography/Bathymetry, National Elevation Data set (NED), and the National Oceanographic and Atmospheric Administration (NOAA) Coastal Relief

Model (CRM) bathymetry. The data was smoothed by SAJ to produce a topographic data set with uniform 1,000-foot grid spacing. Additional Digital Elevation Model (DEM) data was merged with this data set to ensure coverage across the entire model domain. The vertical datum of the final topographic data is NGVD29.

Traditionally, topographic information is often used to define the surface of the 3-D computational mesh or grid of a groundwater model with recharge and evapotranspiration applied to the surface as a flux boundary condition. However, since the purpose of the Phase II regional models is to evaluate flow in the FAS, the model was simplified by assigning specified heads in the Surficial Aquifer System (SAS) as explained in Section 3.3.1. Because there are no calculations made in the SAS, the top elevation becomes unimportant to the model calculations. The topographic data was useful for visualization of the SEAWAT results, development of regression correlations used to apply surface boundary heads, and for determining the layer outcrop locations in the Atlantic Ocean for both models.

This topographic data was also used to determine open intervals for monitoring wells and pumping wells. Usually, surface elevations at wells were not provided and the pumping and/or sampling intervals were reported as depths below ground surface. To estimate the elevations of pumping and sampling intervals at wells, the topographic data set was linearly interpolated to the well points and the depths were subtracted from the interpolated surface elevations. Well interval elevations were then compared to geologic layer elevations to determine the hydrogeologic unit tapped by the well's open interval. Any error introduced by using these interpolated well surface elevations is small compared to the accuracy of the geologic layer elevations.

3.2 Geology

A wealth of geologic and hydrogeologic data is available for the regional model domain. Geologic interpretations were based primarily on the USGS Scientific Investigations Report (SIR) 2007-5207 (Reese and Richardson, 2008) and a Draft report developed by Reese and Richardson (2004) entitled "The Draft-Final Report – Task 3.0 Define Preliminary Hydrogeologic Framework" (referred to herein as the Preliminary Hydrogeologic Framework). The following subsections describe the hydrostratographic layering and hydrogeologic data for the regional model.

3.2.1 Regional Geology

SFWMD used SIR2007-5207 and the Preliminary Hydrogeologic Framework to define the surfaces of the hydrostratigraphic units in the Phase II models and provided grids of the elevations (NGVD29) of the tops of the major geologic units. These gridded surfaces were used to develop the computational grid and mesh. Figures 2.2 to 2.4 show a gross conceptualization of all the geologic units used in the Phase II modeling and defined by SFWMD.

For the Phase II models, the FAS is divided into 4 producing units: the Upper Floridan (UF), Avon Park Permeable Zone (APPZ), Lower Floridan (LF1), and Boulder Zone (BZ); and three confining units: Upper Middle Confining Unit (MC1), Lower Middle Confining Unit (MC2), and the Lower Confining Unit (LC). The Framework documents divide the LF into LF1, LF2 and LF3, which are not all found at every location.

However, the LF, as simulated in this model, represents the first permeable zone of the Lower Floridan Aquifer (LF1). The LC is a composite of any remaining units (permeable or confining) between the first permeable zone and the BZ. The cited studies did not report the precise location of the base of the BZ, but estimated its thickness to be between 200 and 700 feet. The model was built with a uniform thickness of 500 feet for the BZ layer and a sensitivity analysis of the thickness was performed (see Section 5.4).

The thickness of each hydrogeologic unit (UF through LC) as defined in the model is presented in Figures 3.1 through 3.6. Although these figures were created from the SEAWAT computational grid, the same thicknesses were applied to the layering of the WASH123D computational mesh.

It is also important to note that the term 'confining unit' is somewhat relative. The MC1, MC2 and LC are confining units only by comparison to the producing units of the Floridan system. Anderson and Woesner (1992) define a confining bed as a 'unit of porous material that retards the movement of water.' The hydraulic conductivities of the MC1, MC2 and LC do not seem very low when compared to those found in other systems. (Materials such as glacial till, clay, unfractured shale or unfractured basalt can have hydraulic conductivities less than 10^{-6} ft/d, which is several orders of magnitude lower than most of the conductivity values used in the model for the confining units.) Because the conductivities in the MC1, MC2 and LC are a few orders of magnitude lower than those in the UF, APPZ, LF1 and BZ, they impede groundwater movement and are designated as confining units.

As indicated in Figure 2.3, the hydrogeologic layering was subdivided for the layers of the SEAWAT computational grid. The confining units (MC1, MC2, and LC) were each equally divided into two model layers. The aquifers were also equally subdivided into a number of layers based on the expected importance of each aquifer to the planned ASR production runs. Initial plans indicate that all of the CERP ASR wells will be open in the UF, so this layer was equally subdivided into 6 layers. The APPZ was equally subdivided into 3 layers because of the slight possibility that the ASR wells in the UF might impact the heads in the APPZ. Some members of the PDT have expressed an interest in testing ASR wells in the APPZ layer, so the additional layer may become important in the future. The LF1 and BZ layers are not expected to be impacted by the CERP ASR pumping, so they were given 2 layers and 1 layer, respectively, in the SEAWAT model.

The FAS is overlain by a complex system of alternating aquifers and confining units often referred to as the Surficial Aquifer System (SAS) and the Intermediate Aquifer System (IAS). Since they are not the focus of this modeling effort, these systems are greatly simplified for the model conceptualization. In the model, the SAS is simplified to a vertically homogeneous unit between the topographic surface to the top of the IAS, as defined in SIR2007-5207. The IAS consists of everything between the SAS and UF and is conceptualized in two components: the Intermediate Aquifer (IA) and the Intermediate Confining Unit (ICU). The IA exists only in west-central and southwest Florida (Miller, 1997), but non-continuous layers (pinch-outs) are difficult to simulate in either the computational grid or mesh. The IA was modeled by assigning IA aquifer parameters to the west-central and southwest third of layer 3 of the SEAWAT model. The ICU was modeled in layer 2, 4 and the non-IAS section of layer 3. Thus, layer 3 has two distinct sections with starkly different aquifer parameters (see Figure 2.3). These simplifications are

acceptable since the primary function of the SAS and the IAS in the model is to conduct water from the surface to the FAS.

Similarly, the Hydrogeologic Framework (Reese and Richardson, 2008) indicates that the APPZ does not exist in the southwest section of the model (most of Collier and Monroe Counties). This pinchout was approximated by making these layers extremely thin in this area. Each of the three layers thins to a minimum of 2 feet, resulting in a 6-foot thickness for the entire layer (see Figure 3.3). Since this is also the limestone section of the APPZ, the hydraulic conductivity is very low and the APPZ does not conduct much flow in this area.

As previously mentioned, the BZ thickness is assumed to be universally 500 feet across the model domain. However, Reese and Richardson (2008) report that the BZ does not occur in west-central Florida. To model the non-existence of the BZ, the hydraulic conductivity for layer 22 in west-central Florida is set to values similar to that of the LF1. Since the LF1 conductivity is much smaller than the generally present BZ conductivities, this approach results in greatly diminished BZ flow. (Because of the assumed constant thickness of the BZ, a figure similar to Figures 3.1 through 3.6 is not provided for the BZ.)

The layering of the WASH123D model was similar to the SEAWAT model as can be seen by a comparison of Figures 2.3 and 2.4. Most of the hydrogeologic unit layers were defined by the same number of model layers. The MC1, MC2 and LC confining units were all divided equally into two model layers. The UF, APPZ and LF1 aquifers were divided into 6, 3 and 2 layers, respectively, just as in the SEAWAT model. However, because of computational differences between the two models, the BZ was divided into two layers and the IAS was divided into four.

The additional layer is added to the IA to account for differences between finite difference (SEAWAT) and finite element (WASH123D) computational points and the application of hydraulic conductivity to those points. In SEAWAT, the hydraulic conductivity is assigned to a cell and the center of the cell is the computational point. In WASH123D, the conductivity is assigned to an element and the computational points are at the nodes on the element faces. Figure 3.7 is a diagram that shows the comparison between the SEAWAT and WASH123D computational points in the area where the IA is present. The WASH123D computational point 3 in Figure 3.7 uses the aquifer conductivity from Layers 2 and 3 to compute the heads in the aquifer in a similar way to computational point 2 for SEAWAT Layer 3. The WASH123D computational points 2 and 4 use an average conductivity from the confining unit and the aquifer. Splitting the IA into two layers in the WASH123D model provides a layer of nodes that are assigned the aquifer conductivity and ensures an accurate representation of the recharge entering and moving through the IA. Similarly, the BZ is divided into two layers to provide the model with at least one layer of nodes assigned a BZ hydraulic conductivity value.

Pinchouts in the APPZ and BZ in the WASH123D model are handled in the same way as the SEAWAT model. Since the mesh is layered, it is difficult to remove the elements from the mesh. Instead, the elements were made thin and the hydraulic conductivity was used to approximate the condition. As mentioned above, the model simulated APPZ in Collier and Monroe Counties is very thin with a low

hydraulic conductivity. The absence of the BZ in the northwest part of the model is simulated by setting the hydraulic conductivity to values similar to the LF1.

The SAS was not defined as a WASH123D model layer because no flow calculations were made in the SAS. The SAS heads (interpolated from available data) were assigned to the top nodes of Layer 1 of the IAS, as described in Section 3.3.1 and Appendix C.

3.2.2 Hydrogeologic Properties

Hydrogeologic properties such as hydraulic conductivity and specific storage were estimated for each model layer based on the available data. Then, during the calibration process (see Section 4), the property values were adjusted until an adequate calibration to available data was achieved. During calibration, the parameter values were required to remain within reasonable ranges as defined in the Preliminary Hydrogeologic Framework, SIR2007-5207 and APT (Aquifer Pump Test) data provided by SFWMD. Additional information for the Phase II conceptual model was collected from other sources and from online databases including SFWMD's DBHYDRO, USGS's South Florida Information Access (SOFIA), the National Park Service's South Florida Natural Resources Center (SFNRC), CH2MHill's Groundwater Numerical Model Development Support and Data Collection Report, and a number of published reports and papers (see Section 8).

The available field data used to guide the calibration process is presented in Figures 3.8 through 3.15. This field data includes horizontal hydraulic conductivity data for the aquifers (Figures 3.8 through 3.10), vertical hydraulic conductivity data for the confining units (Figures 3.11 through 3.13) and specific storage for the UF and APPZ (Figures 3.14 and 3.15). (Specific storage was converted from storage coefficient by dividing by the aquifer thickness.) The final calibrated hydraulic conductivity and specific storage distribution for each model layer will be presented later in Section 4 (See Sections 4.1.2 and 4.2.4 along with Figures 4.31 through 4. 40 and 4.111 through 4.118). Differences between WASH123D and SEAWAT resulted in slight differences in the material parameters used in the calibration model.

Additional properties such as porosity, dispersivity and molecular diffusion coefficient, were found to have little effect on the calibration of the model. Sensitivity analyses of these parameters are presented in Section 5.2 and 5.3.

3.2.3 Regional Anisotropy

During the Phase I modeling, the SEAWAT grid angle was set at 18 degrees west of north to align with the axis of the Floridan peninsula. Bittner, et al. (2008) analyzed a number of options for improving the agreement between the initial model results and the estimates of pre-development heads in the UF from Meyer (1989). This paper concluded that both the inclusion of anisotropy in the aquifers and the inclusion of temperature effects on density could improve the calibration of the model.

A lineament study (Fies, 2004) and preliminary results from some image log fracture analysis work at SFWMD indicated that the dominant fracture orientation was NW to SE at an angle of about 38 degrees west of north. For this reason, the regional grid for Phase II modeling was designed with a 38 degree angle, in place of the 18 degree angle used in earlier reports. However, additional analysis by SFWMD

indicated that the NW to SE orientation was based on a lumped view of all the UF fractures from all the wells. When the data was split out to look at the dominant orientations from individual wells, it became clear that the dominant orientations varied geographically. The lumped view gave additional weight to a large volume of fractures in the UF at the Kissimmee River pilot location. This led to the conclusion that there is currently no conclusive evidence of regionally dominant orientation for fractures in the UF. The anisotropy option was, therefore, not used in this regional model (although the grid angle of 38 degrees remained). Greater detail will be available on this study when the final report on the lineament study is completed in time for inclusion in the final Technical Data Report (TDR) for the regional study.

3.3 Boundary Conditions

Specified head boundary conditions were applied to the sides and top of both Phase II regional models. In SEAWAT, the time-variant specified-head boundary (CHD) package was used to specify the heads in the cells on the top and sides of the model. Similarly, in WASH123D, a DB card (Dirichlet boundary condition) was listed in the input file for each node on the sides and top of the mesh. No boundary condition was applied to nodes on the bottom of either model. By default, unassigned nodes on the boundary of the mesh and unassigned boundary cells of the grid are considered to be no-flow nodes. The use of the no-flow boundary on the bottom of the model is appropriate because of the much lower conductivity of the Sub-Floridan confining unit, which underlies the Boulder Zone. Preferential flow in the Boulder Zone is expected to be horizontal with only insignificant flows in or out of the bottom of the model.

The following subsections provide a brief summary of the methodology used to set the specified head boundary conditions on the Phase II regional models. Additional details are provided in Appendix C.

3.3.1 Surficial Head Boundary Conditions

The heads assigned to the top boundary of the models simulate recharge (precipitation less evaporation, transpiration and runoff) and provide one of the primary sources of water to the models. Generally, groundwater models use a flux-type boundary condition at the surface to simulate recharge. The flux is often calculated using a flow budget, subtracting such sinks as evapotranspiration and runoff from precipitation to determine the volume of water seeping through surface soils into the model. Runoff and evapotranspiration are usually approximated using empirical equations with estimated parameters based on sparse data. Because of the inherent uncertainty in these calculations, recharge is often used as a calibration parameter and is varied along with hydrogeologic material properties until the model result matches measured aquifer conditions.

For these regional ASR models, a specified head was assigned to the top surface of the models, based on an interpolation of available head data from monitoring wells open in the SAS. This approach avoids the difficulties and inaccuracies inherent in calculation of recharge values and seepage rates and makes possible the direct usage of the abundance of SAS head data. The purpose of the Phase II regional models is to evaluate regional flow characteristics in the FAS and estimate the aquifer effects from the proposed CERP ASR wells. Since the ASR pumping is not expected to affect the heads in the SAS, the use of specified heads is considered valid.

In the SEAWAT model, the SAS was modeled as the top layer of cells with the top of each cell corresponding to ground surface and the bottom of each cell set at the elevation of the bottom of the SAS. Each cell was assigned a specified head as described above and SEAWAT made no horizontal flow calculations in the top layer. The specified head was calculated based on an interpolation of the average head data at all available wells for each month of the calibration and validation period as described in Appendix C.

The same interpolation process was used to assign specified heads to the top layer of nodes in the WASH123D model. The elevations of these nodes correspond to the elevation of the bottom of the SAS layer. Thus, the SAS was not included in the computational mesh. This makes the two models comparable since neither one made horizontal flow calculations in the SAS. See Appendix C for additional details

3.3.2 Simulation of Ocean Boundary

Along the eastern boundary, each modeled hydrogeologic layer extends to its projected outcrop in the Atlantic Ocean. The outcrop location was defined by cutting each layer when the geologic unit surface grids provided by SFWMD (see Section 3.2.1) intersected the bathymetry data (see Section 3.1) for the floor of the Atlantic Ocean. The assigned boundary head simulated the level of the ocean and was based on the monthly mean sea level measured at two NOAA tide gauges – one at Virginia Key, near Miami, and the other at Naples, on the west coast of the Florida peninsula. The tide gauge locations are marked on Figure 1.1 and the monthly average water levels for each gauge, plus the average value used in the model are plotted in Figure 3.16. There is some monthly variation in the ocean level, with slightly higher levels in the fall and lower levels in the spring and summer. The annual variation of monthly mean sea levels is less than 1 foot, which is much smaller than the variation in monthly average heads at most observation wells in the model domain. Note that with the coarse time discretization, this model does not attempt to reproduce daily tidal cycles.

3.3.3 Aquifer Head Boundary Conditions

Ideally, the west and south boundaries would also extend out to the locations of the outcrops for each layer in the Gulf of Mexico. However, these outcrops occur nearly 150 miles from the Florida coastline. Extension of the model boundary to these outcrops would add significantly to the model size, computational requirements, and the time required to reach a converged solution. This would also add a large area to the model which has not been extensively studied and for which there is no significant data regarding heads, water quality or aquifer characteristics. Instead, the north, west and south boundaries coincide with available water level data points. For each aquifer (IAS, UF, APPZ, LF1, and BZ), heads assigned are based on monthly averaged measured values from wells located near the boundary. Figure 3.17 shows the areas where specified head boundary conditions were applied to the models as well as the location of the available data points. The process used to assign specified heads to the sides of the aquifer layers of the model accounted for all available data and incorporated the conceptual model for the site. It is described in detail in Appendix C.

Some concerns have been raised that the use of specified head boundary conditions at these coastal and inland locations might cause inaccuracies since there are numerous pumping wells located very close to the boundary. However, these errors are mitigated by basing the boundary heads on measured heads, which already include the drawdown effects of regional pumping. Near-field effects of pumping would likely not be captured, but they are beyond the scope of this model and not important to the goals of the regional model (See Section 2.0).

3.3.4 Confining Unit Head Boundary Conditions

No-flow boundaries were used at nodes (WASH123D) and cells (SEAWAT) along the side boundaries of the confining units, except where they outcropped to the ocean. The horizontal flow through the model boundary in these confining units is not believed to be a significant source or sink when compared to flow through the aquifers. A sensitivity analysis confirmed this assumption and is presented in Section 5.5.3.

3.3.5 TDS and Temperature at the Boundaries

SEAWAT and WASH123D both allow the user to define the water quality of the flows entering the model at any boundary condition. In SEAWAT, the SSM package (Source & Sink Mixing) was used to assign the TDS and temperature to each cell with a CHD boundary condition and all injection wells. WASH123D has a similar requirement in the form of an RS2 and RS6 card (variable boundary TDS concentration and temperature, respectively) corresponding to each of the specified head nodes and a PS2 and PS6 card (point source TDS concentration and temperature, respectively) for each of the injection wells.

For the boundary cells and nodes, the water quality of the incoming water was set based on the initial conditions at that location (see Section 3.4). For injection wells, the TDS values were assigned using available data (see Appendix E). At injection wells where no data was available, it was assumed that TDS values would be similar to nearby injection wells of the same type. The two types of injection wells were deep injection wells (typically have high TDS values) and existing ASR wells (typically have low TDS values). Injected temperature values were assumed to be consistent with the temperature initial conditions for the SAS (see Section 3.4.2).

3.4 Initial Conditions

The initial conditions applied to the model included initial head, salinity and temperature. The initial head condition was based on early test runs of the model. It is important to note that while the initial head condition affects the speed at which the steady state solution is reached, it has no effect on the model results. For the transient model, the first stress period was solved in steady state mode to give the starting head condition for the subsequent transient simulation. The initial salinity and temperature conditions were used by the models in the initial calculation of groundwater density. Studies have shown that regional groundwater flow patterns in the FAS can be significantly affected by variations in the groundwater fluid density [Hughes, Vacher, and Sanford (2007), Meyer (1989), Sanford et al (1998), Kohout (1965), Kohout et al (1977)]. The ability of SEAWAT and WASH123D to model density-dependent flow was the main criteria in selection of these models. The following subsections describe the data and methodology used to create these initial condition distributions.

3.4.1 Salinity (TDS) Distribution

For this study, reported measurements of total dissolved solids (TDS) are used as proxy for salinity. The terms 'TDS' and 'salinity' are used interchangeably in this report. The model requires that initial salinity concentrations be specified at every computational point in the model domain. In order to meet this requirement, an extensive data collection effort was undertaken to identify representative water quality data from the SAS to the BZ. Where possible, water quality data from the beginning of the calibration period (October 2003) was used; however, in areas where data was sparse, reported measurements from other time periods were used to fill data gaps. Since the regional water quality does not normally change drastically over a period of a few years, this method of filling data gaps was considered to be adequate. It is important to note that data at or near injection wells was not used if the samples appeared to reflect the quality of the injected water instead of the native water quality. A variety of data sources were used to collect the available TDS data, including USGS, DOH, SFWMD, SJRWMD, and SWFWMD. Additional details on the data collection effort are summarized in Appendix A.

Once the TDS data was collected, it was carefully evaluated by the modeling team to ensure that it reflected the known regional water quality. Several recording errors (e.g. data transposed between zones, significant fluctuation in water quality readings, etc.) were identified and corrected. The TDS at the ocean outcrops was set to 35,000 mg/l to reflect the salinity of seawater. Since the quantity and quality of the TDS data in the confining units was limited, the interpolation results in these layers were compared to the overlying and underlying aquifer water quality to ensure consistency. The validated data for each aquifer was then interpolated to the corresponding model layer. Figures 3.18 to 3.24 show the final TDS initial condition distribution by layer. The quantity of data used in the interpolation and assumptions specific to each layer are explained on each figure. Figure 3.25 shows the same data as a 3-dimensional fence diagram.

For the SEAWAT model, the TDS initial condition values for the FAS (Layers 5 through 22) were specified based on the corresponding aquifer and confining unit values shown in Figures 3.18 through 3.24. The SAS (Layer 1) was given a uniform TDS concentration of 100 mg/l in the land areas and 35,000 mg/l at the ocean. The TDS values for the ICU (Layers 2 and 4 and a portion of Layer 3) were determined by taking the average of the SAS and UF layers. Available data in the IA was interpolated to determine the initial conditions for the aquifer portion of Layer 3.

In the WASH123D model, the assignment of the initial conditions were somewhat different than for the SEAWAT model as a result of the differences between finite difference (SEAWAT) and finite element (WASH123D) computational points. For the SEAWAT grid, the computational points are located at the centers of the grid cells, so the initial conditions are required at each grid cell center. The WASH123D computational points and initial condition assignments are located at the nodes on the element interfaces. Figure 3.26 is an illustration that shows the comparison of the SEAWAT and WASH123D computational point locations and the differences in the assignment of TDS initial condition for the two models. In this example of a vertical column of grid cells and mesh elements, there are two confining units and two aquifers, each with a different TDS concentration. For SEAWAT, the assignment of initial conditions for each aquifer and confining unit was straightforward and based on the interpolation of

available data as explained previously. However, for the WASH123D assignment, the aquifer TDS values (from the interpolation of the available data) were assigned to any computational point within or at the top or bottom of the aquifer. For confining units, the TDS values from interpolation were only assigned to nodes that were completely surrounded by a single hydrogeologic unit. So, points 2, 3 and 4 were given the interpolated aquifer TDS value of 2000 mg/L, but only point 5 had the interpolated TDS value of 5000 mg/L which was associated with that confining unit.

Although the SAS was not explicitly modeled in the WASH123D model, the SAS initial TDS values used in the SEAWAT model were assigned to the top layer of nodes in the WASH123D model, top of Layer 1. The initial TDS values in the remaining layers of nodes representing the IAS, nodes on the interfaces of Layers 2 and 3, were the average of the values for the SAS and UF layers.

In general, fresher zones in the deeper geologic units are seen in the northern portion of the model beneath the Polk County recharge area and south of Orlando. The TDS concentration increases to the south and near the geologic outcrops at the ocean. Additional details concerning the procedure used to develop the TDS data sets and initial conditions are presented in Appendix E.

Because of the short calibration period (14 months) and validation period (10 months), no appreciable change in the TDS distribution was noted in the model results. Final TDS distributions are quite similar to initial TDS distributions, except in the immediate vicinity of injection wells. Because of the coarseness of the model grid, the model-calculated TDS close to an injection well cannot be expected to be accurate, and is not important to the regional goals of this study. For this reason, model results of water quality data are not presented in this report. Water quality will be of greater import during the production runs on the local-scale models, which will look at ASR efficiencies and near-well effects.

3.4.2 Temperature Distribution

The models also required the definition of the initial groundwater temperature at every computational point in the model domain. Temperature data was collected to construct a data set of values from the IAS to the BZ throughout the horizontal extent of the model domain. For the SAS, an average temperature value of 24°C can be assumed for the entire unit because shallow density variations have little impact on model results. Where possible, temperature data from the calibration period was used; however, in areas where data was sparse, reported measurements from other time periods were used to fill data gaps. This approach is based on the assumption that regional water temperature does not vary significantly over a period of a few years. As noted for the TDS data analysis, data at or near injection wells was not used if the samples appeared to reflect the temperature of the injected water and not the native water temperature. In some of these cases, well drilling reports containing native water temperature measurements were available and were used in place of more recent temperature measurements. Several data sources were used to collect the available temperature data, including USGS, SFWMD, SJRWMD, and SWFWMD. On the ocean boundary, temperature variation was estimated using a general temperature-depth of ocean water profile compiled by the University Corporation for Atmospheric Research (Figure 3.27).

The collected data was analyzed to determine the values that best represented the regional temperature in each aquifer and confining unit. The details of this analysis are included in Appendix E. Figures 3.28 to 3.35 show the initial condition temperature distribution for each hydrogeologic layer. The number of data points used in the interpolation and assumptions specific to each layer are described on each figure. The same data is displayed in a 3-dimensional fence diagram in Figure 3.36.

The temperature initial condition values were assigned to the SEAWAT and WASH123D models in a similar manner to the assignment of the TDS initial condition values. See Section 3.4.1 for a description of the differences in model assignments resulting from the differences in the location of their computational points.

In general, the temperature increases with depth on the western side of the peninsula and decreases with depth on the ocean boundary. This trend creates a very large temperature variation, from 5^{o}C to 44^{o}C, in the BZ where temperature effects on density have the largest impacts on model results. The warmer west coast temperatures also extend through the mid-section of the state toward Lake Okeechobee in most of the geologic units.

Because of the short calibration period (14 months) and validation period (10 months), no appreciable change in the temperature distribution was noted in the model results. Final temperature distributions are quite similar to initial temperature distributions, except in the immediate vicinity of injection wells. Because of the coarseness of the model grid, the model-calculated temperature close to an injection well cannot be expected to be accurate, and is not important to the regional goals of this study. For this reason, model results of water quality data are not presented in this report.

3.5 Sources and Sinks

In addition to the model boundaries, pumping wells constitute a significant source/sink for groundwater in South Florida. This pumping includes withdrawal wells (irrigation, water supply, etc.), existing ASR wells, and Class I injection wells. An extensive data collection effort was performed by SAJ to compile and evaluate detailed data sets of the pumping distribution within the model domain. Over 30,000 wells were identified as active during the calibration/validation periods within the model domain. However, many of the wells were missing specific location information such as horizontal coordinates or open interval depths. Also, monthly transient pumping rate records for many wells were often either unavailable or incomplete. As part of the data collection effort, estimates were made to fill these data gaps. Additional details on the data collection effort for the pumping wells and the methodology used to fill the data gaps are summarized in Appendix A.

Additional effort was required to appropriately assign the pumping to the grid and mesh. The depths of the top and bottom of the open interval for each pump were converted to elevations based on the approximate ground surface elevation at the point. These elevations were compared to the model-simplified geology to determine the aquifer (or aquifers) impacted by each well. The pumping elevations were adjusted to prevent the model from pumping in confining units. Pump rates for wells covering more than one aquifer were prorated based on the length of open interval and the estimated hydraulic conductivity of each aquifer. SEAWAT requires all pumping to be applied to the center of a

cell; WASH123D requires all pumping to be applied to a node. To accommodate these requirements, the wells were moved horizontally to nearest computational point. In SEAWAT, any well located within a grid cell, was automatically moved to the center of the cell and added to the pump rates of any other wells located in the same cell. Vertically, the pumping from each well was divided among the cells or nodes in the aquifer according to the vertical location of the open interval of the well. See Appendix D for more details. For a regional scale model, this methodology is sufficient, but it should be noted that near-field effects of individual pumping wells are not well-portrayed in this regional model, since cell and element sizes are as large as 10,000 feet on a side.

During of the early stages of calibration, the substantial influence of pumping on the FAS water levels was noted. A substantial portion of the pumping data had been estimated because monthly pumping rates were not available (see Appendix A). For the October 2003 to December 2004 period, there were 5,669 irrigation wells with reported data for all months, 4,206 irrigation wells with reported data in some of the months, and 6,628 wells with no data. A detailed evaluation of the pumping data and its correlation to observed water level and climatologic trends indicated that critical errors were present in this estimated pumping data. The methodology used to estimate missing transient pumping data was reevaluated to better correlate with observed pumping trends and the climatologic patterns that drive irrigation. Additional details on the methodology used to estimate missing transient pumping data are presented in Appendix D.

The pumps located in each aquifer are shown in Figures 3.37 to 3.41 and summarized in Table 3.1.

4.0 Calibration/Validation

Model calibration is the process of varying model input parameters within a reasonable range until the model output matches observed conditions within some acceptable error criteria. This calibration can be either to steady-state or transient conditions. Steady-state model simulations eliminate the time terms in the governing equations (see Equations 2.3 through 2.6) and provide a snap-shot of the hydraulic conditions in a stable aquifer system. An inherent assumption with this type of simulation is that the system has achieved an equilibrium condition. Steady state results are also commonly used as initial conditions for subsequent transient simulations. For models that are affected by a variety of constantly changing stresses, transient calibration is necessary to ensure that the model is providing a reliable representation of the system.

Once a model is considered calibrated, it is then validated against at least one different set of observed conditions using the hydraulic parameters established during calibration. A model is considered validated when the set of model parameters from the calibration process yields a similar satisfactory degree of agreement between field observations and computed model results for the independent validation period(s). If the validation results are not satisfactory, then the model calibration process resumes, continuing until a satisfactory agreement is obtained for the calibration and validation data sets.

For the Phase II ASR Regional model, a steady state calibration was first performed to the October 2003 and February 2004 observed water level data sets. Once the steady state model was calibrated, a

transient calibration was performed for the 15 month period from October 2003 to December 2004. Finally, a transient validation simulation was performed for a 10-month transient period from October 1993 to July 1994. Observation wells for calibration were selected from the monitoring well database provided by SAJ. Generally, observation wells were selected when at least 50% of their open section (between the cased and drilled depths) coincided with the model-simplified geology at that location. Additional wells were removed for a number of reasons: because their data indicated the effects of local pumping; their data was quite sparse; the data indicated a probe error; etc. Some wells located in the Hillsborough River valley north of the Polk County recharge area were removed because there were so many wells in this area that the calibration statistics were being skewed to an area far removed from the proposed CERP ASR sites. Table 4.1 lists all of the wells in the SAJ database and their use in the model (either for boundary conditions or calibration) or the reason for removal from the model.

The steady state and transient calibration/validation descriptions below are only for the final calibration of the SEAWAT model. After the draft regional model calibration was completed using both the SEAWAT and WASH123D codes, it was determined that the codes both provided a reasonable calibration of the steady state and transient flow fields. However, it was more difficult to incorporate the widespread heterogeneity of the hydrogeologic model parameters in the WASH123D model due to the zonal method of assigning these parameters in the WASH123D code. Appendix F provides details on the excessive number of WASH123D zones required to provide the necessary heterogeneity in hydrogeologic parameters. In addition, because SEAWAT provides several solver options, it is possible to make many model runs using a less accurate solver (standard finite difference method with upstream weighting) to get close to calibrated results. Once the solution is nearly calibrated, a more accurate but slower running solver (third-order TVD) can be used to take the last steps to reach the final calibrated solution. The WASH123D code is not equipped with a fast, less accurate solver. The combination of difficulty in assigning widespread heterogeneity and fewer solver options means that the WASH123D model requires more time for calibration. Because programmatic constraints have made it difficult to support the use of more than one code for the future of the project, a decision was made to proceed solely with the SEAWAT model. A comparison of the WASH123D and SEAWAT model results for the draft calibration are included in Appendix F. Although these results are from the draft calibration, the fact that the similarly-constructed WASH123D and SEAWAT models computed similar results provides reinforcement for the SEAWAT final calibration results.

4.1 Steady State Calibration

A steady state calibration was performed for October 2003 and February 2004 by varying the input parameters (principally hydraulic conductivity) until the model output (heads) matched the measured heads at non-pumping monitoring wells with data for either month. The model for each month was provided with a separate set of specified heads around the edges of the aquifers and at the surface, simulating different hydrologic conditions as reflected in the available data (see Section 3.3). The pumping data was also different for each month and based on the available reported pump rates and estimates as described in Section 3.5. Starting conditions (salinity and temperature), hydraulic conductivity, and all other input parameters were identical for the two steady state calibration models (see Section 3.4).

October 2003 was selected for steady state calibration to ensure a good starting condition for the transient calibration. However, analysis of the available head data indicated that water levels declined sharply in many wells during October 2003 as shown in Figure 4.1. This indicates that the aquifers were responding to pumping stresses and that the measured heads in October 2003 do not represent an equilibrium or steady state condition. For this reason, February 2004 was added as an additional steady state calibration period. This month was chosen because many of the monitoring wells have relatively constant heads for a period of a few months ending in February, indicating a more equilibrium condition and less variation in pumping. Calibration to October 2003 continued in order to provide a quality starting condition for the transient calibration, but the measured water levels from the end of October 2003 were used for calibration instead of the average head over the month, since the heads at the end of the month would be expected to be closer to the steady state level caused by the pumping from that month. During February, there was much less pumping and the model calculated heads were compared to the average measured heads for the month. The calibration for both months continued in tandem, with slightly more emphasis placed on the month of February. When head levels at a certain well could not be matched in both months using the same input data set, efforts were made to select parameter values that would calculate the head in one month a little higher than measured and the other a little lower. Table 4.2 lists the wells used for steady state calibration, the observed water levels during the calibration periods, and the modeled water level.

The quality of the steady state calibration was evaluated in several different ways, including error statistics, calibration target figures, gradient analysis of well clusters, and comparison to other published information, such as estimates of recharge to the UF and pre-development heads. The following paragraphs describe each of these evaluations of the steady state calibration. Details pertaining to each model's calibration will be presented in later sections.

A model's calibration is measured mathematically by the use of error statistics. The three criteria generally used are the mean error (ME), mean absolute error (MAE), and the root mean square (RMS) error, defined by Equation 4.1, 4.2 and 4.3.

$$ME = \frac{\sum_{i=1}^{n}(c_i - o_i)}{n} \qquad \text{Equation 4.1}$$

$$MAE = \frac{\sum_{i=1}^{n}|c_i - o_i|}{n} \qquad \text{Equation 4.2}$$

$$RMS = \sqrt{\frac{\sum_{i=1}^{n}(c_i - o_i)^2}{n}} \qquad \text{Equation 4.3}$$

Where:

c_i = Model calculated head at observation point *i*

o_i = Observed head at observation point *i*

n = Number of observation points

The mean error (Equation 4.1) is the average of the differences between the observed and calculated heads (or residuals) and can indicate the overall comparison between computed and observed data. Negative and positive residuals can cancel each other out, resulting in a mean error close to zero even when the calibration is not good. The sign of the mean error is an indication of the overall comparison of the model to the data (e.g. a positive mean error indicates the model is generally computing too high).

The mean absolute error (Equation 4.2) is the average of the absolute values of the residuals. The absolute value prevents positive and negative residuals from canceling each other, providing a clearer picture of the magnitude of errors across the model, without an indication of the direction (high or low) of the errors.

The root mean square (RMS) error (Equation 4.3) is the square root of the average of the squares of the residuals. The RMS adds additional weight to points where the residual is greatest. If the residuals at all points are very similar, the RMS will be close to the mean absolute error. Alternatively, a few points with high errors can add significantly to the RMS for an otherwise well-calibrated model. For all three of these criteria the optimal value is zero.

The spatial variation of the fit between model calculated heads and field measured heads is shown in the calibration target figures which are provided for each of the main aquifers in each model (Figure 4.2 through 4.11, with zooms to specific locations in Figures 4.12 through 4.17). The calibration figures show the head contours (interpolated from the model-calculated heads at each cell for a specific model layer) and a set of targets placed at the location of each measured head. The targets indicate the calibration quality at that point with its color and the direction of the colored bar. Green bars indicate computed results within 2 feet of the observed head; yellow bars indicate computed results within 4 feet of the observed head. Red bars are for locations where the difference between computed and observed heads is more than 4 feet. The bar in each target is drawn above the center line for points where the computed head is higher than the observed head (positive residual). Conversely, targets below the center line indicate computed heads lower than observed heads (negative residual). The details of the quality of the calibration as shown through these figures will be discussed in Section 4.1.3.

The quality of the calibration can be assessed using these figures by noting the color and direction of the target bars. Generally, a well-calibrated model will show a random field of small errors with no clustering of either positive or negative residuals. Often the reasons for poor calibration at an individual monitoring well can be assessed by noting the location of the point – perhaps it is in an area of steep slopes or close to a large pump. The steady state calibration figures also show a plot of computed vs. observed values with a point plotted for each observation point. In a perfect calibration, all points will lie along the line y=x (shown as a black line). For good calibration, all points should lie close to this line and points should not be clustered in any other part of the plot.

The quality of the steady state calibration was also assessed using a gradient analysis of a number of well clusters. This analysis ensures that minor head residuals are not compounded, resulting in

unrealistic gradients between aquifers. Figures 4.18 through 4.28 show the model-calculated head at the center of each cell in a vertical column compared with the heads measured in a number of wells located within this column but screened at different depths. The gradient analysis helps verify that both the direction of flow and the slope of the gradient are accurately reproduced in the model.

Finally, the model results were compared to a published estimate of recharge/discharge to the UF (Figure 4.29) and a published estimate of pre-development heads (Figure 4.30). Although this is not a comparison to actual measured data and therefore, cannot truly be termed calibration, this model's similarity to other independent, published analyses helps to strengthen its credibility.

As stated in Anderson, 1992, "The judgment of when the fit between model and reality is good enough is a subjective one. To date, there is no standard protocol for evaluating the calibration process…" A common rule of thumb is that in a well-calibrated model, the RMS should be less than 10% of the head difference across the domain. This rule is not especially applicable to the ASR Regional Model, where the head difference across the model domain is over 200 feet. Few would find 20 feet of error acceptable for this model.

In reality, the acceptable level of calibration varies across the area and depends on the conditions at each location. In the northern portion of the model, particularly in the Polk County recharge area, the hydraulic gradient is relatively steep. Many of the high residuals at observation wells in this area are due to grid resolution, which is too coarse to accurately portray every nuance of the highly variable hydrogeologic conditions. For example, the pumping wells had to be moved up to 5000 feet to the nearest cell center (see Section 3.5) but the observation points were not moved. Additionally, near well effects are not accurately modeled when the cells are this large. For these reasons, calibration errors up to a few feet might be acceptable in this area.

On the other hand, much less head variation is observed in the southern portion of the peninsula. Here, errors caused by grid resolution or the placement of monitoring and pumping wells are less likely to be significant. Thus, acceptable residuals at observation points in this area would be much smaller.

Acceptable calibration error also depends on what question the model is answering. This regional model is built specifically to predict the large-scale effects of the CERP ASR program on the heads and salinities in the groundwater. For this reason, greater residuals are often acceptable for observation wells far from the area of interest or for wells which are directly impacted by local pumping.

4.1.1 Calibration Process Description

For reasons described above, the steady state regional ASR model was calibrated to head data collected in both October 2003 and February 2004. The calibration process was a combination of "trial and error" calibration and automated calibration. The "trial and error" calibration involved making small changes to the input files, running SEAWAT and assessing the improvement made. This type of calibration is time consuming, but it also allows the modeler to inject his own knowledge and understanding of the hydrogeologic system into the calibration process. Further, through this tedious process, the modeler

develops an important understanding of the hydraulic stresses impacting the model and the sensitivities of both the input parameters and the calibration points.

The automated calibration technique employed for this model was an open source code called PEST (Parameter ESTimation), developed by Watermark Numerical Computing. PEST implements a variation of the Gauss-Marquardt-Levenberg method of nonlinear parameter estimation and can be strapped around a modeling code so that it calls the code numerous times with slightly different parameter values and analyzes the results (Watermark, 2004). In many cases, PEST can be very efficient, especially when running in parallel. During the course of this project we found it necessary to link up to 30 computers into a "pest nest." This allowed PEST to run 30 SEAWAT simulations simultaneously, resulting in a significant speed up in the calibration process. A drawback to automated calibration is that PEST only knows as much about the system as the modeler is able to tell it. Not all hydrogeologic knowledge is easily imparted in the PEST input files. Sometimes PEST can move too far from known data in an effort to closely match observed data.

During the course of the steady state calibration, it was found that the best calibration method was a combination of "trial and error" calibration with PEST calibration. The calibration results described in this section are the result of thousands of "trial and error" SEAWAT runs and tens of thousands of PEST-generated SEAWAT runs. The process also included numerous discussions with scientists from SFWMD to "truth-check" the calibration parameters against their superior local hydrogeologic knowledge and experience.

The main parameters varied for the steady state calibration were horizontal and vertical hydraulic conductivity for layers 2 through 22 (IAS through BZ). Although hydraulic conductivities were assigned to the SAS in the SEAWAT model, no calculations were made in this layer. The assigned hydraulic conductivities had a minor effect on the infiltration of recharge, but the effect was trivial enough that these conductivities were not varied during calibration.

The initial conductivity fields for all layers were designed by combining all the available information from the literature along with that provided by SFWMD or available in various online data repositories. The conductivity values were assigned in zones with constant values across each zone. The shapes of the zones were occasionally based on known structural changes, but more often were placed arbitrarily based on the locations of data points. As the calibration proceeded, many of these zones were split into smaller ones and some were combined or reshaped. A reasonable calibration was achieved using this method, although it often resulted in unrealistic sharp corners to head contour lines caused by sudden changes in conductivity between neighboring zones.

Eventually, the decision was made to convert the zonal hydraulic conductivity fields to a smooth, interpolated conductivity field. Although the placement of the interpolation points can be as arbitrary as the shape of the conductivity zones, this method allowed for a more credible conductivity field with few sudden changes in flow characteristics. The use of both the "trial and error" and automatic calibration using these interpolated conductivity fields achieved a much better calibration.

In PEST, the method for creating the smooth conductivity field is called the "pilot point method." Each aquifer or confining unit was given a set of "pilot points" placed somewhat randomly, but with a greater density in areas of expected heterogeneity. A hydraulic conductivity value was assigned to each point and a kriging algorithm (distributed with PEST for use with MODFLOW) was applied to assign a unique hydraulic conductivity value to each grid cell. This added an extra step to the calibration process. Each change to the input parameters was made by changing the conductivity of one or more pilot points, and then the kriging was repeated with the new points before SEAWAT was run with the new conductivity surface.

When running PEST for automated calibration, an option called "regularization" was employed to reduce the number of degrees of freedom and minimize the heterogeneity of the calibrated conductivity fields. The use of the pilot point method often leads to an under-constrained problem, where there are more pilot points than there are observation points. This can lead to non-uniqueness of the calibration solution. In other words, if there are too many pilot points, there will be numerous, possibly quite different, conductivity fields which will yield the same quality of calibration. Some of these sets of conductivity values can be eliminated because of known characteristics of the aquifers, but some cannot be eliminated without additional data. In the regularization method, PEST gives preference to solutions that minimize the variance of conductivity values assigned to neighboring pilot points. Thus, the result of a PEST regularization run is the smoothest set of conductivity fields which will yield a solution that matches the observed data within a user-defined tolerance.

4.1.2 Calibrated Hydraulic Conductivity Fields

Figures 4.31 through 4.40 show the final calibrated maps of hydraulic conductivity for all model layers. Aquifers are shown with horizontal hydraulic conductivities (vertical conductivities were always 1/10 of the horizontal value). Confining units are shown with vertical hydraulic conductivities (horizontal conductivities were always twice the vertical value).

The IAS layers are shown in Figures 4.31 through 4.33. In reality, this geologic layer is a complex combination of interbedded confining units and sub-regional aquifers. Because of the complexity of this system and because the ASR wells are not expected to impact this layer substantially, the IA and ICU were combined into layers 2 through 4 of the SEAWAT grid. The aquifer section was modeled in the northwestern portion of the model domain in layer 3 of the SEAWAT grid. The boundary between the aquifer and aquitard in this model layer is based on a figure in "The Hydrogeology of Florida" (Miller, 1997). All ICU layers have identical vertical hydraulic conductivities in the areas outside of this aquifer zone in both models. (Note that Figure 4.32 shows horizontal hydraulic conductivity, not vertical conductivity, so the colors are slightly different.) Variability was allowed between the ICU conductivities overlying (layer 2) and underlying (layer 4) the aquifer portion of the IAS to provide some variation in the source of pumped water in the IA. It is important to remember that the conductivity distributions for these layers are not expected to replicate reality. The model was not calibrated in the IAS and no attempt has been made to correctly simulate flow in this section. These layers act simply as a conduit for recharge water traveling to the UF and discharge water traveling to the surface. The objective was merely to correctly define these flows.

Figures 4.34 and 4.36 show the calibrated horizontal hydraulic conductivity values for the UF and APPZ. Small dots indicating measured conductivity values are overlain on the calibrated conductivity field in both figures for comparison between the model calibration and the field data. There was a significant amount of data available for both these layers; consequently, conductivities were not allowed to vary significantly from what has been measured during the calibration process. The UF (Figure 4.34) shows a zone of somewhat low conductivity along the Kissimmee River, with higher conductivities in the southern portion of the model. It is important to note that the lower conductivities found in the west portion of the model coincide with greater thickness, so the transmissivity does not drop as low as it may seem from this figure. This is also the area where the Hawthorn and Suwannee units are found. This model has combined both of these units into the UF, so the conductivities may vary somewhat from known measurements in either of these units. It is also interesting to note that the Kissimmee River ASR Pilot Project (KASR) is located in a small area of high conductivity. The drop in conductivity towards the east is documented, but the exact location and nature of this anomaly is unknown. The areas of lower conductivity which surround KASR may significantly impact the efficiency of the proposed CERP ASR wells in this area.

The conductivities in the APPZ (Figure 4.36) are low along the north-south ridges west of Kissimmee River and reach higher levels on the east side of the model, including an area of very high conductivity directly beneath the low conductivity area in the UF near KASR. The line between the northern dolomite rock and the southern limestone is one of the few sudden changes in conductivity in this model. The location of the interface between the two rocks is based on USGS Scientific Investigation Report 2007-5207 (Reese and Richardson, 2008) though its exact location may be unknown. Suggestions were made to try to soften the conversion from dolomite to limestone. Some early sensitivity analyses were run to determine the importance of the placement of that line, but the effects were minor and localized. Since the precise location of this line did not affect the regional calibration, the location of this interface was kept consistent with that depicted in USGS Scientific Investigation Report 2007-5207 (Reese and Richardson, 2008).

Figures 4.38 and 4.40 present the horizontal hydraulic conductivity fields for the LF1 and BZ layers of the model. Very little data was available for either layer. The final calibrated results show generally increasing conductivity to the southeastern portion of the model domain. This distribution is consistent with the current understanding of these deeper aquifers (Reese and Richardson, 2008). As mentioned previously, the northwest section of the BZ has been assigned conductivity values similar to those found in LF1 to account for the absence of the BZ in this area.

Finally, Figures 4.35, 4.37, and 4.39 show the vertical hydraulic conductivity values selected for the three confining units in the Floridan system. Although some data was available for these layers, it was used only as a loose constraint on the range of conductivities in each layer. The conductivity values in these layers were valuable tools in the calibration process since the model was highly sensitive to these parameters.

4.1.3 Description of the Steady State Calibration Quality

Figures 4.2 through 4.11 show the calibration target plots and the error statistics separated by layer and month. The UF steady state head solution and corresponding calibration targets in Figures 4.2 and 4.6 (February 2004 and October 2003, respectively) shows a good calibration. The RMS in both months is less than 2.2 feet with the mean error values very close to zero. The majority of the calibration targets are green, indicating a match within 2 feet of the measured head value. The exceptions are due to steep head gradients, near-well pumping effects or the inability to calibrate both months simultaneously (likely due to errors in the pumping estimates or lack of a local steady state condition). Some of these exceptions are described below:

- **ROMP 33 TMPA/SWNN in Manatee County and ROMP TR 5-2 SWNN and ROMP 22 SWNN in Sarasota County (See zoom on Figure 4.12)**: All three points calibrate well in one of the two steady state calibration months, but have a residual error of 2.0 to 2.5 feet in the other month. The inability to better calibrate these points for both October 2003 and February 2004 is likely due to pumping estimates or simplifications in the model in these counties. This error is considered acceptable for an area distant from the proposed ASR wells.

- **ROMP 32 SWNN and ROMP 25 SWNN near the boundary between Manatee and Hardee Counties (See zoom on Figure 4.12)**: The calibrated model calculates 2.5 and 3.2 feet low in October 2003 and about 3.0 and 1.5 feet high in February 2004 for ROMP 32 and ROMP 25, respectively. The inability to calibrate these points for both October 2003 and February 2004 is likely due to pumping estimates or simplifications in the model. In these situations, the aim was to model a state between the two months' data with a closer emphasis on February data.

- **L-2528 and L-2435, two wells in the Cape Coral area of Lee County (See zoom on Figure 4.13)**: These wells are greatly affected by large scale pumping. Because of the resolution of the grid, these near-field effects are not accurately simulated in the model. Additionally, the actual pumping locations had to be altered to coincide with cell centers, while observation well locations were not moved. Better calibration in this area cannot be expected on a model of this regional scale and is not necessary to evaluate the CERP ASR program. These wells are responsible for much of the RMS error of the UF. When these 2 wells are removed from the calculations, the RMS in February 2004 is 1.13 ft and in October 2003 is 1.26 ft.

- **ROMP DV-1 SWNN, CONE RANCH CM-10S UPL SUR, and Alston Deep FLDN in the northeast corner of Hillsborough County; and Lake Sawyer Well in the southwest corner of Orange County (see zoom in Figure 4.14)**: These wells are located in the steep gradient area around the recharge zone. Small changes to the horizontal locations of the substantial number of monitoring wells in these areas would result in improvements in the calibration. Since this area is not near the area of interest for the CERP ASR program, the resolution of the grid is coarse near these calibration points, preventing a better calibration. Further, the flow at these wells is from the recharge area towards the boundary and will not affect the CERP ASR sites, which are the main areas of emphasis for this model.

- **PBF-2 and PBF-3 in the central coastal area of Palm Beach County (see zoom in Figure 4.15)**: The calibrated heads for PBF-2 in October and February are both low by about 3 feet. A much better match is shown at PBF-3, approximately 3 miles away, where the calibrated heads for both months are only about 1 foot high. The model contours show that the computed heads drop off toward the coast along the length of Palm Beach County. Because the 2 wells are only 2 model cells apart and because the well closer to the coast (PBF-2) had a higher observed head, it would be very difficult for the model to calibrate both points. The calibration goal was to split the error between PBF-2 and PBF-3. Because PBF-3 is part of a UF, APPZ, LF1 well cluster, this well was favored in the calibration split.

The statistics and calibration targets for the APPZ steady state calibration are shown on Figures 4.3 and 4.7 (February 2004 and October 2003, respectively). These plots show slightly less error than the UF with the RMS less than 1.6 in both months. Most of the calibration points in this layer show a close similarity between calculated and measured heads. A few exceptions, described below, skew the statistics, but do not materially affect the usefulness of the model.

- **ROMP 86A AVPK located in Pasco County near the northwest boundary of the model (see zoom in Figure 4.16)**: This well is located at the edge of the recharge zone in an area of very steep gradient. A small change to the horizontal location of this well would result in improvement to the calibration at this point. Since this area is not near the area of interest for the CERP ASR program, the resolution of the grid is coarse near these calibration points, preventing a better calibration. Further, the flow at this well is from the recharge area towards the boundary and will not affect the CERP ASR sites, which are the main areas of emphasis for this model.

- **ROMP 30 AVPK and ROMP 25 AVPK in Hardee County and ROMP 28 AVPK in Hillsborough County (see zoom in Figure 4.17)**: The model calculates the October 2003 head 2.3, 1,4 and 2.2 feet low, respectively and the February 2004 head 1.4, 3.7 and 0.5 feet high, respectively. The inability to calibrate these points for both October 2003 and February 2004 is likely due to pumping estimates or simplifications in the model. In these situations, the aim was to model a state between the two months' data with a closer emphasis on February 2004 data.

- **ROMP 33 AVPK in Manatee County (see zoom in Figure 4.17)**: This well calibrates high by 2.2 feet in February 2004 and low in October 2003 by about 0.4 feet. Wells in this area are greatly affected by the Manatee County pumping, so the calibration error at this well is probably due to errors in pumping estimates or grid resolution.

Figures 4.4 and 4.8 show the head solution and calibration information for the LF1, while Figures 4.5 and 4.9 show the same data for the BZ. The unusual shapes in the head contours are due to the influence of density as caused by salinity and temperature and a great depth. At this depth, there is much less data for comparison, but the figure shows that all data has been matched very closely and the RMS values are impressive at less than 1 foot. Due to the small number of calibration points in the LF1 and BZ, an expanded calibration was performed in these layers.

Figures 4.10 and 4.11 show the head solution and a comparison of model results from the LF1 and BZ to data that has been collected for these units during a time period other than the calibration period. Since the water level data used for this expanded calibration was not from the modeled period, these figures use a confidence interval of 5 ft rather than the 2 ft interval used in the other calibration plots (i.e. green bars indicate agreement within 5 feet). The error statistics for this expanded calibration are consistent with that seen in the other layers of the model.

Another important aspect of the calibration is the comparison of gradients in the model to those measured in the field. Minor head differences in neighboring wells, if the residuals are of opposite signs, can impact flow rates significantly due to changes in gradient. This series of figures (4.18 through 4.28) presents the vertical gradients computed by the SEAWAT model (February 2004) as compared to gradients measured in the field.

Figure 4.18 presents the gradient comparison for the calibration model in February 2004 at the Alligator Alley well cluster in western Broward County. The model and the field data match very closely through the UF wells (G-2619 and G-2618) and the APPZ well (G-2617), showing almost no vertical gradient. Although there is no field data to verify the model-computed gradient changes in the confining unit, the overall gradient between the APPZ (G-2617) and the LF1 (G-2296) is nearly identical in the two plots.

Some readers may feel some concern about the shape of the head gradient plot presented at the left of Figure 4.18. Initially, it may seem that the plot indicates upward flow from the UF/APPZ to the surface and *downward* flow from the APPZ to the BZ. The reason for this seemingly anomalous result is that the heads presented here are observed heads, not equivalent fresh water heads. When the density effect is included by converting the observed head values to equivalent freshwater heads, the resulting gradient plot looks like that shown in the upper right corner of Figure 4.18. The deep layers with high levels of TDS actually exert a greater pressure on the water column resulting in an upward gradient in all layers. The remainder of the gradient plots will be shown with observed head values since this is the data measured in the field. However, the reader should be aware than these heads are not necessarily indicative of water flow direction. (See Section 2.1)

The majority of the well clusters shown in Figures 4.18 through 4.28 indicate a close agreement between model-calculated head gradients and field measured head gradients. All figures show February 2004 calibration results from the SEAWAT model. The following bullets will present a few comments on the plots of well clusters with poorer correlation in vertical gradient.

- **ROMP 86A in southwest Pasco County (Figure 4.19)**: This well is poorly calibrated with a head residual of about 5 feet in both the Suwannee and Avon Park zones. This well is located on the north side of the recharge area and so flow at this location has no effect on the ASR well locations to the south. However, it is encouraging to note that despite the head error (due likely to steep gradients and coarse grid resolution) the model is correctly calculating the gradient between the UF and APPZ layers of the model as shown by a nearly identical slope in the two lines.

- **ROMP 13 in the southeast corner of De Soto County (Figure 4.21) and ROMP TR 7-4 in Manatee County (Figure 4.23)**: Both the modeled gradient and the measured gradient at these wells are nearly flat between the UF and APPZ zones. The main differences in the plots are in the IAS layers and the SAS. As explained in Section 4.1.2, this model made no attempt to model either the SAS or the IAS section of the subsurface. The SAS was included only to simulate recharge and the IAS layers were intended only as a pass-through layer to regulate water reaching the UF or exiting at the surface. The small differences in gradient shown at these clusters are not important to the purposes of this ASR Regional Model.

- **Intercession City well cluster just west of the Kissimmee River in Osceola County (Figure 4.22)**: Here the gradient calculated by the model closely matches that measured in the field, with the exception of OSF-97. In this area, there is a very sudden, stark change in salinity which may not be replicated in the model because of lack of data and coarse vertical grid resolution. Because there is only one layer of cells in the BZ, the location of the salinity change in the model must be linear between the two bottom cells, making it difficult to precisely match the head at OSF-97. This area is deep and far from the ASR locations, so this minor error is not expected to be of great concern to the purposes of the model.

- **Hillsboro ASR well cluster in Palm Beach County (Figure 4.28)**: The model calculated gradient through the UF and APPZ layers closely matches the field measured data. Although the head variations in the MC2 layer cannot be verified because of a lack of field data, the overall gradient between the APPZ and the LF1 is nearly perfect at this well.

4.1.4 Comparison of Model Results to some Published Information

In an effort to further verify the model, the results were compared to the conclusions from two published reports. It is important to note that the conclusions in these reports were based on numerous assumptions, other models and sometimes minimal data. Minute differences between these published conclusions and the ASR regional model are not of concern. The purpose in this comparison was simply to show general agreement with other published work and analysis.

First, the model calculated recharge and discharge to the Upper Floridan layers was compared to the generalized recharge map published in USGS Water-Resources Investigations Report 88-4057 (Aucott, 1988). The recharge map presented in this USGS publication included data collection, analysis and some modeling. Figure 4.29 shows the comparison between the regional ASR model results and the USGS estimated recharge/discharge areas. Although there are minor differences, it is encouraging to note that the coastal areas and the southern half of the model domain are generally shown to be discharge areas by both analyses. Interestingly, the location of the model-calculated change from discharge to recharge north of Lake Okeechobee is very close to the estimated interface shown in the USGS figure. The northwest boundary area of the ASR regional model shows small areas of large discharge, interspersed with small areas of large recharge. These areas are likely caused by large changes in topography and coarse grid resolution in the ASR Regional Model. The fact that these areas of discharge are not shown in the USGS map is not cause for concern, especially since this area is separated from the ASR locations by the main recharge area.

The second comparison was made by rerunning the calibrated February 2004 SEAWAT model with all pumping removed (See Figure 4.30). The result of this "no-pumping" simulation was compared to the USGS (Bush and Johnston, 1988) published pre-development head contours for the UF. Because of the specified head boundary conditions along the south, west and north boundaries of the calibration model, it is impossible to completely remove pumping from the model. Drawdown caused by pumping would necessarily impact the measured heads in wells near the boundary, which were used to set the specified heads. However, despite this drawback, the correlation between the USGS estimated pre-development heads and the ASR no pumping heads is reasonable. The maximum head at the top of the recharge zone is nearly perfect, though the location is slightly different. The southern extent of the computed 70-foot contour is in good agreement with the USGS contour although along the eastern and western sides of the recharge area, the model underpredicts the USGS 70-foot contour by 5 to 10 feet. This discrepancy is the result of the discharge of the UF to low-lying river valleys where the surface heads are low. Another feature of the predevelopment heads captured in the model is that the 50-foot contour curves out along the eastern shore in Saint Lucie and Martin Counties more than the Bush and Johnston contour. Differences in the 40- and 50-foot contours along the west coast are mostly due to the implicit inclusion of pumping effects in the data used to determine the specified heads at the western boundary.

The most notable difference between the USGS predevelopment head contours and the computed head contours is the discontinuity of the computed 60-foot contour between the area of recharge from the surface and the southern 60-foot high southwest of Lake Okeechobee. Computed heads in this "trough area", in the vicinity of Lake Okeechobee and west along the Caloosahatchee River, are between 55 feet and 60 feet. While the difference is within the range of other differences observed between the predevelopment heads and computed heads, the trough indicates that Upper Floridan water south of Lake Okeechobee originates from a location other than the recharge area north of Lake Okeechobee. Bush and Johnston (1988) argued against this hypothesis. No data from the predevelopment time period exists to clarify whether the head trough existed. Head data from 2003-2004 at LaBelle and Kissimmee River Pilot site is less than 53 feet indicating a shallow trough similar to that shown in the model results exists under current "with-pumping" conditions. Geochemical data from a recently published study (Morrissey, S. K., et al, 2010) provides evidence that water found in the Upper Floridan aquifer in south Florida "is consistent with recharge from meteoric water during the last glacial period" rather than recent recharge from areas north of Lake Okeechobee. Considering this new evidence, it is entirely possible that a head trough such as that shown in the predevelopment model head results through the Caloosahatchee River/Lake Okeechobee area was present prior to development.

Although the match between the ASR regional model and these published conclusions cannot be considered to carry the same weight as comparisons to actual measured data, the close agreement helps to validate the model and shows concurrence with the conclusions being drawn by other scientists in South Florida.

4.2 Transient Calibration/Validation

In order to model the successive recharge, storage and recovery periods for the ASR wells, it was necessary that the ASR regional model be transient (i.e. include the time term in Equations 2.3 through 2.6). The addition of the time term necessitates a substantial increase in the number of parameters which can be varied during calibration. The hydraulic conductivity values had been tentatively set during the steady state calibration, though some iteration between the steady state and transient models occurred. Most of the transport parameters (porosity, dispersivity, and molecular diffusion coefficient) proved to be relatively insensitive on a regional scale due to the minimal TDS and temperature transport occurring on the small time scale of the model calibration and validation periods (15 months or less). Specific storage was found to be the most sensitive parameter during the transient calibration.

The convergence of the transient model was good in all timesteps for both flow and transport. Table 4.3 shows the mass balance and percent discrepancy for the flow portion of the model. The maximum percent discrepancy between flows in and out of the model is 0.0539%. Table 4.4 shows the percent discrepancy in the transport of the two modeled constituents: TDS and temperature (heat). All discrepancies are on the order of 10^{-8}% and 10^{-6}% for constituent transport.

The transient SEAWAT calibration proceeded in a manner similar to the steady state SEAWAT calibration. Initial specific storage values were assigned to polygonal zones and based on the available data. The storage data provided was divided by the aquifer thickness to derive the specific storage term used in the model. Storage data was much sparser than conductivity data. Calibration proceeded as a combination of "trial and error" calibration and automated calibration. PEST was again used as the code for automated calibration. Eventually, when significant progress had been made using the zonal specific storage fields, the pilot point method was again implemented to create smoothed fields of specific storage.

Figures 4.41 through 4.94 show the SEAWAT calibration at a number of observation wells which had significant data available. In each case, the observed and calculated heads are plotted during the 15 month calibration period (October 2003 through December 2004). Note that because of differing ranges of heads measured and calculated at each well, each plot has a different head scale on the y-axis. In order to facilitate the analysis of these plots, every graph has a horizontal grid line at every foot of head. In this way, the reader can tell, at a glance, whether the well has a large swing in heads (many grid lines) or has very little head variation (few grid lines).

4.2.1 Calibration Statistics

In addition to the visual inspection of the calibration at each observation point, a number of statistics were calculated at each point to aid in the calibration process. Each statistic compared the mean monthly heads in the observation dataset with the mean monthly heads from the model output. The first statistics were the mean residual error (ME), mean absolute error (MAE) and the RMS error. These equations were provided in Section 4 with the discussion of the steady state calibration (see Equations 4.1, 4.2 and 4.3). Additional statistics included the Coefficient of Determination (r^2) and the Nash-

Sutcliffe Model Efficiency Coefficient (E) as shown in Equations 4.4 and 4.5. The statistics for each point are listed in tables on Figures 4.41 through 4.94 and all are shown together on Figures 4.95 through 4.99.

$$r^2 = \frac{\left(\sum_{i=1}^{n}(c_i - \bar{c})(o_i - \bar{o})\right)^2}{\sum_{i=1}^{n}(c_i - \bar{c})^2 \sum_{i=1}^{n}(o_i - \bar{o})^2} \qquad \text{Equation 4.4}$$

where

r^2 = Coefficient of Determination

c_i = Average model calculated head during month *i*

$\bar{c}$ = Average calculated monthly head over all months

o_i = Average observed head during month *i*

$\bar{o}$ = Average observed monthly head over all months

$$E = 1 - \frac{\sum(o_i - c_i)^2}{\sum(o_i - \bar{o})^2} \qquad \text{Equation 4.5}$$

where

E = Nash-Sutcliffe Model Efficiency Coefficient (Nash and Sutcliffe, 1970)

None of these statistics alone can perfectly describe the calibration quality at every point. Each provides some information, but they all must be used together, coupled with a visual inspection of the model results. The mean error (Equation 4.1) shows the average residual between model calculations and observed data. Its optimum value is zero. The drawback to the use of this statistic is that positive and negative errors can cancel each other out, resulting in an unnaturally low mean error. An example of this effect is shown in the plot for Sarasota Well 9 (Figure 4.58). Here, the positive residual during the summer of 2004 cancels out the negative residual during the fall of 2004, resulting in a mean error of only 0.346. This low mean error overstates the calibration quality at this point.

This canceling effect can be best captured with a comparison between the mean error and the mean absolute error (Equation 4.2). In the calculation of the mean absolute error, the absolute value of the residual is taken before it is averaged. Again, the optimum value is zero. When the mean absolute error is very close to the mean error or when it is a similar value with the opposite sign, the cancelation effect is small. See OS0231 (Figure 4.52) where the mean error is -1.319 and the absolute error is 1.319 showing that there has been no cancelation of positive and negative residuals – all residuals in this case are negative. For Sarasota Well 9 (Figure 4.58), the mean absolute error is 1.991, much higher than the mean error, indicating significant cancelation of positive residuals with negative residuals.

The root mean square error (RMS) gives additional weight to large residuals and minimizes the impact of residuals less than 1.0 (Equation 4.3). Its optimum value is also zero. This result can help indicate the

variations in the residuals when it is compared to the mean absolute error. See, for example, PBF-2 (Figure 4.72). Here, the mean absolute residual is 2.997, while the RMS is only slightly higher at 3.036. The similarity of these two numbers indicates that every residual value was very close to -3 feet. Conversely, at ROMP 33 TMPA/SWNN (Figure 4.57), the mean absolute error is 3.691 while the RMS is larger, at 4.647. The difference in these two values is caused by a few months where the residual is large (November 2003, April 2004 and December 2004).

The mean error, mean absolute error and RMS do not take into account the ranges of observed heads at each well. All observation wells are held to the same standard whether they have wide swings in head values, or stay at a relatively constant head level. To account for this, the figures report each RMS value as a percentage of the range of observed heads at the well. Compare, for example, the Edgeville Deep Well 3 (Figure 4.60), with an RMS value of about 2.5, to BF-4S (Figure 4.74), which has an RMS value of about 1.5. A visual inspection of the two plots shows that, despite its higher RMS value, the Edgeville well calibration is much better than that at BF-4S. The variability at the Edgeville well is much larger – over 25 feet, compared to a range of only about 4 feet at BF-4S. The closer calibration at Edgeville is quantified by comparing the RMS values as percentages of the observed range – about 10% at Edgeville and 34% at BF-4S. Some modelers advocate a rule of thumb, requiring that the RMS of a calibrated model be less than 10% of the range of observations. The optimum value is, of course, zero.

The coefficient of determination (r^2) is a measure of the correlation of the observed vs. computed head values to a straight line (Equation 4.4). Its optimum value is 1.0. The importance of this statistic can be understood if one imagines a plot with the calculated heads on the y-axis and the observed heads on the x-axis. The model results and the observed dataset are used to place a point for each month in the calibration period. In a perfectly calibrated model, the computed head would equal the observed head, and all points would fall along the line y=x and the r^2 value would be 1.0. However, the r^2 value will also be 1.0 if the points fall along any straight line with any offset from the x axis or any slope. See, for example, TFRO-5 (Figure 4.84). The r^2 value at this well is 0.916, which is quite high compared to many of the other points. Although this point is fairly well calibrated, the model calculated head consistently falls about 1.8 feet higher than the observed head. The high r^2 value is an indication that the observed vs. computed heads would fall along a line with the equation $y = x + 1.8$. Some of the other statistics, such as the mean error and mean absolute error, alert us to the fact that the model is calculating slightly high. In this case, the high r^2 value when combined with an equivalent mean error and mean absolute error indicate that although the initial condition (based on a steady state run) is not perfectly calibrated, the heads at this well correctly respond to model stresses. The rise in head caused by the fall wet season closely matches that seen in the observed data.

ROMP 30 AVPK (Figure 4.80) is another example of a well where the high r^2 value (0.925) is deceiving. Here, the model is over-estimating the heads during the summer dry period and underestimating the heads during the fall of 2004 when the observed heads rise. The line that these points fall along is $y=mx + b$ where m is less than 1.0 and b is greater than zero. Despite these points, this well is not a particularly poorly calibrated point. The RMS is only 12% of the observed range of heads, but the quality of calibration is not as high as that indicated by the coefficient of determination.

The final statistic presented is the Nash-Sutcliffe Model Efficiency Coefficient (Equation 4.5). This equation was developed for quantifying the efficiency of a model for forecasting river flow and is seldom used for groundwater modeling studies. It is included at the request of IMC reviewers. When the Nash-Sutcliffe value is greater than zero, the model output is better than the observed data as a predictor of future conditions. When it is less than zero, the model is inefficient, i.e. the variation between calculated and observed values is greater than the variance in the observed data. The optimum value is 1.0. The comparison to the observed data variance takes into account the different head ranges at each well. In other words, points with smaller variations are held to higher standards than those with large variations.

When taken together, these statistics can help to quantify the calibration quality at any of the points. For example, OS0230 (Figure 4.52) has possibly the closest agreement between the observed and model calculated data. All of the statistical measures of the calibration at this point are very close to optimum values. Conversely, the worst calibration probably occurs at ROMP 17 SWNN (Figure 4.61) where all the statistical measures are far from optimum.

4.2.2 Transient Calibration Analysis - Heads

Because of the time discretization (constant boundary conditions and pumping for each month) it is impossible for the model to correctly calculate the head every single day. The goal of the calibration effort was to match gross seasonal variations in head, including the average head during the driest period (usually during the month of June 2004) and the average head during the wettest period (usually late fall 2004).

Because the model can only attempt a calculation of the average monthly heads, it is not surprising that the model will seldom match the lowest measured head (usually during the first few days of June 2004). Further, the time discretization often results in the lowest model-calculated head occurring several weeks after the lowest measured head. During June 2004, the head changes on nearly all observation wells indicate that significant pumping occurred during the first few days of the month and then abruptly stopped, causing a steep rise in water levels. Because of the ASR regional model's time discretization, this high pumping is averaged over the entire month, resulting in the lowest heads being calculated at the end of the month. See for example, the results at ROMP 9 SWNN in Sarasota County (Figure 4.62). The continued pumping during the month of June causes the model to calculate a lower head for the whole month of June, but the measured data shows a sudden, steep increase in head beginning in the first week of June.

It is significant that the pumping across the region exerts a much greater effect on the transient head data than the specific storage values. Section 3.5 and Appendix D detail some of the difficulties in collecting and using the pumping data. A huge percentage of the pumping data had to be estimated based on well type and seasonal averages.

These estimates of pumping caused additional problems during calibration. These are made clear by comparing the results at Edgeville Deep Well 3 in Manatee County (Figure 4.60) and BF-6 in Broward County (Figure 4.73). At Edgeville, the calibration is good until the last month of the model (December

2004). During December, the model results indicate a significant reduction in pumping which is not replicated in the measured data at this well. This implies that the pumping in the model in this area is incorrect – likely due to the failure of the assumptions made during the pumping estimated (described in Appendix D). There are a number of observation wells that show similar problems in the calibration during the month of December 2004.

Conversely, at BF-6, there is clearly a reduction in pumping during the months of November 2003 and January 2004, with a return to normal, seasonal pumping rates during December 2003 and after January 2004. In this case, the pumping data used in the model appear to closely match reality, as shown by the close similarity of the heads at this well.

Pumping estimation errors can also be the cause of the failure of the model to reproduce the low heads in the summer of 2004 or the high heads in the fall of 2004. As will be explained later in Section 6, the pumping data quality represents the single largest source of error to this model. The estimates made to fill in missing data are only sufficient to provide enough accuracy for gross, regional-scale estimates of the effects of the CERP ASR program. Because of pumping errors, the regional model cannot be used for near-scale problems or to answer questions requiring high accuracy.

The greatest effort during calibration was exerted to improve the agreement of the model to the observed heads near Lake Okeechobee and the other proposed ASR sites. For this reason, calibration near the north boundary is often poor. Especially near the Hillsborough River Valley, there are numerous wells and some are clearly reacting to stresses not included in the model. Many of the wells are located very close to the boundary, which was given a specified head boundary condition based on an average of the measured heads in nearby wells. Many wells near the model boundary can be recognized from their stair-step model results. See, for example, the Green Swamp Marsh well and the Eva Well Deep (Figure 4.45). Because these wells are so close to the boundary, they feel the effects of head changes immediately, and the computed head is nearly constant during each stress period. No changes to conductivity or storage would improve the calibration at the Eva Well. Only a change to the boundary condition could change this. However, the Eva well was determined to be too far from the boundary for use in the selection of boundary condition heads (See Appendix C).

Some wells (especially in the northwest) are very closely controlled by the specified heads in the SAS. See for example, the Alston Deep Well (Figure 4.46). Perhaps some improvement in the calibration at this point could be brought by reducing the hydraulic conductivity in the ICU layers, to reduce the impact of the SAS on the UF calibration point. However, this point is north of the Polk County recharge area and so the heads here will have little impact on the proposed CERP ASR sites.

The calibration in the northeast quadrant of the model (north of Lake Okeechobee and east of the Kissimmee River) is generally quite good. Most of the observation wells show a steep drop in head between February and May 2004, with a matching steep rise in head from June to October 2004. The model easily reproduces this effect. There are a few points with some possible data errors, which impact the statistics. For example, the observed data at SLF-74 (Figure 4.84) shows a sudden drop of about 1 foot during December 2003. The model more closely matches the data after this apparent

probe movement. The model is not able to perfectly reproduce the head rise during the late summer of 2004, but it does correctly time all major slope changes. SLF-76 (Figure 4.84) is at the same location in the APPZ and similarly does not perfectly match the rising head slope. This could be the result of slight errors in the regional pumping.

A similar probe error seems to have occurred at TCRK_GW2 (Figure 4.83) in June 2004. The model closely matches the observed heads before this time and follows the expected trend after this error. The statistics, which cannot account for the probe movement, are slightly worse than they would be if the error had not occurred.

The east coast calibration is fairly good between St. Lucie and Biscayne Bay. Generally, the steady state result used as the starting condition is within 1 or 2 feet of the observed value. However, because the variability in observed heads over the 15-month calibration period is so low, some of the statistics (notably the RMS as a percentage of observed range and the Nash-Sutcliffe value) are lower than could be hoped. Generally, the model is able to reproduce the effects of simulated stresses, despite the small errors in starting condition. For example, see PBF-2 and PBF-3 (Figure 4.72). PBF-2 is located closer to the coast, but its head is generally measured about 2 feet higher than PBF-3. This is caused by an unknown anomaly which is not included in the model. Therefore, the model computation sets the starting condition at PBF-2 about 2.5 feet too low while that at PBF-3 is about 1 foot too high. Because heads tend to drop close to the coastline towards the ocean outcrops, no acceptable changes to hydraulic conductivity can improve the steady state calibrations of these points. Since the error in starting condition is large compared to the range of measured heads, the statistics are far from optimum values. The Nash-Sutcliffe values are greatly negative in each case and the RMS values are large compared to the observed range of heads. The r^2 values are reasonable, which is an indication that the model is correctly reproducing the effects of seasonal stresses at these wells. The shape of both calibration plots is similar to that shown in the observed dataset, but the heads are shifted up or down. This calibration is as good as can be expected without a more detailed, more highly refined model. Without a better understanding of the local effects resulting in the reversal of heads in this area, no model can hope to reproduce these observations.

BF-4S (Figure 4.74) is an example of a problem with the pumping database. The model easily reproduces the sudden reduction in pumping which occurred in late January 2004, but does not hold the high heads long enough, nor does it reproduce the sudden resumption of pumping in June 2004. The model also shows the effects of a short stoppage in the pumping in October 2004 which is not shown in the observed water level dataset. The problems in collecting the pumping data and implementing it in the model are described in detail in Section 3.5 and Appendix D. This well shows an area where the assumptions used in that process did not hold true. No changes to either hydraulic conductivity or specific storage could improve the calibration at this point. Only better pumping data could improve the calibration in this area.

The calibration in the southern portion of the model (south of Lake Okeechobee and inland of the eastern coast) is generally quite good. At most points, the model calculated heads are within 1 or 2 feet of the observed heads and gross trends are correctly reproduced. As observed near the east coast,

some of these wells also suffer from poor statistics because of the small head variations seen in the observed datasets. While the mean error, RMS and r^2 values are generally quite good, the RMS as a percentage of the observed range and the Nash-Sutcliffe values are both poor. This is not especially worrisome since the model reproduces the trends seen in the observed datasets and the actual differences between observed and calculated heads are small.

The section of the model just south of Tampa Bay (Manatee and Sarasota Counties) is generally well calibrated. The statistics in this area are all near optimum values and the visual comparison between calculated and observed heads shows a close similarity. The largest head swings in the model occur in this area, resulting in an advantage in the statistics.

The area which caused the greatest problems during the transient calibration is the area surrounding Port Charlotte (DeSoto, Charlotte and Lee Counties). The statistics in these areas are generally poor and visual inspection of the results indicates that the heads at several wells are not acceptably reproduced by the model. During trial and error calibration, substantial heterogeneity was added to the storage in this area. Wells located near each other were found to have quite different storage requirements. It is believed that the calibration issues in this area are the result of a number of complications. Head variations in the IAS in this area exert a marked effect on the lower layers. There is a great deal of pumping in this area, including the Peace River ASR. The model has also been simplified in this area by combining the Suwannee and Hawthorn aquifers into the UF and by simplifying the IAS and ICU layers. Because this area is away from the proposed CERP ASR sites, the cell sizes are large. The main conclusion after extensive calibration efforts focused on this area was that this model is too coarse and over-simplified in this region to accurately reproduce the measured heads in all of the observation wells. This is not unexpected in a regional model of this scale and is not worrisome since most of the ASR locations are away from this area. The closest CERP ASR site to this area is located at Riverbend on the Caloosahatchee River, which is about 10 miles east of the problem area. LAB-MZ1 (located close to the Riverbend site; Figure 4.66) calibrates quite well.

The greatest effort in calibration was applied in the areas around Lake Okeechobee where most of the CERP ASR wells are proposed. Calibration at these points is generally good. See Figures 4.68, 4.70, and 4.71 for a visual analysis of the calibration in the UF. Statistics at these wells (L2-PW2, MF-37, PBF-7U, and OKF-100) are also quite good, with Nash-Sutcliffe values all above zero, r^2 values above 0.5, and RMS values less than 25% of the observed head ranges.

The calibration near the Hillsboro Pilot Site (and proposed site for 30 CERP ASR wells) is not as good as that around the Lake Okeechobee sites. See the calibration plot for PBF-10R in Figure 4.73. Although the steady state calibration resulted in a starting condition about 1 foot higher than the observed October 2003 head, the transient model reproduced relative head changes quite well until September 2004. During the last few months of the model, the head in this area seems to be heavily impacted by the cessation of pumping nearby. But this impact is not felt in the observed dataset. This is probably the result of an error in the pumping dataset or in the assumptions used to estimate missing data. These few months of poor calibration, in conjunction with the small range of heads measured at this well (just over 2 feet of variation), result in the poorer calibration statistics at this point.

4.2.3 Transient Calibration Analysis – Vertical Gradients

Figures 4.100 through 4.110 show the vertical gradient plots (similar to those in Figure 4.18 through 4.28 for the steady state calibration). In these plots, the model results are compared to measured data at the end of May 2004 and October 2004. May and June 2004 generally represent the lowest heads of the period, while the highest heads of the period are often measured in October 2004.

Generally the gradients do not change significantly during the year. The model tends to do a better job of predicting fall 2004 gradients and heads than it does for summer 2004. As explained above, this is generally due to coarse time and grid discretization and the likelihood of errors in the pumping data, especially where it was estimated.

4.2.4 Transient Calibration Analysis – Conclusion

In general, the model is a good representation of groundwater conditions on a regional scale. Although some measured data in a few areas could not be reproduced by the model, the areas nearest the proposed ASR sites have good calibrations. This meets the goal of the regional modeling effort, since it was never the intent to reproduce local anomalies or near field effects of pumping wells with this scale of model.

The specific storage terms used in the calibrated transient model are presented in Figures 4.111 through 4.118. Conductivity values were the same as those used for the steady state model (See Section 4.1). Table 4.5 presents the other transport parameters used in the transient model. These parameters were selected to be similar to generally accepted values. Their sensitivity will be discussed in Section 5.2 and 5.3.

In addition to the 2003/2004 calibration period, the final set of hydraulic conductivity and specific storage values were applied to the validation period from October 1993 to July 1994. These results are presented in Figures 4.119 through 4.150. Like the calibration model, the first timestep of the validation model (October 1993) was run in steady state mode to develop a starting condition for the model. There is less agreement between the field data and the model results in October 1993 than in October 2003 (start of the transient calibration model period). This causes an initial offset in the transient validation result plots. Some of the problem wells had no available data in the 2003/2004 calibration period, so they were not included in the steady state calibration process. Others are probably the result of errors in the assumptions made during the estimation of missing pumping data or in the estimation of missing head data for the boundary conditions. Still, despite these starting condition errors, the model was able to reproduce the general shape of the head plots in the majority of the observation wells.

ROMP 58 NRSD in Polk County (Figure 4.140) was measured with a nearly constant head around 120 feet for the last 8 months of the validation period. However, the model produced a widely varying head signature with the highest heads about 110 feet in the winter and fall seasons, and the lowest heads, about 100 feet, in the late spring. It is believed that the data for this well is faulty or a pump that was not operational during the validation period was wrongly incorporated into the model, resulting in modeled heads that are lower and have more variation than the observed data.

As with the calibration period, the statistics for the transient validation run are shown spatially on Figures 4.151 through 4.155.

The validation exercise indicates that this regional model can be used for answering broad, regional questions whenever the pumping and boundary heads are known to a reasonable degree. Use of this model to reproduce D13R periods or to predict future aquifer changes must be made only with the understanding that the results are only as good as the estimates for pumping and boundary conditions.

4.3 Model Analysis

An analysis of the model calculations of velocity, flow directions and boundary flux can be instructive. Figures 4.156 through 4.159 show the model results when converted to equivalent freshwater head using Equations 2.1 and 2.2. Unlike the observed type heads output from the model, equivalent freshwater heads (which include density effects) are a measure of potential energy, and groundwater flows perpendicular to these contours from areas of high to low head. Because of the shallow depths and low salinity levels, the UF equivalent freshwater heads are not significantly different from the model output observed heads (see Figure 4.156), with the exception of the Atlantic Ocean outcrop location (where salinities are high). Generally, recharge occurs in Polk County and water flows towards the ocean to the east, south and west. Significant pumping is clear at several points along the west coast, especially in the Pasco County Area and in Lee County. Both figures show an area of high heads southwest of Lake Okeechobee.

Differences between observed head and equivalent freshwater head are also minor in most areas of the APPZ (Figure 4.157). Most differences are at the coastline where salinities are higher. As with the UF, the main source of water is the recharge in Polk County. The bubble of high head in Hendry County is also visible

More significant disparity is observed when the model output is compared to equivalent freshwater heads in the LF1 layer (Figure 4.158). Here, the high salinity has caused a significant depression in measured heads in many areas of the model. Flow is still infiltrating from the surface in Polk County and significant flows still move east and west towards boundary sinks in Hillsborough and Brevard Counties. Additional flow seems to be moving northward from the Everglades area. Much of this flow moves upward into more shallow layers (APPZ, UF) in the center of the peninsula (Charlotte, Glades, and Palm Beach County) instead of continuing northward in the LF1 layer.

Because of its high salinity, great depth and large temperature variation, the calculation of equivalent freshwater head has the greatest impact on the BZ layer (Figure 4.159). Density effects cause huge changes in head values. The recharge from the surface in Polk County is still visible. But a large contingent of the flow comes in from the east and south coast, moving north and northwest to exit in Hillsborough or Orange Counties. The BZ provides a significant amount of pressure on the upper layers and is an important component of the groundwater system in south Florida.

Flow vectors are shown for a number of cross-sections of the model in Figures 4.160 and 4.161. Vectors in these plots are printed for every eighth cell, so closely spaced vectors occur where cell sizes are small

to provide additional resolution and accuracy (see Section 2.3). These figures make several important points clear:

- Flow is mostly horizontal in the aquifers and vertical in the confining units
- Recharge in Polk County causes downward flow all the way to the BZ.
- Inward flow in the BZ along the lower east coast is a significant source of water pressure throughout the model.
- Most flow is upward in the southern half of the model (south of Lake Okeechobee)

Figure 4.162 shows the discharge and recharge to the top of the IAS, UF, APPZ and LF1 layers. In this figure, recharge (green, yellow and red colors) indicate downward flow while discharge (blue colors) indicates upward flow. As expected the southern and eastern parts of the model show upward flow in every layer. The Polk County recharge area is clearly depicted with downward flow in every layer. As explained previously, the mottled red and blue sections at the northwest boundary of the model are caused by significant variability in the topography and the specified surface heads, combined with a course grid resolution.

Finally, Figure 4.163 tabulates the flow in and out of the boundaries of the model in each aquifer layer. Of note are the large flow into the model through the BZ Atlantic boundary and the larger flow out of the model through the UF Northern Boundary. Initially it appears that the majority (78%) of the BZ Atlantic inflow (589 mgd) is being lost through the western boundary (460 mgd). However, the BZ is also home to a number of large injection wells, which add a significant amount of flow to the model. Major injectors include 17 Miami-Dade South wells, 4 of the 5 G.T. Lohmeyer wells, 6 Broward County wells and 3 City of Sunrise wells. Together, these wells inject nearly 200 mgd during February 2004. Most of this flow exits through the western boundary in the BZ, accounting for over 40% of the outward flow through the western boundary.

When taken together these visualizations of the model results indicate that the major sources of flow to the model are the Boulder Zone along the southern and eastern boundaries of the model and the precipitation recharge in the highlands of Polk County. BZ flow continues north and west, eventually moving upward to meet other layers of the model. The effects of recharge in Polk County reach as deep as the BZ and result in radial flow vectors out to the south, east and west from the recharge area. An area of high freshwater head is also found southwest of Lake Okeechobee from which flow vectors move radially outward (See Section 4.1.4 for additional details).

5.0 Sensitivity Simulations

In order to evaluate the effect of various assumptions made in the modeling process, several sensitivity analyses were performed. The following subsections describe these analyses and the uncertainty inherent in the model.

5.1 Advection Solution

SEAWAT provides several solver options for the advection solution. The majority of the model runs made during calibration used the standard finite difference method with upstream weighting. The timesteps were set to about 5 days. (See Section 2.4) Using these settings, a steady state solution could be computed in less than 3 minutes and a transient solution in less than 1.5 hours, for most available computers. This method is known to be less accurate than the third-order TVD scheme, but it is also much faster. In order to ensure that the accuracy loss due to time constraints was not excessive, a sensitivity run was made for the transient calibrated model using the TVD scheme. Since the first timestep of the transient model computes a steady state solution, both model types were tested together in this way. When this solution method is used, the model selects the timestep size based on the user defined Courant number. The transient model was run with Courant number set to 1.0 and 0.5. With these settings, the transient models took between 12 and 15 hours to run to solution.

The transient TVD model results are compared to the transient FDM results at the timestep with the maximum differences in Figure 5.1. This timestep corresponds to December 10, 2004 which is Day 407 of the total of 428 days modeled. The head difference between the TVD and FDM solutions was over one foot at only a few isolated cells. None of the calibration points show changes significant enough to have affected the calibration. The maximum head change at any observation point during the first (steady state) timestep was less than 0.5 feet, with the average difference less than 0.2 feet. For the transient solutions at each timestep, the maximum head difference was 2.7 feet, but the average was less than 0.1 foot. Most of the differences are found during precipitous changes in head. At these times, the TVD solution has a slightly greater change (perhaps 0.5 feet) immediately after the change begins, but within 2 or 3 timesteps, it again matches the FDM solution. Only nine observation wells were impacted by more than 1.0 foot when the solution method was changed. All nine are located in Hillsborough, Manatee, De Soto or Sarasota County and have head variations of 20 to 45 feet over the calibration period, indicating significant impacts from pumping. Similarly, the head differences shown in Figure 5.1 across the model domain are most significant in this area.

Salinity and temperature results when the TVD advection scheme is activated are also nearly identical to the calibration run salinity and temperature results. A few, isolated cells where the initial salinity gradient between neighboring cells is large (especially near the ocean outcrop) were affected with differences up to about 1,050 mg/L TDS for the final timestep. The temperature differences in the Floridan aquifer at the final timestep vary from -1.3˚C to 0.6˚C in isolated cells near the model boundaries.

That the selection of a solver had little effect on the model results or the calibration supports the early decision to calibrate with the FDM solver, despite concerns about the accuracy of the results. The biggest impact occurred where pumping and head variations were largest. Because the ASR program will involve significant pumping and large head changes, final production runs of the CERP ASR program should be calculated using the TVD solver. However, because the differences are minor, intermediate runs will continue to be made using the FDM solver in order to take advantage of the significant time savings. The opportunity to achieve these time savings using the SEAWAT FDM solver is part of the

reason that the WASH123D model will not be used in the future phases of this project. WASH123D does not provide a faster solver alternative.

5.2 Porosity

Transport properties such as porosity were largely ignored during calibration. Because the model does not have a traditional "plume," with a sharp front, whose movement through the model domain is being estimated, porosity was not expected to be a significant factor in the model results. In the calibrated model, aquifers were given a porosity of 0.25, the IAS, a value of 0.4 and all other confining units, a value of 0.3. Three additional sensitivity runs were made to ensure that the results were not sensitive to porosity. The porosity values used are shown in Table 5.1.

These porosity changes made no discernible difference to any of the heads at the calibration points. Across the grid, the head differences were minor. When compared to the calibration run, the greatest difference in head occurred in the Boulder Zone in Porosity Sensitivity Run 1 during the last time step of the model. During this time step, there were 39 cells with a difference in head ranging from 1 foot to 14.5 feet. The areas that showed the greatest difference were isolated and coincident with the locations of deep injection wells along the coast in Indian River, Palm Beach, Broward, and Miami-Dade Counties. Porosity Sensitivity Run 3 resulted in smaller head differences when compared to the calibration run, with 25 cells having a difference between 1 foot and 6 feet in the Boulder Zone during the last time step. The differences were observed in the same locations as the differences in Run 1. Porosity Sensitivity Run 2 showed no differences in head greater than 1 foot when compared to the calibration run. Over the majority of the model domain, the difference was less than 0.1 feet for all the sensitivity runs. Regionally, the differences were small enough to eliminate the need for a figure.

Variations in porosity also caused only minor differences in calculated salinity and temperature. The greatest difference occurred in the Boulder Zone during the final time step of Sensitivity Run 1. A few isolated areas of the Boulder Zone in Broward County had differences of up to 5,500 mg/L TDS and 2˚C in this time step, but most differences were less than 10 mg/L TDS and 0.1˚C across the rest of the model.

These runs indicate that the sensitivity of the regional model is within the acceptable error of the calibration. The difference caused by changes to input porosity is negligible. It is anticipated that porosity will have a more marked effect on the local scale models which simulate the ASR pumping schedules in more detail.

5.3 Dispersion/Diffusion

Like porosity, dispersion and diffusion were expected to have minimal effects on the flow of temperature or salinity in the groundwater because the concentration and temperature gradients are usually not very sharp. During calibration, the longitudinal dispersivity was set at 2.5 feet with the ratios for horizontal to transverse and vertical to transverse dispersivity set to 1 (meaning dispersivity in every direction was 2.5 feet). In order to verify that this parameter is unimportant to the regional model, four additional model runs were made with varying dispersivity as shown in Table 5.2.

Figures 5.2 through 5.9 show the difference in head between the calibrated model and each sensitivity run. Runs 2 through 4 (Figures 5.4-5.9) had only minor effects on the calibration point heads. Run 1 (Figures 5.2 and 5.3), which increased longitudinal dispersivity from 2.5 feet to 25.0 feet, did have a marked effect on some of the calibration points. Most of the differences in head between the calibrated model and the sensitivity runs can be attributed to wells injecting fresh water into a comparatively more saline aquifer. Overall, there is little effect near the proposed ASR project sites.

Additional calibration of the dispersivity values will be performed with the local scale models using the ASR pilot study data at the Kissimmee and Hillsboro sites. Further, the results of this sensitivity run indicate that a range of dispersivity values should be used in the running of the production runs on the regional model.

Molecular diffusion was ignored for both salinity and temperature during calibration by setting the effective molecular diffusion coefficient to 0.0 ft^2/d. To test its sensitivity, an additional run was made using published information to estimate effective molecular diffusion coefficients for salinity and temperature.

Fetter (1999) provides a table of diffusion coefficients for common ions and recommends multiplying by ω, a coefficient related to tortuosity. The ions in Fetter's table have diffusion coefficients ranging from 5.5e-4 ft^2/d to 8.7e-3 ft^2/d. Fetter quotes Freeze and Cherry (1979) as giving a range for ω of 0.01 to 0.5. When this range is applied, the result is a range of effective molecular diffusion coefficients of 5.5e-6 ft^2/d to 4.3e-3 ft^3/d. 5.0e-4 was selected since it is close to the upper end of this range and is near the value for Na^+.

The source for the diffusion coefficient for heat was obtained from the 2007 SEAWAT manual (Langevin, et al). This report provides the following equation for molecular diffusion of heat:

$$D_{m\_temp} = \frac{k_{Tbulk}}{\theta \rho c_{Pfluid}} \qquad \text{Equation 5.1}$$

Where

k_{Tbulk} = Bulk thermal diffusivity
ϑ = Porosity
ρ = Fluid density
c_{Pfluid} = Specific heat capacity of fluid

Langevin, et al, suggests calculating the bulk thermal diffusivity using either an arithmetic mean or geometric mean (weighted by volume) of the water and solid. The accompanying table lists the bulk thermal diffusivity of freshwater at 0.58 W/mK and for limestone at 1.26 – 2.15 W/mK. However, this calculation (with a range of porosities from 0.25 to 0.4) yields a range of bulk thermal diffusivities of 0.92 to 1.61 W/mK. When applied to Equation 5.1 with the same range of porosities, a density of 2.7e3 kg/m^3 for limestone and specific heat capacity for freshwater of 4.186 (both from Table 2 in Langevin, et al), a range of effective diffusion for heat is 0.2 to 0.5 ft^2/d. The maximum value (0.5) was used in the sensitivity analysis. Clearly, this can only be an estimate since not all materials in the model are

limestone and not all the water is fresh. However, the variation is sufficient to indicate the sensitivity of the parameter.

As expected, molecular diffusion proved to be an insensitive parameter. At the calibration points, there was no discernible difference between the calibration run and the sensitivity run. When compared at each cell in the Floridan aquifer, a few cells (primarily in deep layers) had head differences up to about 2.5 feet, but the vast majority of the cells had head differences less than 0.1 feet. The highest head differences occurred at isolated locations in the Lower Confining Unit in Hardee County and on the border of Manatee and Sarasota Counties, well away from the proposed ASR locations. Differences in salinity caused by the diffusion coefficient changes were negligible, with a maximum difference of less than 100 mg/L TDS. Similarly, the diffusion coefficient changes caused no more than about 2° C change in the temperature calculated at the end of the 15 month simulation. As with porosity, the sensitivity of diffusion was not significant enough to warrant a figure.

5.4 Boulder Zone Thickness

As explained in Section 3.2.1, there was no specific data on the thickness of the Boulder Zone. Available estimates of the thickness were roughly averaged to 500 feet. This thickness was applied uniformly to the bottom layer of the model. However, because the flow in the Boulder Zone can have a large impact on flow and pressure conditions in all areas of the model, a number of sensitivity runs were made in an attempt to quantify the uncertainty introduced to the model by this assumption. The first two sensitivity runs simply changed the thickness of the layer across the domain. One doubled the thickness to 1000 feet and the other halved the thickness to 250 feet.

The next two sensitivity runs were made by changing both the thickness of the bottom layer and the assigned horizontal and vertical conductivity values for this layer. Data on the hydraulic material properties for this layer were nearly as sparse as thickness data. Although the thickness may be wrong, the calibrated conductivity value is based on this thickness and there may be a number of combinations of thicknesses and conductivity values which will lead to the same result. In the absence of local flow impacts such as wells, Darcy's law indicates that when the thickness of the aquifer is doubled, horizontal flow rates can be preserved by halving horizontal conductivity. Conversely, vertical flow can be retained by doubling vertical conductivity. Thus, two additional sensitivity runs were made to test this theory. The complete list of sensitivity runs testing the effect of the Boulder Zone thickness is shown in Table 5.3.

For the transient model, these changes had no effect on the rate of head change or the shape of the head vs. time plot. The Boulder Zone properties only affected the initial steady state stress period and thus, the starting condition of the plot. Each run was a nearly perfect copy of the calibration run with an offset which varied based on the location of the well and the particular sensitivity run. For this reason, the remainder of this section will deal only with the steady state solution comparisons.

As expected, Runs 1 and 2 resulted in rather large changes to the steady state head solution. The heads in the south and east portions of the model were significantly higher for Run 1 (with a thicker BZ layer) than for the calibration run and they were lower for Run 2 (which had a thinner BZ layer). This is

because the BZ provides a large portion of the water to the southern part of the model. The heads in the northwest section of the model were much less affected by Boulder Zone changes. Runs 3 and 4 were much less different from the Calibration results. The changes to the conductivity did not perfectly remove the effects of the thickness change due to complexities in the flow conditions.

The calibration statistics for the February 2004 steady state model are shown in Table 5.4. Notice that Run 2 and 4 often have statistics nearly as low as the calibration run, and in some cases, the statistics are lower than the calibration run. Figure 5.10 shows the Upper Floridan aquifer solution and the calibration targets as an example. Similar effects were seen in the deeper layers.

This study indicates that although the thickness of the Boulder Zone is an unknown and can cause marked effects on the results of the model, the effects of the zone thickness can be offset by the effects of the zone conductivity values, which are equally poorly known. The combination of Boulder Zone thickness and Boulder Zone conductivity have resulted in a calibrated model which can be used to estimate the effects of ASR wells on a gross, regional scale. When the production scenarios are built to evaluate the CERP ASR program, a range of BZ thicknesses and conductivity values will be used to ensure that uncertainty due to this data gap is considered in evaluating model predictions.

5.5 Specified Head Boundaries

As explained in Section 3.3, the use of specified head boundaries is not recommended where there is the possibility of impacts to boundary heads from interior hydraulic conditions. The reasons for selection of specified heads despite the drawbacks are outlined in Section 3.3 and Appendix C. There are two areas of the boundary where available head data was sparse and specified heads assigned are questionable: along the north boundary between Orlando and Tampa, and along the boundary as it passes through Everglades National Park. In order to ascertain the impacts of the assumption of specified heads at these areas, several additional sensitivity runs were made.

5.5.1 North Boundary

Between Orlando and Tampa, the north boundary of the model passes through some areas of increased head and low salinity, caused by high recharge. Some data is available in the upper layers of the model, especially the UF and APPZ. As explained in Appendix C, the gradient in this area was assumed to be downward, but not especially steep. Equivalent freshwater heads in the deeper layers were set just slightly below the values found in the upper layers.

Two sensitivity runs were made to verify that possible errors in the assumptions made in setting up the northern specified head boundaries are unimportant to the purposes of the model. A section of cells from Tampa to Orlando were selected. In one run, the specified heads in the LF1 were dropped by 5 feet and the heads in the BZ were dropped by 10 feet. This assumes a small but significant downward gradient. For the second run, the specified heads in the LF1 were decreased by 20 feet and the heads in the BZ were decreased by 40 feet. This assumes a large downward gradient. For simplicity's sake, the change in boundary conditions was not gradual near Tampa or Orlando, so the local flow conditions at

each end of the selected section of cells are expected to look unusual. However, this simple method is sufficient to determine the regional impact of possible errors in the head assigned at the boundary.

These changes to the north boundary had only a localized effect on the results of the model. The effect was only to the starting condition (initial steady state solution for October 31.) The transient solutions were parallel to the transient calibrated solution. Only a few observation wells displayed differences in head. The largest differences were at the Intercession City observation well in both the LF1 and the BZ. The first sensitivity run (which reduced the Boulder Zone specified head by 10 feet and the LF1 specified head by 5 feet) resulted in a reduction in head at the Intercession City well of about 1 foot in both aquifers. The second run (reducing the Boulder Zone head by 40 feet and the LF1 by 20 feet) caused a drop at Intercession city of about 4 feet in both aquifers. Smaller differences were also observed at two northern LF1 observations wells, OSF-82L and OS0025. The differences at these wells were 0.1 feet and 0.5 feet at OS0025 and 0.7 feet and 2.8 feet at OSF-82L for the first and second sensitivity runs, respectively.

Figure 5.11 shows the head changes caused by these alterations to the BZ and LF1 boundary conditions. As expected, the greatest changes are in the immediate vicinity of the northwest boundary. The effect of the boundary condition extends less than 50 miles from the boundary and does not affect the heads at the proposed ASR well locations. No discernible differences were observed in any of the other aquifer layers. Although there may be disagreement about the applied gradient at the northwest boundary of the model, it has no effect on the end purposes of the ASR Regional Model.

5.5.2 Southwest Boundary

Some concern has been raised about the specified head assigned through the Everglades because of the impression that there is very little data available in this area. As shown in Figure 3.17, there are actually several wells in this area which were used for assigning the specified heads at this boundary. However, in order to verify these values, two sensitivity runs were made to show that there is very little impact to the interior of the model. In one sensitivity run, all of the specified heads in the UF were removed from the counties of Collier, Monroe and the western half of Miami-Dade. This is equivalent to defining a no-flow boundary at this location. The second run removed all specified heads in same area for all layers.

Neither of these sensitivity runs had significant effects on the calibration of the steady state model as shown in Table 5.5 which compares the RMS of the calibration runs to the RMS from these two sensitivity runs. Cutting off flow through the UF boundary on the southwest edge of the model resulted in no change to the calibration statistics in the UF, APPZ, and BZ and a change of only 0.01 in the LF1. The change is greater when the flow in all aquifers is cut off, but it is still very small, with a maximum change in RMS of 0.4, occurring in both the APPZ and the LF1.

Figures 5.12 and 5.13 show the difference between the head calculated by the calibration model run and each of these sensitivity runs. When the outbound flow in the UF is blocked along the southwest boundary, the head in the UF rises in the area of the Everglades and decreases in the Naples area. However, the area of difference is small – about 25 miles from the boundary -- and the head change is less than 1 foot. This boundary change also impacted the APPZ in about the same area, though the

heads right at the boundary are fixed, so there is no change in the first line of cells. Some small changes occurred in the IAS, but there was no impact to either the LF1 or the BZ.

When the flow was blocked to all aquifers (Figure 5.13), the magnitude of the head changes are greater and the area of impact is greater – extending nearly 100 miles in from the boundary for the UF, APPZ, LF1 and BZ. The extent of the effects in the IAS is smaller – extending only 55 miles from the boundary. However, the highest magnitude changes in head occur in the IAS with a maximum drop of 73 feet. In the calibrated model, significant IAS pumping in Collier County pulls water into the model from the boundary. When this boundary inflow is blocked, pumping drawdown increases.

It is also interesting to note that the effects are less pronounced in the BZ. Initially, this appears to contradict the flow regime shown in Figure 4.163, which indicates a significant flow component exiting the model through the BZ in the Everglades region. However, because of the larger conductivities present in the BZ, the excess water is able to more easily move to a secondary exit location (the south end of the model in Miami-Dade county, just outside the Everglades boundary). Layers above the BZ (LF1 and APPZ) have a smaller flow component crossing this boundary in the calibration model, but the effects of the boundary condition change are greater because lower conductivity values make it harder for water to find other avenues to leave the model and the heads build up.

Although the results of the sensitivities show that some minor impacts would extend to areas near proposed ASR wells, the sensitivities represent an extreme condition. By assigning a no-flow boundary to all the layers along the southwest boundary, the heads respond in a way that is not supported by available data. Figure 3.17 shows there are several available data points along the southwest boundary in the IAS, UF, APPZ, and LF1 that were used to set a specified head. Thus a no-flow boundary is not reasonable in this region.

5.5.3 Confining Units Boundary

As explained in Section 3.3, the SEAWAT model uses time-variant specified-head boundary conditions for the aquifers and Atlantic Ocean outcrops of the confining units. No-flow boundaries were assigned to the confining units on the inland sides of the model (north, west, south) because horizontal flow in these cells is limited and not believed to be a significant source or sink of groundwater. IMC reviewers raised the concern that horizontal flow in these units might be important. To determine the effect of boundary condition choice on the computed model results, a new steady state SEAWAT simulation was created using data from October 2003 and changing the no-flow boundary conditions to specified heads along the north, west and south boundaries of the confining unit layers. Linear interpolation between the overlying and underlying aquifer heads was used to determine the head for each new specified head cell. A steady state simulation was run using the newly created specified head boundary conditions, and the results were compared to the October 2003 calibration.

Only minor differences in head were observed when comparing the two model runs, with none of the observed differences having an effect on the groundwater at the proposed CERP ASR sites. The greatest differences in head are located along the boundaries of the confining units. Figure 5.14 shows the difference in head in the confining unit layers between the October 2003 calibration and the sensitivity

run. The difference in head is mostly observed along the boundary or within one or two cells of the boundary. The exception to this is seen in layers 2, 3, and 4 in Collier County and is due to a minor oversight in assigning the original boundary conditions to the IA (layer 3). When the boundary conditions were initially set, the specified head boundary applied to layer 3 was terminated just north of the southern border of Collier County (see Figure 3.17) at the last point with available observation data. However, the aquifer portion of layer 3 extends slightly farther southeast into Monroe County, leaving a small section of the aquifer with no boundary condition assigned. This section of aquifer boundary without an applied specified head boundary condition resulted in the difference in head seen in Figure 5.14 in layers 2 through 4. Even with this omission, the effects do not extend to any of the proposed CERP ASR sites.

In the aquifers, the only notable difference in computed head was observed within one to two cells of the boundary in the vicinity of Cape Coral. These differences were also only seen in the UF and APPZ. The maximum head difference in the UF is less than 0.9 feet, and less than 100 cells were changed by more than 0.1 feet. In the APPZ, the maximum head difference is less than 0.6 feet, with less than 50 cells being changed by more than 0.1 feet. These results indicate that the use of a no-flow boundary condition on the land boundaries of the confining units is an acceptable simplification to the model.

5.6 Ratio of Horizontal to Vertical Hydraulic Conductivity

As explained in Section 4.1.2, the ratio between horizontal and vertical conductivity was set at 10:1 for aquifers and 2:1 for confining units. The exception to this rule was the third layer, whose western section represents the IA, while the remaining part is lumped with layers 2 and 4 to simulate the ICU. In layer 3, the horizontal to vertical conductivity ratio was set to 10:1. The ratios were set using MODFLOW's array multiplier option, so only a single multiplier could be used in any layer. These ratios were selected with little data based on the expectation that the majority of the flow would be horizontal in the aquifers and vertical in the confining units, so the calibration would be insensitive to the conductivity in the cross-flow direction. IMC comments indicated that this might not always be true, and recommended a sensitivity run to quantify this effect.

Four separate sensitivity runs were developed as follows:

1. Set the ratio of horizontal to vertical conductivity to 1:1 in all layers (2-22), keeping the horizontal conductivity in the aquifers and the vertical conductivity in the confining units at their calibrated values.

2. Set the ratio of horizontal to vertical conductivity to 1:10 in the aquifers (layers 3, 5-10, 13-15, 18-19,22) and 1:2 in the confining units (layers 2, 4, 11-12, 16-17, 20-21), keeping the horizontal conductivity in the aquifers and the vertical conductivity in the confining units at their calibrated values.

3. Repeat Run 1 in layers 5-22 only. Layers 2 through 4 keep their calibrated values and ratios.

4. Repeat Run 2 in layers 5-22 only. Layers 2 through 4 keep their calibrated values and ratios.

The reason for runs 3 and 4 is related to the use of MODFLOW's array multipliers to make these changes quickly and easily. No single multiplier could keep the horizontal conductivity in layer 3 constant in the west (IA), while keeping the vertical conductivity the same in the east (ICU). Although this effect could have been achieved by changing the arrays, the decision was made to check the sensitivity on the existing runs before expending the effort to redevelop the arrays.

The results generally support the original hypothesis – that the calibration is not sensitive to either horizontal conductivity in the confining units or vertical conductivity in the aquifers. The few exceptions include the recharge area and a few areas with heavy pumping, where one might expect significant vertical movement of water in the aquifers.

The effect of the changes on the calibration was minimal. For the runs with changes to layers 2 through 4, the maximum head change at any calibration point for the February 2004 run is less than 2 feet, with the average at about 0.2 feet. When layers 2 through 4 were left unchanged from the calibration values, the maximum head change at any calibration point was less than 0.5 feet and the average change was about 0.03 feet.

As expected, Runs 1 and 2 caused more significant and widespread effects on the February 2004 steady state run in layers 2 through 4. Figure 5.15 shows the differences in head in these layers for the first two sensitivity runs for these upper layers. These differences propagate down into deeper layers, but they diminish with depth and are largely undetectable in the LF, LC and BZ layers.

Figure 5.16 shows the comparison between the first two and last two runs in the UF and indicates the areas of greatest impact at the major pumping location in Lee County. Overall, the effects to proposed CERP ASR sites are minimal – even with Runs 1 and 2, which caused such large changes in the IAS. These results indicate that flow is generally horizontal in the aquifers and vertical in the confining units, except in areas of changes to the direction of flow or where there is significant recharge or pumping.

Because the CERP ASR plan calls for significant pumping in several areas, it is possible that the ratio of horizontal to vertical conductivity will affect the outcome of the production scenarios as flow directions change to provide water to the ASR wells. To quantify this uncertainty, the ratio will be the subject of some sensitivity and Monte Carlo simulations on the final selected CERP ASR regional model run.

6.0 Sources of Uncertainty

Overall, the model does a good job replicating observed field conditions. There is a high degree of confidence that it will provide valuable insights to the CERP ASR program. As with all models, uncertainty exists in the input data and in the simplifying assumptions. It is important to identify these areas of uncertainty and quantify them so that the model results can be used in an informed way. The following subsections describe the major sources of uncertainty, including some of these assumptions, and how they may affect model results and overall goals of the project.

6.1 Pumping Rate Data Limitations

Limitations in the pumping data constitute the principal source of error in this model. Figure 6.1 shows the drawdown occurring throughout the UF due to seasonal pumping in February 2004, which is a relatively low pumping period. Drawdown exceeds 30 feet in some areas of the northwest part of the model (Manatee, Hillsborough and Polk County) and in the Cape Coral area. A huge portion of the peninsula is impacted by pumping activities to a lesser, but significant degree. Head changes in numerous monitoring wells show swings in head greater than what can be caused by seasonal rainfall changes. The available data indicates head changes on the order of only 1 to 5 feet in the SAS within our model domain. (See Figures 4.41-4.94 for measured head changes during the calibration period.) Pumping rate errors are the likely reason for poor calibration at almost all the observation points described in Section 4.1.3. Clearly, it is important that the model correctly incorporate pumping.

As explained in Section 3.5 and Appendix D, the information on the pumping rates of permitted wells is sparse. SAJ made valiant efforts to gather as much available data as possible, but a large part of the data had to be estimated based on the well type, capacity/allocation information and other available pumping data. Figures 3.37 through 3.41 and Table 3.1 show how much of the pumping in the model is based on estimates. In each month of the calibration period, between 20% and 25% of the volume of pumped water is based on estimates. It is of special importance that the largest estimated pump rates occur at wells in the middle swath of the model – along the Caloosahatchee River, the southern reach of the Kissimmee River and into St. Lucie County. These areas caused the greatest problems in the calibration of the model and contain many of the proposed CERP ASR sites.

Figure 6.2 presents the results of a sensitivity analysis on the October 2003 steady state model to demonstrate the effect of the estimated pumping on the model calculation. All of the estimated pumping for this month was reduced by 50%. Reported (known) pump rates remained the same. Figure 6.2 shows the difference between the heads calculated by the calibrated model and this sensitivity run. Differences of one foot or more are found covering nearly half of the model domain. Smaller areas with much larger head differences are scattered across the region. It is clear that errors or poor assumptions in the estimation of missing pumping data can have a marked effect on the model results. Any pumping errors have a significant impact on the calibrated aquifer parameters and will influence predictions made by the model and recommendations based on model predictions. A variety of sensitivity analyses will be performed on the ASR production simulations. During the PDT evaluation of the CERP ASR program, the uncertainty due to pumping must be kept in mind and carefully evaluated.

6.2 Temporal Distribution of Pumping Data

Because of the difficulties associated with gathering pumping data for over 30,000 wells in the South Florida region, an early decision was made to average the pumping over each month of the model period. This resulted in a much simpler (though still arduous) data collection effort and likely had only minimal effects on the calibration. For consistency, the same process was applied to heads assigned as boundary conditions on the edges of the aquifers and on the surface of the model. The temporal distribution of the pumping data and boundary conditions meant that the transient calibration could not

be expected to match measured head data on a daily basis, but rather that it was calibrated until the general trends and average monthly heads were similar to measured data.

When the model is used to evaluate ASR well placement, pump rates and schedules, this coarse temporal distribution of the pumping data may have a minor effect on the results of the model. Although the time constraint may be lifted for ASR wells, boundary conditions and nearby pumping will still be on the monthly schedule and some daily effects might not be entirely accurate.

6.3 Salinity Distribution

The initial condition salinity distribution was developed as an interpolation of the available TDS data. Data is more plentiful in the shallower layers and becomes much sparser in the deep layers. Unfortunately, since the impact of density differences becomes greater with depth, the model is much more sensitive to the TDS in the deep layers than in the shallow layers. Early sensitivity runs showed that density changes (caused by TDS) can have a great effect on both the direction of flow and the impact of head changes. The results of these early tests led to the use of measured TDS data whenever possible. Further, a Monte Carlo analysis is planned for the production runs to determine the effect of variation in TDS on the ASR system predictions.

6.4 Temperature Distribution

The initial condition temperature distribution was developed as an interpolation of the available temperature data. Like TDS data, temperature data was sparser in deep layers of the model. Temperature exerts a much smaller impact on the density of water – even at deep elevations. Errors in the temperature data probably exert only a minor effect on the calibration or the future production runs of the ASR regional model.

6.5 Surficial Aquifer Boundary Assumption

The decision to apply a specified head boundary condition to the surface of the model was made to simplify both data collection and model implementation. As explained in Section 3.3.1, the application of a flux boundary condition at the surface to simulate recharge and discharge would have required additional data such as rainfall, evapotranspiration, seepage rates, etc. This data is available only sparsely and in most models, the inability to appropriately assign recharge/discharge rates at the surface leads to problems with the model. Many models include recharge as a calibration parameter.

By applying specified heads to the surface, many of these problems were alleviated and the heads used to interpolate the SAS head boundary had already been collected as part of the data gathering effort. The downside of this type of boundary condition is that ASR scenarios which impact the SAS will not be accurately simulated in the model. This is expected to be a minor problem since impacts to the SAS will most likely occur after other performance measures (rock fracturing potential, impacts to nearby wells) have already eliminated the scenario as a viable option.

6.6 Spatial Discretization

Due to time and computational constraints, the spatial discretization of the model is quite coarse. In the SEAWAT grid, the largest cells are 10,000 feet on a side (nearly 2 miles). Even at the ASR well locations, cell sizes only drop to 2,000 feet. At this discretization level, only regional effects of the ASR well scenarios can be simulated. Near-well effects for ASR wells or any other wells cannot be evaluated on this model.

In order to minimize the impact of the spatial discretization to the ASR program, the next study will utilize a number of telescopically refined models. These models will be smaller in regional extent and will have smaller grid cells. They will take their boundary conditions from the regional model. With smaller computational cells at the ASR wells, near well effects will be more easily simulated. The small regional extent will allow the models to reach converged solutions on available computers in a reasonable amount of time.

6.7 Variability in Transport Parameters

Very little attention was paid to the transport parameters inherent in the SEAWAT equation. These parameters include porosity, dispersivity and molecular diffusion. Because the calibration models were run for no more than 15 months, the salinity and temperature did not change significantly from the initial conditions (except near injection wells). Some sensitivity runs were made to verify their low sensitivity and are presented in Section 5.2 and 5.3.

The selection of transport parameters likely has little effect on either the calibration models or any short-term production runs. However, as the process moves forward and longer ASR runs are made to evaluate the freshwater bubble at the ASR wells or seawater intrusion, these transport parameters may become more important. Production simulations will be conducted for an extended time period time period (10 years or more). Variability in the transport parameters will be evaluated as part of this modeling effort as well as in the local scale modeling during the next study phase.

7.0 Conclusions/Recommendations

The goal of this modeling effort was to develop a tool to evaluate the regional impacts of the CERP ASR program on the hydrogeologic conditions in the FAS. An extensive data collection and multi-phase modeling effort has been undertaken to ensure that the models achieve this goal. This report presents the details of the construction, calibration and sensitivity analysis of the models that will be used to evaluate the regional effects of the CERP ASR program.

As with any numerical model, uncertainty in the input data and computational methodology are inherent in the ASR Regional Model. In order to address these issues, numerous sensitivity analyses have been performed to determine how the model reacts to various input stresses. Pumping (both into and out of the FAS) has a substantial impact on the water levels in the FAS. Unfortunately, the pumping data used for this regional modeling effort also has a high degree of uncertainty, primarily resulting from the lack of pumping records. On-going improvements in the recording of FAS pumping will be critical in protecting the long term water quality of the aquifer. In addition to pumping, various other model

inputs (including BZ parameters and density distributions) were determined to be sensitive in the regional model calibration. Given this uncertainty in the input data, the calibrated regional models do an excellent job reproducing the FAS flow system and will serve as a useful baseline against which the CERP ASR program can be evaluated. However, to appropriately assess the impacts of the CERP ASR program it is anticipated that additional sensitivity analyses will be performed on any production simulations that will be performed on this calibrated model.

The complex numerical methodology required to address the variable density flow system present in the FAS may also have inherent uncertainty. In order to address this issue, the ASR Regional Model was developed using two numerical codes: WASH123D and SEAWAT. The model inputs for these codes were nearly identical. As presented in Appendix F, both codes replicate the regional steady state and transient flow fields of the FAS. As such, it would be reasonable to perform subsequent model simulations (regional production and local scale modeling effort) using either code. However, due to programmatic constraints it will be more efficient to proceed with the ASR modeling effort using a single numerical code. Although the finite element distribution afforded in the WASH123D mesh provides an efficient framework for placing higher resolution in the areas of interest, the substantial complexity and heterogeneity of the FAS is difficult to incorporate. This is primarily due to zonal methodology used by WASH123D to incorporate hydrogeologic parameters. The hydrogeologic complexity of the local scale models is anticipated to be greater than that of the regional model in order to accurately replicate the formation, mixing and collapse of the ASR freshwater "bubble". In these local scale models, parameters such as dispersivity and porosity, which were relatively insensitive in the regional model, are expected to be more sensitive, requiring a greater degree of variation. Other hydrogeologic parameters, such as hydraulic conductivity and storage, are also anticipated to be highly heterogeneous in the local scale models. This hydrogeologic complexity can be more easily incorporated into SEAWAT. Therefore, it is anticipated that SEAWAT will be the primary model used in the local scale modeling effort.

It is also anticipated that refinements of the regional hydrogeologic properties based on the local scale model calibration will be incorporated into the calibrated regional model. This iterative process will ensure consistency between the models and provide the best numerical platform against which the CERP ASR program can be evaluated.

In conclusion, the models developed and calibrated in this Phase II modeling effort do an excellent job of replicating the regional flow system in the Floridan Aquifer System. A variety of previous modeling and scientific studies have been used to develop and evaluate this model. The hydrogeologic framework is consistent with numerous detailed studies of specific areas of the FAS. Improvements have been made to this framework during the course of the modeling study as various hydrogeologic theories have been evaluated using the physics in the models. The final calibrated model not only calibrates to steady state snap shots of the aquifers, but also reasonably replicates the effects of transient stresses in the FAS. As such, this model will be a useful tool in the evaluation of the proposed CERP ASR system.

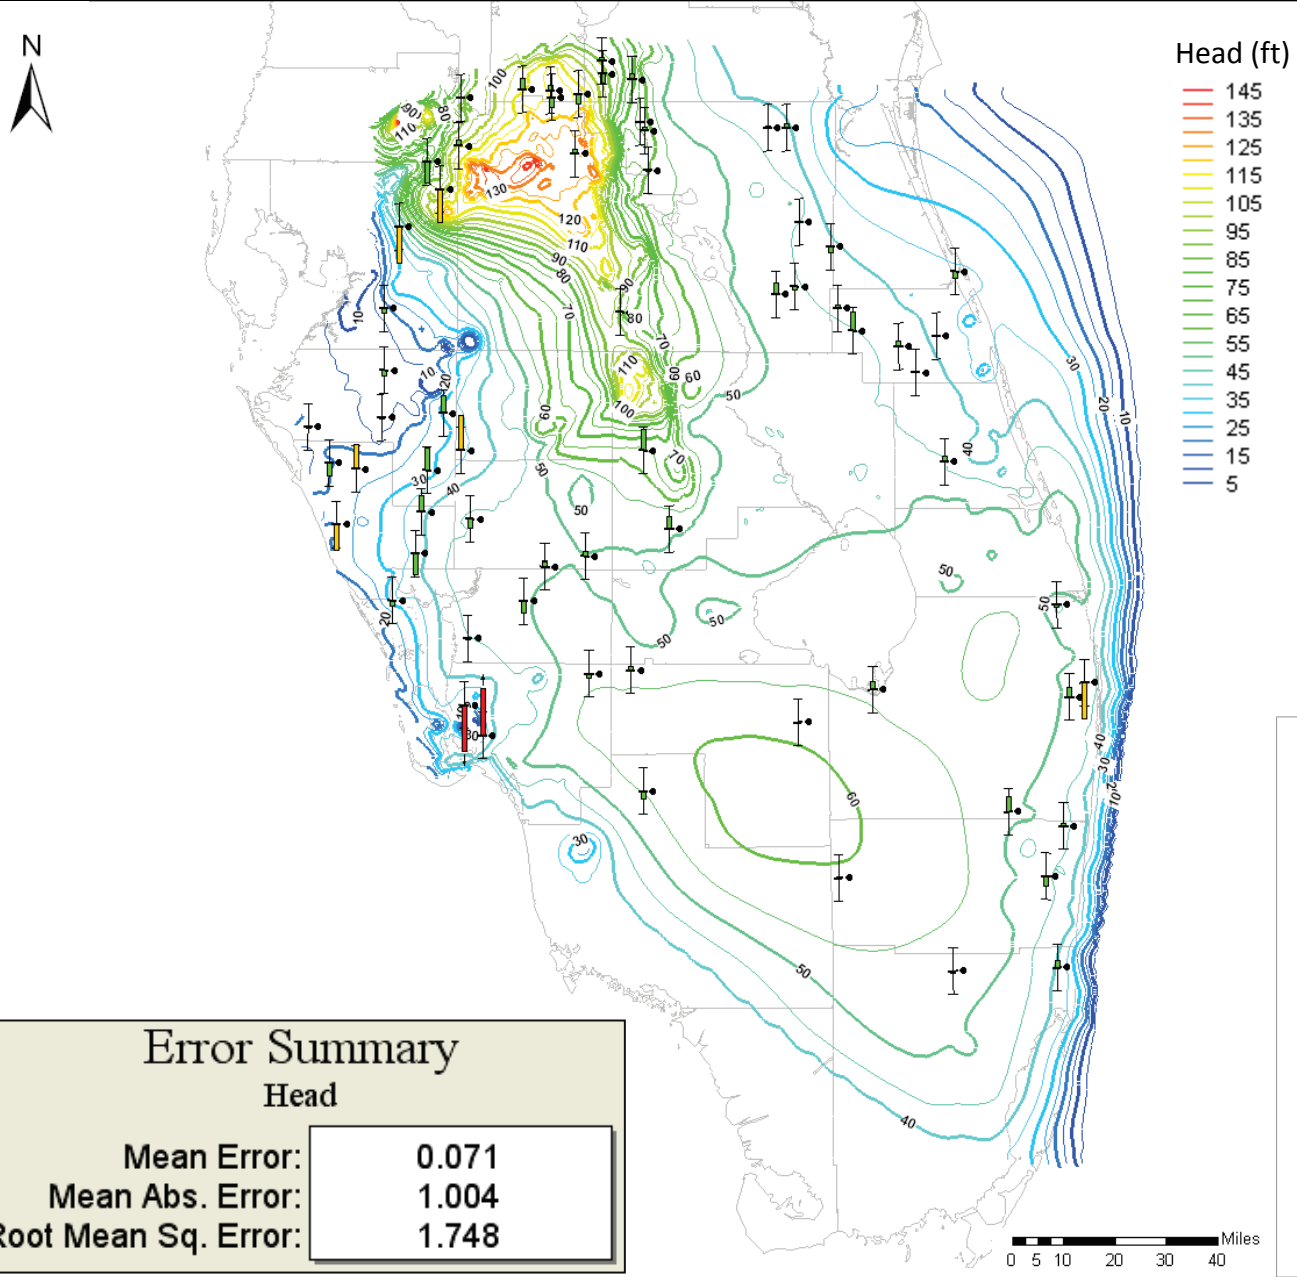
Figure 4.1



Notes:

Statistics (mean error, mean absolute error and root mean square error) are calculated based on equations presented in Section 4.1.

Calibration targets are green when the calculated value is within 2 feet of the measured head, yellow when within 4 feet and red when the model calculates a head more than 4 feet different from the measured value.

The direction of the colored bar on the calibration target indicates the sign on the residual: bars above the middle line indicate the model calculated higher heads than measured; bars below the middle line indicate negative residuals.

Regional SEAWAT Calibration
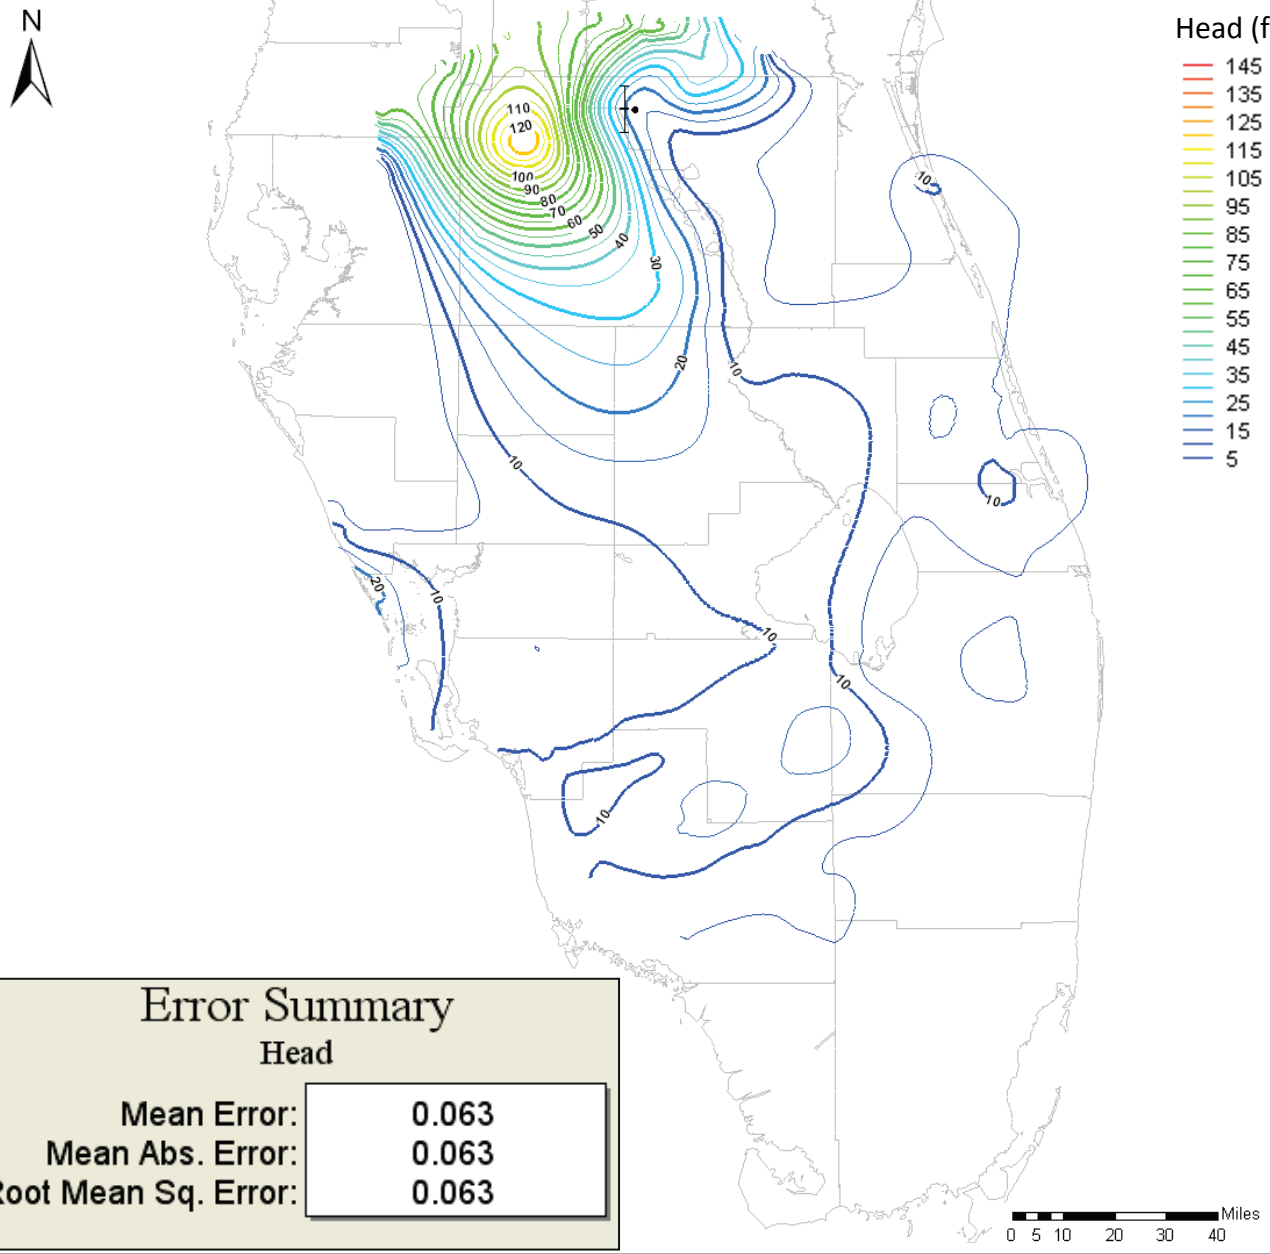
Lower Floridan (LF1) Aquifer - February 2004
Final Groundwater Model Calibration Report

Figure 4.4

October 2010



Notes:

Statistics (mean error, mean absolute error and root mean square error) are calculated based on equations presented in Section 4.1.

Calibration targets are green when the calculated value is within 2 feet of the measured head, yellow when within 4 feet and red when the model calculates a head more than 4 feet different from the measured value.

The direction of the colored bar on the calibration target indicates the sign on the residual: bars above the middle line indicate the model calculated higher heads than measured; bars below the middle line indicate negative residuals.

- Observed Head-Feb 2004
- Cluster Location

Model-Simplified Geology

- Upper Floridan
- APPZ
- Lower Floridan (LF1)
- Boulder Zone

Notes:

The plot at left shows the head changes in a vertical column of the model compared to measurements made at a well cluster. Colored stripes indicate the model-simplified stratigraphic units.

Model calculated heads are from the February 2004 calibrated model. Measured values are averaged for the month of February 2004.

The location of the cluster is marked on the inset map at bottom right.

The plot at left may seem unusual as it seems to indicate downward flow from the APPZ towards the LF1. However, when the heads are converted to equivalent freshwater heads in the plot at top right, the gradient is shown to be upward as expected. Figures on the following pages will not show equivalent freshwater heads.

- Model Calculated Head

Notes:

Figures 4.41 through 4.94 show the comparison between measured head values and model-calculated head values at a number of observation wells for the calibration period. Although the scales vary on each plot, all plots have a horizontal grid line at each foot. This is to make it easy to determine the range of heads at a glance.

The model used month-long stress periods, so pumping and boundary conditions were input as step functions with constant values throughout each month and sudden changes at the end of each month. For this reason, the model cannot be expected to accurately predict day-to-day head variations in any of these wells. Calibration efforts were aimed at matching general trends and monthly averages.

Starting head conditions for this model were based on the October 2003 steady state calibrated model. Transient calibration efforts were focused on matching the head changes, not the actual heads, so it is not uncommon for residuals in the starting condition to be carried through the entire calibration period. This indicates that the model is correctly predicting responses to hydrogeologic forces even if the calculated head values vary somewhat from the measured values.

Notes:

Figures 4.41 through 4.94 show the comparison between measured head values and model-calculated head values at a number of observation wells for the calibration period. Although the scales vary on each plot, all plots have a horizontal grid line at each foot. This is to make it easy to determine the range of heads at a glance.

The model used month-long stress periods, so pumping and boundary conditions were input as step functions with constant values throughout each month and sudden changes at the end of each month. Although the scales vary on each plot, all plots have a horizontal grid line at each foot. This is to make it easy to determine the range of heads at a glance.

The model used month-long stress periods, so pumping and boundary conditions were input as step functions with constant values throughout each month and sudden changes at the end of each month. For this reason, the model cannot be expected to accurately predict day-to-day head variations in any of these wells. Calibration efforts were aimed at matching general trends and monthly averages.

Starting head conditions for this model were based on the October 2003 steady state calibrated model. Transient calibration efforts were focused on matching the head changes, not the actual heads, so it is not uncommon for residuals in the starting condition to be carried through the entire calibration period. This indicates that the model is correctly predicting responses to hydrogeologic forces even if the calculated head values vary somewhat from the measured values.

Although the scales vary on each plot, all plots have a horizontal grid line at each foot. This is to make it easy to determine the range of heads at a glance.

The model used month-long stress periods, so pumping and boundary conditions were input as step functions with constant values throughout each month and sudden changes at the end of each month. For this reason, the model cannot be expected to accurately predict day-to-day head variations in any of these wells. Calibration efforts were aimed at matching general trends and monthly averages.

Starting head conditions for this model were based on the October 2003 steady state calibrated model. Transient calibration efforts were focused on matching the head changes, not the actual heads, so it is not uncommon for residuals in the starting condition to be carried through the entire calibration period. This indicates that the model is correctly predicting responses to hydrogeologic forces even if the calculated head values vary somewhat from the measured values.

This indicates that the model is correctly predicting responses to hydrogeologic forces even if the calculated head values vary somewhat from the measured values.

Mean Residual Error

- > 4.0 (model predicts high)
- 2.0 to 4.0
- -2.0 to 2.0 (well calibrated)
- -4.0 to -2.0
- < -4.0 (model predicts low)

Notes:

The mean error (ME) is calculated as described in Section 4.1. The ME statistic is calculated using monthly average heads for both the observed and model calculated data.

A perfectly calibrated point would have an ME value close to zero. In these maps, blue points have negative ME statistics (model prediction is low) and red points have positive ME statistics (model prediction is high). Green points are for well calibrated observation wells.

Transient SEAWAT Calibration Comparison
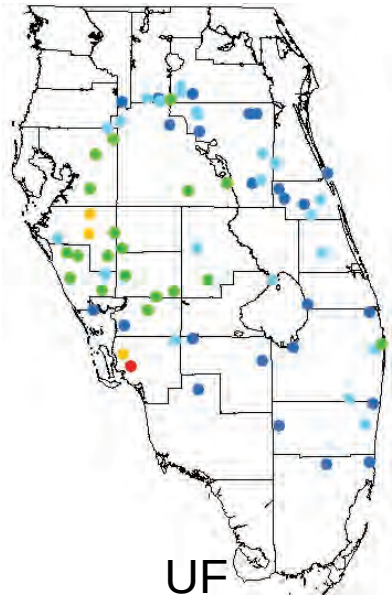
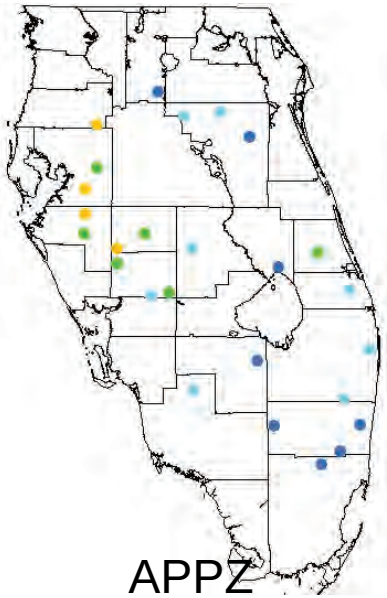
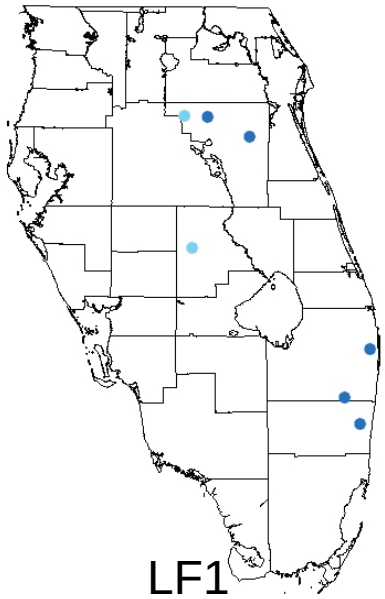
Mean Residual Error (2003-2004)
Final Groundwater Model Calibration Report

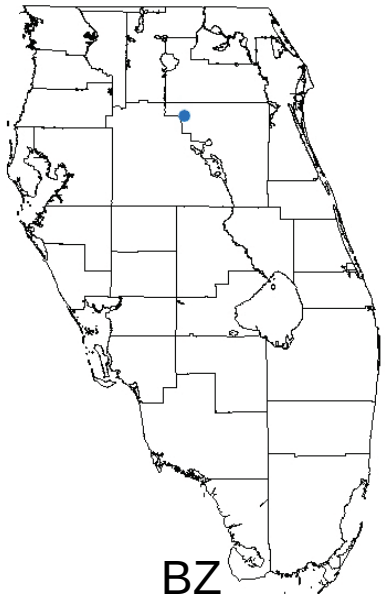
Figure 4.95

October 2010









Root Mean Square Error

- < 1.0 (well calibrated)
- 1.0 - 2.0
- 2.0 - 4.0
- 4.0 - 8.0
- > 8.0 (poorly calibrated)

Notes:

The RMS (Root Mean Square) statistic is calculated as described in Section 4.1. The RMS statistic is calculated using monthly average heads for both the observed and model calculated data.

A perfectly calibrated point would have an RMS value close to zero. In these maps, blue points have low RMS statistics (well calibrated) and red points have large RMS (poorly calibrated).

Transient SEAWAT Calibration Comparison
Root Mean Square Error (2003-2004)
Final Groundwater Model Calibration Report

Figure 4.96

RMS as Percent of Observed Range

- < 10% (well calibrated)
- 10%-20%
- 20%-30%
- 30%-40%
- > 40% (poorly calibrated)

Notes:

The RMS (Root Mean Square) statistic is calculated as described in Section 4.1. This figure shows the RMS for each transient calibration point as a percentage of the range of observed values over the 15 month calibration period. The RMS statistic is calculated using monthly average heads for both the observed and model calculated data.

A perfectly calibrated point would have an RMS value close to zero. When compared to the observed head range, wells with small variability in heads are held to a higher standard. A common rule of thumb is to require that the RMS be less than 10% of the observed range. In these maps, blue points have low RMS statistics compared to the observed head range (well calibrated) and red points have large RMS statistics relative to the observed head range (poorly calibrated).

Transient SEAWAT Calibration Comparison

Coefficient of Determination (r^2)

- > 0.8 (well calibrated)
- 0.6 – 0.8
- 0.4 – 0.6
- 0.2 – 0.4
- < 0.2 (poorly calibrated)

Notes:

The Coefficient of Determination (r^2) is calculated as described in Section 4.2. The r^2 statistic is calculated using monthly average heads for both the observed and model calculated data.

A perfectly calibrated point would have an r^2 value close to 1.0. In these maps, blue points have high r^2 (well calibrated) and red points have small r^2 statistics (poorly calibrated).

Transient SEAWAT Calibration Comparison
Coefficient of Determination (2003-2004)
Final Groundwater Model Calibration Report

Nash-Sutcliffe Model Efficiency Coefficient

- > 0.75 (well calibrated)
- 0.5 – 0.75
- 0.25 – 0.5
- 0.0 – 0.25
- -1.0 – 0.0
- < -1.0 (poorly calibrated)

Notes:

The Nash-Sutcliffe Model Efficiency Coefficient is calculated as described in Section 4.2. This statistic is calculated using monthly average heads for both the observed and model calculated data.

A perfectly calibrated point would have an efficiency value close to 1.0. A negative efficiency value indicates that the calibration error exceeds the variance in the observed data. In these maps, blue points have high efficiency coefficients (well calibrated) and red points have negative efficiency coefficients (poorly calibrated).

- Observed Head-May 31, 2004
- Model Calculated Head-Oct. 31, 2004
- Observed Head-Oct. 31, 2004
- Cluster Location

Notes:

The plot at left shows the head changes in a vertical column of the model compared to measurements made at a well cluster. Colored stripes indicate the model-simplified stratigraphic units.

Two sets of model calculated heads are shown on the plot:

1) May 31, 2004 from the transient model, representing the dry season
2) October 31, 2004 from the transient model, representing the wet season

Observed head for May 31, 2004 and October 31, 2004 is the measured value for each respective day.

The location of the cluster is marked on the inset map at bottom right.

The plot at left may seem unusual as it seems to indicate downward flow from the APPZ towards the LF1. However, when the heads are converted to equivalent freshwater heads in the plot at top right, the gradient is shown to be upward as expected. Figures on the following pages will not show equivalent freshwater heads.

Notes:

Figures 4.119 through 4.150 show the comparison between measured head values and model-calculated head values at a number of observation wells for the validation period. Although the scales vary on each plot, all plots have a horizontal grid line at each foot. This is to make it easy to determine the range of heads at a glance.

The model used month-long stress periods, so pumping and boundary conditions were input as step functions with constant values throughout each month and sudden changes at the end of each month. For this reason, the model cannot be expected to accurately predict day-to-day head variations in any of these wells. Calibration efforts were aimed at matching general trends and monthly averages.

Starting head conditions for this model were based on the October 1993 steady state solution. Transient calibration efforts were focused on matching the head changes, not the actual heads, so it is not uncommon for residuals in the starting condition to be carried through the entire calibration period. This indicates that the model is correctly predicting responses to hydrogeologic forces even if the calculated head values vary somewhat from the measured values.

Notes:

Figures 4.119 through 4.150 show the comparison between measured head values and model-calculated head values at a number of observation wells for the validation period. Although the scales vary on each plot, all plots have a horizontal grid line at each foot. This is to make it easy to determine the range of heads at a glance.

The model used month-long stress periods, so pumping and boundary conditions were input as step functions with constant values throughout each month and sudden changes at the end of each month. For this reason, the model cannot be expected to accurately predict day-to-day head variations in any of these wells. Calibration efforts were aimed at matching general trends and monthly averages.

Starting head conditions for this model were based on the October 1993 steady state solution. Transient calibration efforts were focused on matching the head changes, not the actual heads, so it is not uncommon for residuals in the starting condition to be carried through the entire calibration period. This indicates that the model is correctly predicting responses to hydrogeologic forces even if the calculated head values vary somewhat from the measured values.

Notes:

Figures 4.119 through 4.150 show the comparison between measured head values and model-calculated head values at a number of observation wells for the validation period. Although the scales vary on each plot, all plots have a horizontal grid line at each foot. This is to make it easy to determine the range of heads at a glance.

The model used month-long stress periods, so pumping and boundary conditions were input as step functions with constant values throughout each month and sudden changes at the end of each month. For this reason, the model cannot be expected to accurately predict day-to-day head variations in any of these wells. Calibration efforts were aimed at matching general trends and monthly averages.

Starting head conditions for this model were based on the October 1993 steady state solution. Transient calibration efforts were focused on matching the head changes, not the actual heads, so it is not uncommon for residuals in the starting condition to be carried through the entire calibration period. This indicates that the model is correctly predicting responses to hydrogeologic forces even if the calculated head values vary somewhat from the measured values.

- 2.0 to 4.0
- -2.0 to 2.0 (well calibrated)
- -4.0 to -2.0
- < -4.0 (model predicts low)

Notes:

The mean error (ME) is calculated as described in Section 4.1. The ME statistic is calculated using monthly average heads for both the observed and model calculated data.

A perfectly calibrated point would have an ME value close to zero. In these maps, blue points have negative ME statistics (model prediction is low) and red points have positive ME statistics (model prediction is high). Green points are for well calibrated observation wells.

- 2.0 - 4.0
- 4.0 - 8.0
- > 8.0 (poorly calibrated)

Notes:

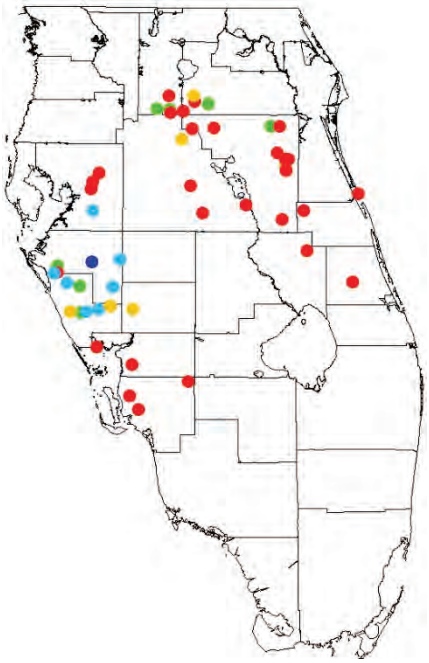
The RMS (Root Mean Square) statistic is calculated as described in Section 4.1. The RMS statistic is calculated using monthly average heads for both the observed and model calculated data.

A perfectly calibrated point would have an RMS value close to zero. In these maps, blue points have low RMS statistics (well calibrated) and red points have large RMS (poorly calibrated).

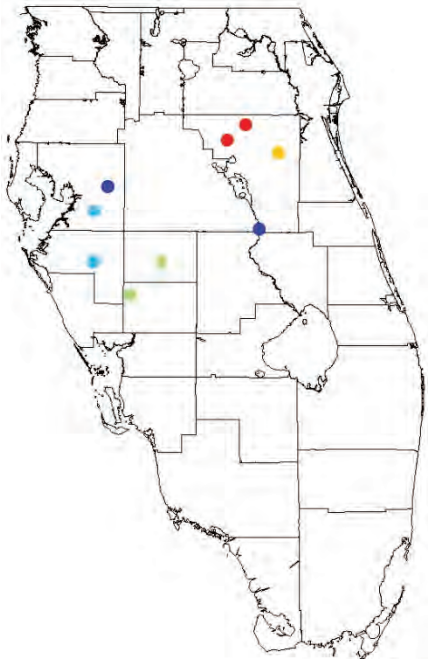
Transient SEAWAT Validation Comparison
Root Mean Square Error (1993-1994)
Final Groundwater Model Calibration Report

Figure 4.152

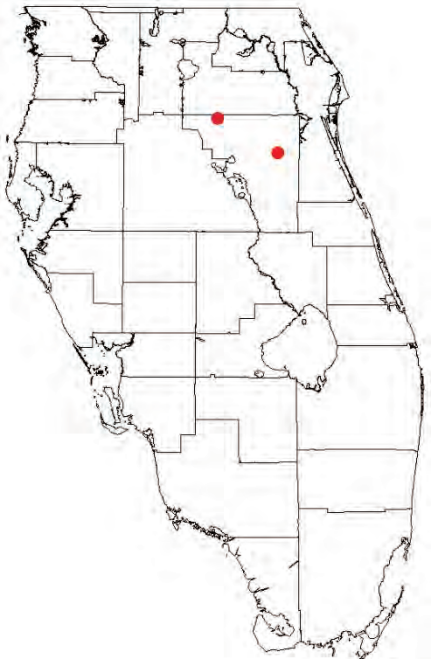
October 2010



UF



APPZ



LF1

RMS as Percent of Observed Range

- < 10% (well calibrated)
- 10%-20%
- 20%-30%
- 30%-40%
- > 40% (poorly calibrated)

Notes:

The RMS (Root Mean Square) statistic is calculated as described in Section 4.1. This figure shows the RMS for each transient calibration point as a percentage of the range of observed values over the 15 month calibration period. The RMS statistic is calculated using monthly average heads for both the observed and model calculated data.

A perfectly calibrated point would have an RMS value close to zero. When compared to the observed head range, wells with small variability in heads are held to a higher standard. A common rule of thumb is to require that the RMS be less than 10% of the observed range. In these maps, blue points have low RMS statistics compared to the observed head range (well calibrated) and red points have large RMS statistics relative to the observed head range (poorly calibrated).

Nash-Sutcliffe Model Efficiency Coefficient

- > 0.75 (well calibrated)
- 0.5 – 0.75
- 0.25 – 0.5
- 0.0 – 0.25
- -1.0 – 0.0
- < -1.0 (poorly calibrated)

Notes:

The Nash-Sutcliffe Model Efficiency Coefficient is calculated as described in Section 4.2. This statistic is calculated using monthly average heads for both the observed and model calculated data.

A perfectly calibrated point would have an efficiency value close to 1.0. A negative efficiency value indicates that the calibration error exceeds the variance in the observed data. In these maps, blue points have high efficiency coefficients (well calibrated) and red points have negative efficiency coefficients (poorly calibrated).

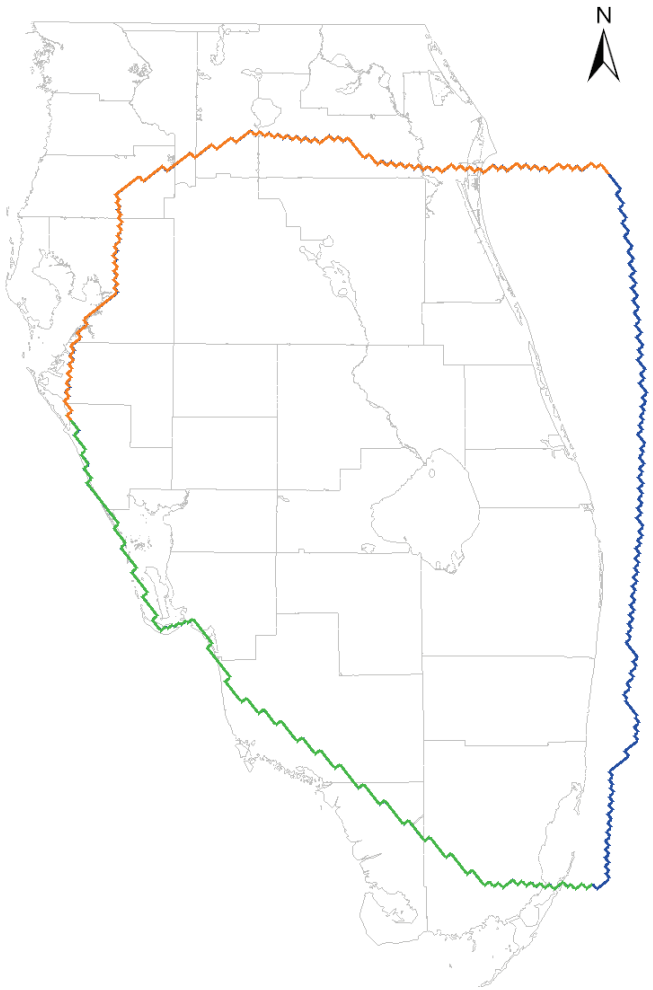
BZ	589.24	0.00



Legend:

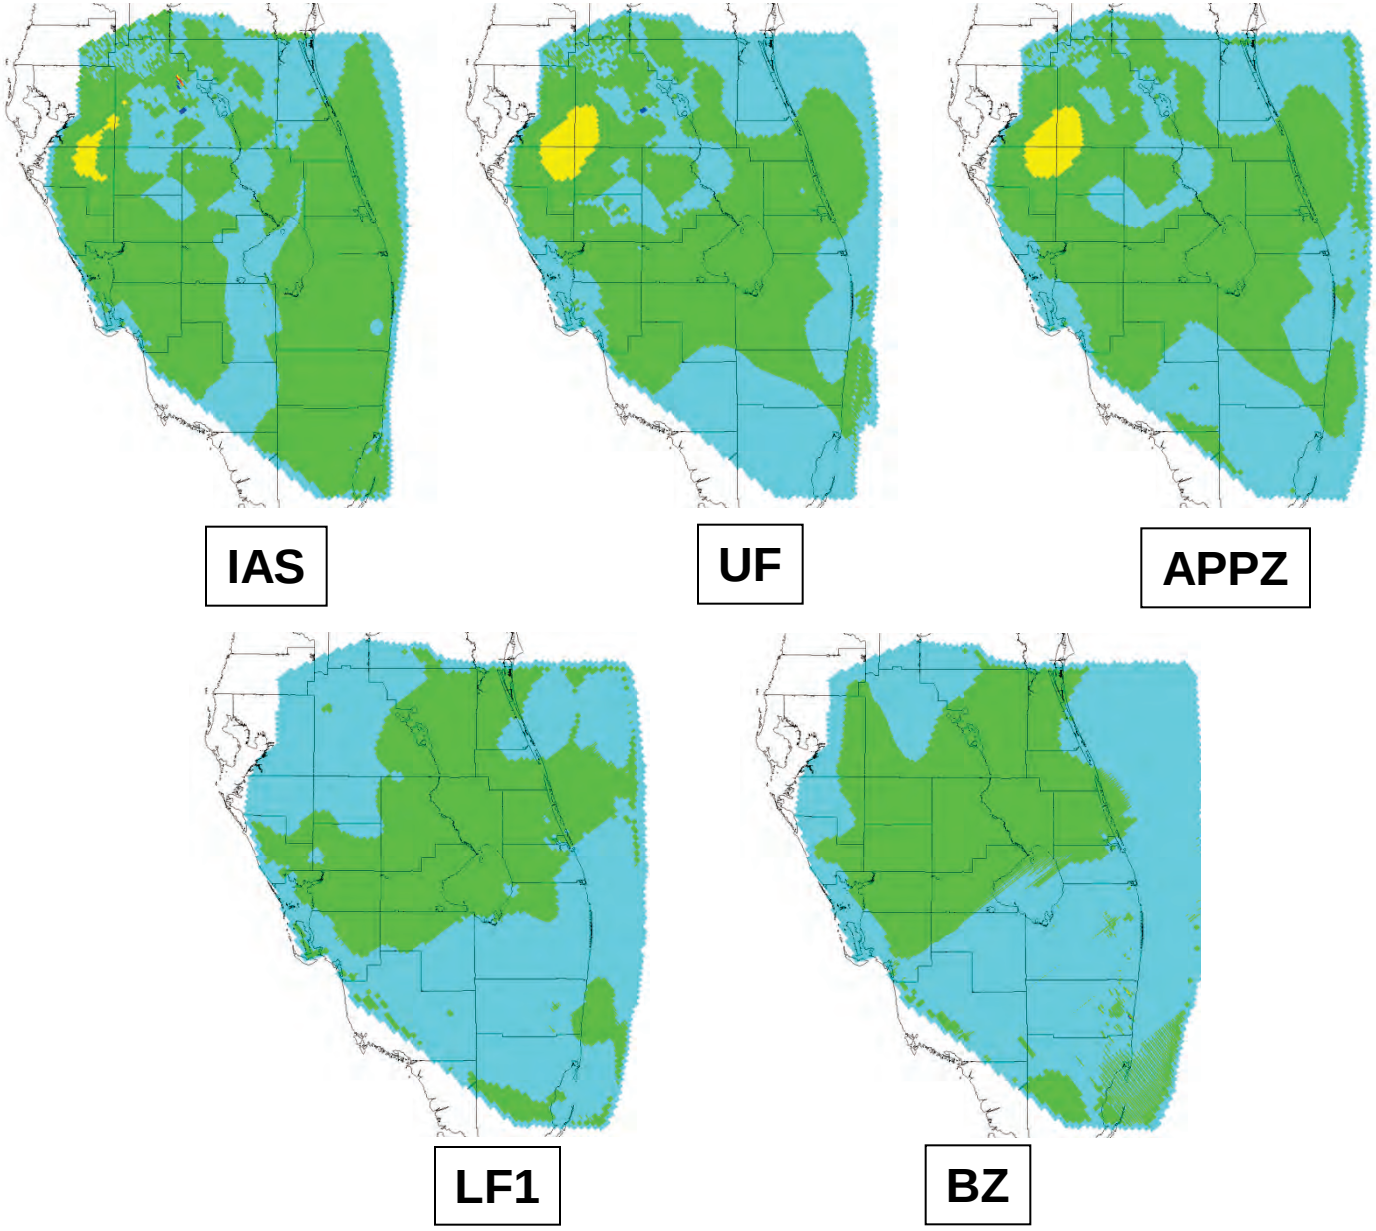
- Northern Boundary
- Western Boundary
- Atlantic Boundary

Notes:

The tables list the flow into and out of the specified head boundary cells of the aquifers. The boundary was broken up into three zones, as shown in the legend.

The aquifer portion of the IAS only extends along part of the Northern and Western boundaries in layers 2 and 3. The remainder of the IAS is considered a confining unit and therefore was not included in the flows reported for the Northern and Western boundaries.

Flow rates are for the February 2004 Steady State model results.



Notes:

Images were made by subtracting the heads calculated using the standard finite difference advection method with upstream weighting from the heads calculated by using the third-order TVD scheme.

Subtraction was made at every cell in the model for the timestep when the maximum differences were observed. This timestep corresponds to December 10, 2004.

Courant number was set to 1.0 for the TVD scheme.

Notes:

This figure shows the UF steady state February 2004 solution and calibration for the calibration run and four sensitivity runs which analyzed the effect of Boulder Zone thickness and conductivity on the results. Descriptions of these sensitivity runs are available in Section 5.4.

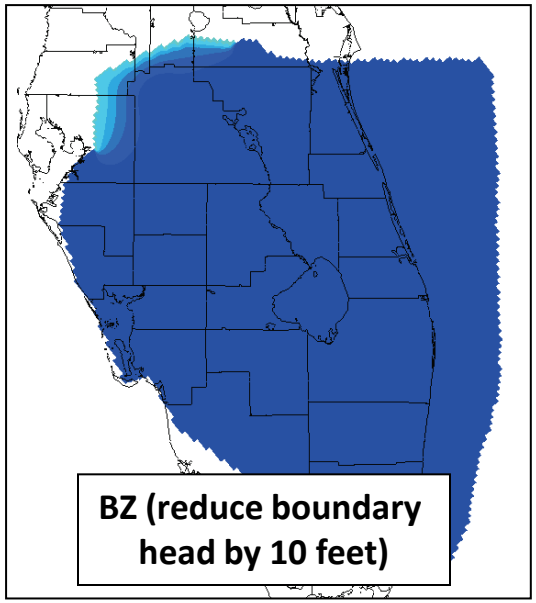
Calibration targets are green when the calculated value is within 2 feet of the measured head, yellow when within 4 feet and red when the model calculates a head more than 4 feet different from the measured value.

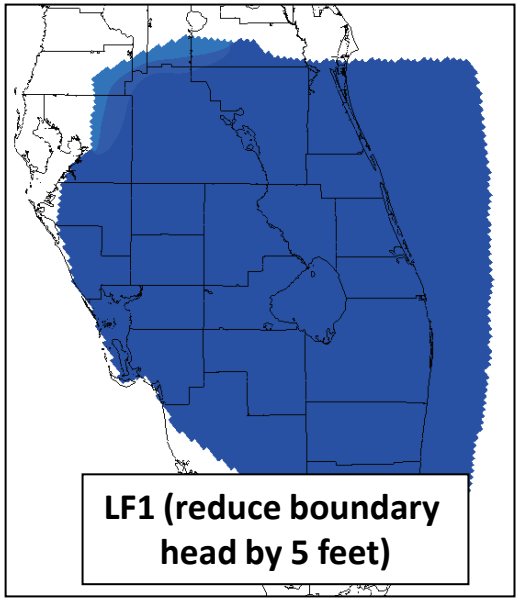
The direction of the colored bar on the calibration target indicates the sign on the residual: bars above the middle line indicate the model calculated higher heads than measured; bars below the middle line indicate negative residuals.

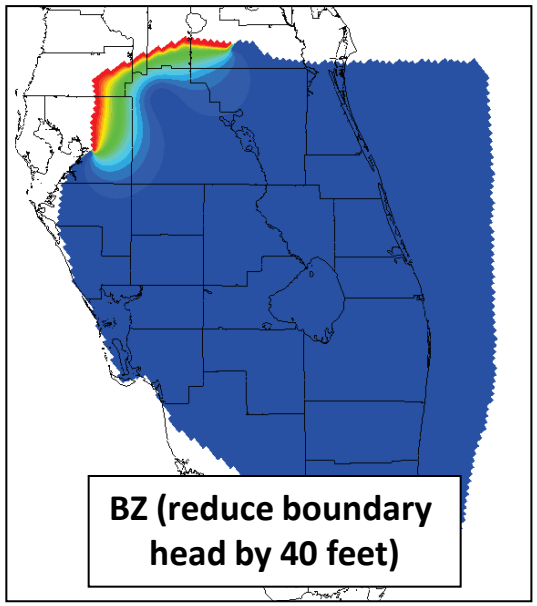
Effect of Boulder Zone Thickness
on Upper Floridan Calibration (SEAWAT)
Final Groundwater Model Calibration Report

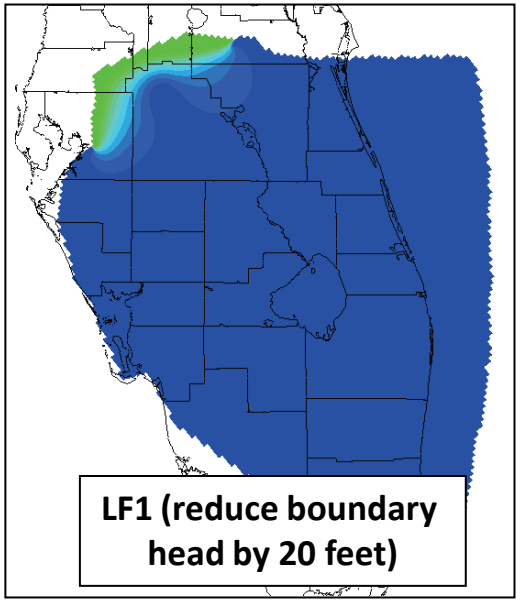
Figure 5.10

October 2010

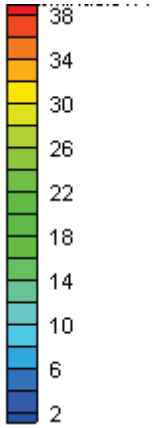








Head Difference (ft)



Notes:

The setup of this sensitivity run is described in detail in Section 5.6.1 of this report. Specified heads along the northwest boundary were reduced in the LF1 and BZ layers by the amounts indicated.

The effects on the resulting head solution are shown as the difference between the calibrated head solution and the sensitivity run solution.

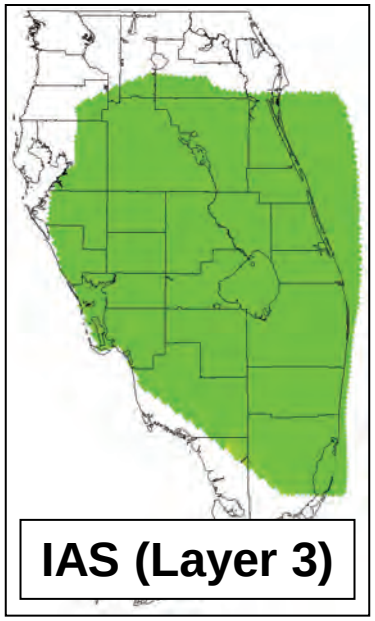
No discernible effects were noted in other aquifers.

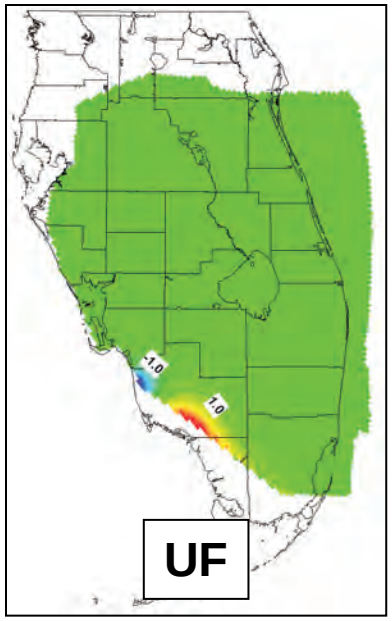
Head Difference as a Result of North Boundary Specified Head Change

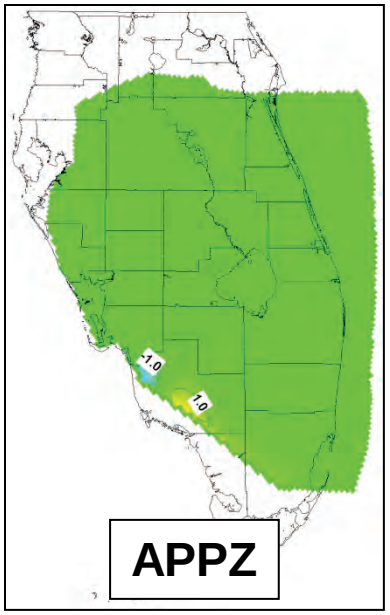
Final Groundwater Model Calibration Report

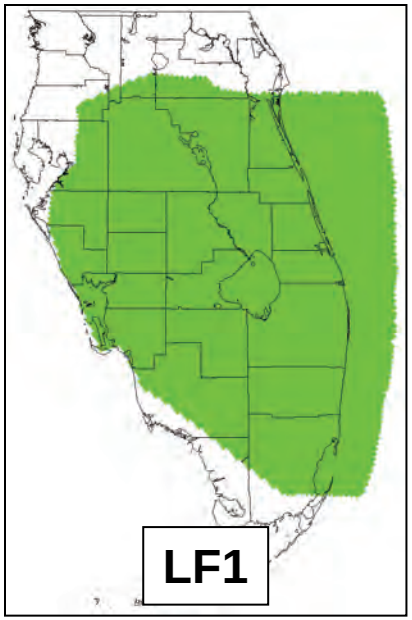
Figure 5.11

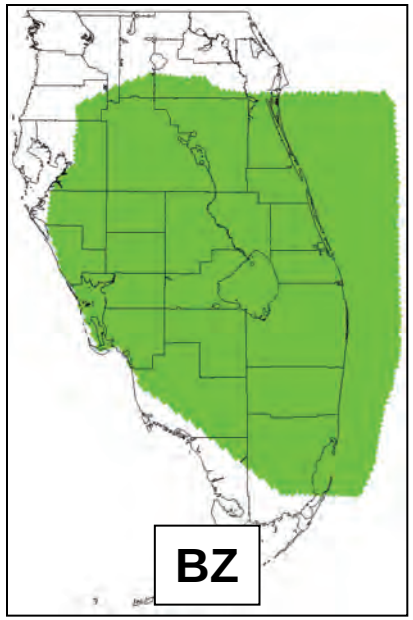
October 2010



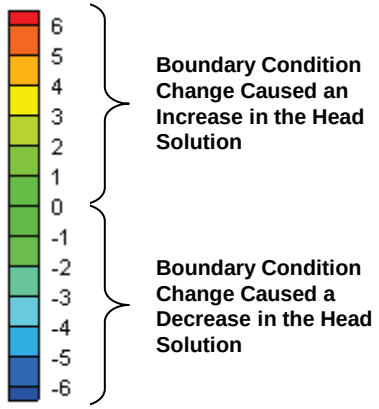








Head Difference (ft)



Notes:

The setup of this sensitivity run is described in detail in Section 5.6.2 of this report. Specified heads along the boundary through Everglades National Park in the Upper Floridan aquifer were removed, resulting in a no-flow condition at the boundary.

The effects on the resulting head solution are shown as the difference between the calibrated head solution and the sensitivity run solution.

Boundary Condition Change Caused an Increase in the Head Solution

Boundary Condition Change Caused a Decrease in the Head Solution

Notes:

The setup of this sensitivity run is described in detail in Section 5.6.2 of this report. Specified heads along the boundary through Everglades National Park in all aquifers were removed, resulting in a no-flow condition at the boundary.

The effects on the resulting head solution are shown as the difference between the calibrated head solution and the sensitivity run solution.

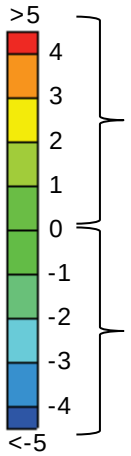
Head Change Due to K_h:K_v Ratio Changes (ft)



Change in ratio resulted an increase in model calculated head

Change in ratio resulted a decrease in model calculated head

Notes:

The figures show the difference in head when the calibrated model is compared to the sensitivity run which altered the ratio of horizontal to vertical hydraulic conductivity. Head differences were calculated using the February 2004 model.

Table 2.1 Model Assumptions List

Category	Parameter	SEAWAT Package	Assumption	Report Section
Pumping	Pumping Rate	WEL	Missing transient pumping data estimated based on available data and permit	Section 3.5, Appendix D
		WEL	Pumping rates in wells open to different zones were pro-rated based on hydraulic	Section 3.5, Appendix D
	Well Construction	WEL	Open hole/screen interval estimated based on available data if well construction	Appendix A
		WEL	Data collection effort assumed to have captured all significant pumping locations	Appendix A
	Model Input	WEL	Pumping assumed to be from the center of the grid cell	Section 3.5
	Water Quality	SSM	TDS and Temperature at injection wells were estimated based on well type if	Appendix E
Boundary Conditions	Head	CHD	Head boundary assigned to deeper units was correlated with overlying units in the absence of observed data	Appendix C
		CHD	Ocean head based on average monthly tidal data	Appendix C, Section 3.3.2
		CHD	Surface heads assumed to not be significantly impacted by CERP ASR	Appendix C, Section 3.3.1
		CHD	Regional pumping influence at or near model boundary is assumed to be captured by assigned specified heads	Appendix C, Section 3.3.3
	No-Flow	CHD	Lateral flow out of the model boundary in confining units is negligible	Appendix C, Section 5.6.3
	Model Input	CHD	Model boundary is sufficiently far away from CERP ASR influence	Section 3.3, Appendix C
	Water Quality	CHD	TDS /temperature observed at model boundary is indicative of incoming flow water quality	Appendix E
Initial Concentration	Model Input	BTN	Regional TDS/temperature does not vary significantly during the modeled period (except at injection locations)	Appendix E
	TDS	BTN	Natural neighbor interpolation was used to assign the initial TDS between data points	Appendix E
		BTN	TDS concentration generally increases with depth	Appendix E
		BTN	Coastal TDS is equal to seawater concentration at ocean outcrops	Appendix E
		BTN	Seawater TDS concentration is 35,000 mg/l	Appendix E
		BTN	Assumed TDS for SAS is 100 mg/l	Appendix E
	Temperature	BTN	Coastal temperature is based on isotherm evaluation at elevation of ocean outcrops	Appendix E
		BTN	Natural neighbor interpolation was used to assign the initial temperature between data points	Appendix E
		BTN	Assumed temperature for SAS is 24 degrees C	Appendix E

Table 2.1 Model Assumptions List

Category	Parameter	SEAWAT Package	Assumption	Report Section
Hydrogeologic	General	LPF	Geologic/stratagraphic simplifications assumed to be reasonable to address regional CERP ASR questions	Section 3.2
	Model Input	LPF	The hydrogeologic interpretation used to develop the model was based on USGS SIR 2007-5207	Section 3.2
		LPF	Hydraulic conductivity and specific storage in each model cell is indicative of the average hydrogeologic condition for that cell and is determined based on available observed data and ability of the model to reproduce observed head variations	Section 3.2.2, Section 4.0
	Hydraulic Conductivity	LPF	Transmissivity was converted to hydraulic conductivity based on the thickness of the well's open section where available and the aquifer thickness derived from the Hydrogeologic Framework where testing zone information was not available	Section 3.2.2
		LPF	Kriging was used to interpolate hydraulic conductivity between pilot points	Section 4.0
		LPF	The portion of the BZ containing voids was modeled with a very high hydraulic conductivity of approximately 10,000 ft/day	Section 3.2.2
		LPF	Due to data limitations the BZ was modeled at a constant thickness of 500 ft.	Section 3.2
		LPF	No regional anisotropy was incorporated into the model	Section 3.2.3
		LPF	Vertical hydraulic conductivity in aquifers is one tenth of the horizontal hydraulic conductivity	Section 5.7
		LPF	Vertical hydraulic conductivity in confining units is one half of the horizontal hydraulic conductivity	Section 5.7
	Specific Storage	LPF	Kriging was used to interpolate specific storage between pilot points	Section 4.0

Table 2.1 Model Assumptions List

Category	Parameter	SEAWAT Package	Assumption	Report Section
Calibration Data	Water Level	HOB	Due to the limited data in the deeper units of the FAS, some data from dates other than the calibration period were used to refine calibration	Section 4.0
		HOB	Monthly average data was adequate for calibration	Section 6.4
	Well Construction	HOB	Observed values used for calibration are indicative of the zone being evaluated and not a blend of over/under lying units	Section 4.0
		HOB	Open hole/screened intervals were used to determine the representative geologic unit for observation wells	Section 4.0
		HOB	Generally, at least 50% of the screened (open) interval must be in the calibrated unit to be used in calibration	Section 4.0
	Model Input	HOB	Calibration data coverage is adequate to address CERP ASR questions	Section 4.0
		HOB	Modeled results were linearly interpolated from computational points to observation data locations	Section 4.0
Model Parameters	General	N/A	Each cell is representative of average conditions across its area	Section 2.3, Section 3.2.1
		N/A	Steady State solution is reasonable as intial condition for transient simulations	Section 2.4
		DSP	Dispersivity and Diffusion values are reasonable and constant	Section 5.3
		LPF	Porosity values are reasonable and constant	Section 5.2
		N/A	Numerical codes are able to accuratly resolve flow and transport equations	Section 2.2
	Time	N/A	All data is monthly averaged	Section 2.4
		N/A	Calibration/Validation period is sufficient to define system to address CERP ASR questions	Section 2.4
	Density Variation	VDF	Linear relationship between variations in TDS/temperature and density	Section 2.1

Table 3.1 Notes:

1.) Well types in this table were based on data from SAJ which used the following abbreviations:

A - Agriculture
AC - Air Conditioning/Withdrawal
AG - Agriculture
AQC - Aquaculture
ARR - Aquifer Remediation and Recovery
ASR Injecting - Aquifer Storage and Recovery Injection
ASR Pumping - Aquifer Storage and Recovery Pumping
CATTLE - Irrigation for Cattle Pasture
COMM - Commercial
COMM/IRR - Commercial and Irrigation
DAI - Dairy
DOM - Single Family
FIR - Fire
FIRE - Fire Protection
FRZ - Freeze Protection
IC - Industrial/Commercial
IND - Industrial
INJ - Injection
IRR - Irrigation
IRR/CATTLE - Irrigation for Cattle Pasture
L DRAIN - Drains Stormwater to Floridan Aquifer
LARGE PWS - Large Public Water Supply
MD - Mining/Dewatering
MND - Mining/Dewatering
OTR - Other
P - Public Supply
PH - Swimming Pool Heating/Withdrawal
PHR - Swimming Pool Heating/Injection
PWS - Public Water Supply
R - Recreation
R DRAIN - Drains Stormwater to Floridan Aquifer
RCG - Recharge (Unspecified)
REC - Water Supply for Recreational Facility (Camp or Marina)
REC GOLF COURSE - Water Supply for Golf Course
S DRAIN - Drains Stormwater to Floridan Aquifer
SMALL PWS - Small Public Water Supply
W DRAIN - Drains Stormwater to Floridan Aquifer

2.) A negative pumping rate indicates extraction; a positive pumping rate indicates injection.

3.) The net pumping rate was calculated as the total injection pumping rate added to the the total extraction pumping rate.

4.) % of Total Pumping was based on the total volume of water passing through the pump within a given month. For example, the percent of total pumping that came from estimated data was calculated as follows:

$$\frac{\left|\text{total estimated injection}\right| + \left|\text{total estimated extraction}\right|}{\left|\text{total estimated injection}\right| + \left|\text{total estimated extraction}\right| + \left|\text{total actual injection}\right| + \left|\text{total actual extraction}\right|}$$

Table 4.1: Usage of SAJ Observation Database in Regional Model Calibration

Model ID[a]	Well Name	Data Source	Easting[b]	Northing[b]	County	Cased Depth (ft)	Drilled Depth (ft)	Dominant Layer[c]	% Open Section in Layer[c]	93/94 Months with Data[d]	03/04 Months with Data[e]	Use for Data in Model Setup/Calibration						Reasoning/Comments

Notes:

(a) The Model ID is a 6-digit identification number assigned in the SAJ monitoring well database.

(b) Easting and Northing are in feet and are based on the State Plane NAD83 Florida East coordinate system

(c) Dominant Layer and "% Open Section in Layer" describe a comparison between the model-simplified geology and the reported open section of each well (between the cased and drilled depths). For example, ROMP 18 SUWANEE (101325) is listed with a dominant layer of UF and a % Open Section in Layer of 67%. This indicates that 67% of the open section of the well overlaps the UF, as defined by the model grid. The other third of the open section coincides with other layers of the model.

(d) The column labeled "93/94 Months with Data" indicates the number of months between October 1993 and July 1994 (validation period) with at least one head measurement for each well.

(e) The column labeled "03/04 Months with Data" indicates the number of months between October 2003 and December 2004 (calibration period) with at least one head measurement for each well.

(f) Boundary condition assignments are described in Appendix C

OSF-82L	LF/BZ (Expanded Calibration)*	550374.73	1424546.73	51.77	49.06	--	48.78
USGS CORE HOLE 2 AT POLK CITY	LF/BZ (Expanded Calibration)*	388669.96	1400176.12	127.10	127.16	--	127.04

* The expanded calibration for the LF1/BZ layers included wells which had available data for time periods other than the calibration or validation periods. They were included as loose constraints because of the small amount of data available for the calibration and validation periods in these layers. Reported observed data for these points in this table is not for October 2003.

Appendix A: Phase II Groundwater Model Data Collection

1.0 Phase II Groundwater Model Data Collection

1.1 Model Boundaries, Spatial and Temporal

1.1.1 Horizontal Boundaries

The Phase II Groundwater Model will be developed, as part of the Aquifer Storage and Recovery (ASR) Regional Study. The model originally included all of peninsular Florida, from Orlando southward to the Keys. This includes all of the South Florida Water Management District (SFWMD), and parts of the Southwest Florida Water Management District (SWFWMD) and the St. Johns River Water Management District (SJRWMD), hereafter regarded collectively as the Water Management Districts or WMD's. As the data collection progressed, the Phase II model has been refined. See Figure 1.1

Figure 1.1: Refined Phase II Model Boundary

1.1.2 Vertical Boundaries

The aquifers included for study are the Floridan Aquifer System (FAS), which includes the Lower-Hawthorne, Suwannee, and Avon Park Aquifers, and the Boulder Zone; and the Intermediate Aquifer, which includes the Mid-Hawthorne and Sandstone Aquifers. Pumping records within these aquifers were collected. Water use in the Surficial Aquifer System (SAS) is not part of the model, so pumping from the SAS was not collected. However, since the SAS is the top boundary layer, water level data in the Surficial Aquifer was collected.

1.1.3 Temporal Boundaries

The period of record (POR) was determined based on the period with the best data representation. A similar groundwater model, "Simulation of Ground-Water Flow in the Intermediate and Floridan Aquifer Systems in Peninsular Florida," (known as the "Mega Model) was produced by Nicasio Sepulveda of USGS for the August 1993 through July 1994 POR (a "USGS water year"). As data collection progressed, it was determined that pumping and groundwater data from the WMD's for calendar year 2004 were the most comprehensive. Thus,

the ASR Regional Groundwater Model was set to be calibrated for the POR spanning October 2003 through December 2004. The last three months of 2003 were added to include a continuous water year. The calibrated model would be verified using the groundwater data from the Mega Model for the 1993-1994 POR. Data collection then focused on these two PORs.

1.2 Data Required

The data required for this model can be separated into three categories: pumping data, transient water level data, and water quality data. Each well with data also needed to have accurate location and depth data. Each type of data came from different well types. The pumping data came from production, injection, and ASR wells, while the water level and water quality data came from monitoring well records, ASR wells, and some production wells (public supply). Each type of well had many different agencies as data sources. The following paragraphs describe the three main types of data, in the order in which they were collected:

1.2.1 Pumping Data

Water is pumped by three types of wells: production, injection, and ASR wells. Production wells, or consumptive use permit (CUP) wells, are wells that only recover water from the aquifer or pump out (a few are free-flowing). Underground injection control (UIC) wells are wells that only inject water into the aquifer or recharge. UIC wells in Florida are either Class I or Class V, based on a state UIC category system. ASR wells both recharge and recover, and are considered Class V UICs (though not all Class V wells are ASRs). There are also a few drainage wells that drain storm water runoff and control lake levels. Monthly pumped volumes were converted to average cubic feet per day (cfd) for each month during the PORs. All water pumped out, or recovered, is reported as negative values. All water pumped in, or recharged, is reported as positive values.

1.2.2 Water Level Data

Water level (WL) data are retrieved from monitoring wells, which are different from pumping wells in that they are designed to monitor groundwater conditions, not recharge or recover large volumes of water. Most of the monitoring wells recorded water levels on a daily basis, providing comprehensive information for the model. Many of the monitoring wells had screened intervals at up to three different depths, and would thus provide water levels for three different aquifers in one location. Water levels are reported as either elevation in feet NGVD or feet below the ground surface (to be converted to feet NGVD in the model).

1.2.3 Water Quality Data

The water quality (WQ) parameters necessary for the model were chlorides, total dissolved solids (TDS), and conductivity. Most of the water quality monitoring was performed on monitoring well water, though the frequency was seasonally or annually instead of daily. Water quality data were also provided for ASR wells

during cycle testing and for public supply CUP wells. These data were collected even less frequently.

2.0 Data Sources

Data was collected from the following sources: SFWMD, SWFWMD, SJRWMD, U.S. Geological Survey (USGS), the Florida Department of Environmental Protection (FDEP), the Florida Department of Health (FDOH), USACE, the Groundwater Protection Council (GWPC), private contractors, and individual facility owners and operators. Agency data sources included permit databases, permitting engineers, general data databases (CERP and DRAM), GIS databases, hydro-geologic reports, and modelers who compiled similar data for similar models. Each source had many types of data, but each had a different strength. The WMDs and FDOH provided the most comprehensive CUP data, both wellhead and pumping records. FDEP and USGS provided the most comprehensive ASR well data. FDEP provided the most comprehensive UIC data. FDOH provided the most comprehensive private well records. The WMDs and USGS provided the most comprehensive water level and water quality data. Comprehensive data sets of each type of well were compiled using data from these respective sources, and the rest of the data were used to fill in data gaps, such as missing depths, capacities, and individual wells.

Data Source Table

Well Type	Subtype	Well Head Data Source	Daily Data Source (Pumping, WL, WQ)
Production/CUP	Surface Water	omitted	n/a
	Ground Water	WMDs, USGS, FDOH, FDEP	WMDs, FDEP
Injection/UIC	Class I	FDEP, GWPC	FDEP, Facility owners
	Class V ASR	FDEP, USGS	Cycle tests, MORs, facility operators, PEs of record, FDEP, USGS
	Class V nonASR	FDEP	None fell within model boundary
Monitoring Well	General	WMD & USGS databases, SFWMD	
	ASR	SFWMD	
	Class I	SFWMD	Tetra Tech

Table 1.1: Data Source Table

3.0 Ensuring Completeness of Wellhead Data

3.1 Production/CUP Data

To ensure the most comprehensive database, geographically overlapping data with incomparable nomenclature were compared using GIS ArcInfo. Once this was complete, data gaps were addressed. Essential CUP wellhead data included the location, drilled and cased depths, and capacities. Locating accurate data, if not provided, was imperative, as any wellhead missing even one piece of the data could not be used. Various methods were used to track down missing data depending on available resources, and logical assumptions were made when necessary. The resources available varied by the original data source. Each WMD had a web-based permit database, which was consulted first for missing information. For the most part, these databases had the same information that we had obtained previously from other sources. When missing data could not be found or was not available, the following assumptions were made:

3.1.1 Assumed Well Depths.

The following methods were used to assume missing depth information:

a. For wells in which only one of the two interval depths was provided, the cased OR drilled depth, the missing depth was assumed based on a 20 foot open interval.
b. Many permits encompassed several wells (henceforth referred to as “co-located” wells). Wells within the same permit (and thus the same use type) were assumed to have similar depths.
c. Many wells had no depth information, and no co-located wells. For these, USGS data was cross-referenced to obtain the aquifer designation. Then, depths were assumed based on other wells in the area with the same aquifer designation and same use type (irrigation, PWS, etc.).
d. FDOH provided a very comprehensive well database, including domestic wells, with precise locations (latitude and longitude instead of row and column in a model). However, most of these wells had no depth information. The following steps were taken to determine how many, if any, of the wells could be reasonably assumed to pull from the IAS or FAS.
    a. Using data from several USGS tables, % withdrawals by aquifer and total households with wells, by county, was assessed. The number of domestic wells provided by the FDOH was also compared to the total number reported by USGS. It was assumed by the data provided that more domestic wells exist than data is available for. See table 3.1.

b. Of the FDOH domestic well depths provided, % withdrawal by aquifer, by county was assessed. The numbers corresponded with those provided by USGS.

WATER USE REPORTED BY USGS

County	% Total Water usage from FAS	% Total Water Usage from IAS	% Total Water Usage from Biscayne/SAS	# of Domestic Wells per USGS	# of Domestic Wells from FDOH
Brevard	86.1%	0.00%	13.9%	22,458	227

Sumter	98.3%	0.00%	1.7%	11,287	164

Table 3.1

c. For the counties that USGS reported pulled more than 95% of their water from aquifers deeper than the SAS, aquifer designations and depths were assumed for all FDOH wells for which no depths were originally provided. IAS and FAS designations were applied according to % given in table 3.1. The counties with 95% or higher are highlighted in red.

If no depth could be logically determined using these methods, the well was omitted.

3.1.2 Assumed Locations.

Two methods were used to assume missing location information:

a. When there were co-located wells in the same permit with only one XY coordinate and missing individual location data, ten feet were added to the known X and Y coordinate values of wells on the same property (then 20 feet, then 30 feet, depending on the number of co-located wells with unknown locations).
b. If no co-located wells with data existed, addresses were looked up and XY values obtained by using Google Earth and GIS, when feasible.

If no location could be determined using any of these methods for a well, it was omitted.

3.1.3 Assumed Capacities.

Seven methods were used to obtain missing capacity information:

a. For wells with no capacity data that did have pumping records, the highest pumping value (i.e., converted to a pumping rate) was used.
b. Data provided by FDEP and FDOH was used to find permitted capacities.
c. Well capacities were were assumed based on known capacities of other wells with the same diameter and same use type.
d. For wells that had only annual averages and no information on diameter or use type, the annual average was used as the capacity. However, if the annual average was 0 for that year, the annual average of a well in the same area with the same use type was used.
e. As a last resort, if no capacity or pumping information was provided, a similar co-location process was used to assume well capacities for wells with the same use type.
f. The private well data provided had no capacity data. Average household flows were calculated per county using average people per household and average daily use per capita, as reported by USGS. Q = (avg. gal/day per person)(avg persons per household)/(7.47 gal/cf).
g. Only annual average flows were provided for the free-flowing wells. Because the free-flowing wells have no pump with a capacity, the annual average was used as the capacity.

If not enough data was present to make a logical capacity assumption, the well was omitted.

3.2 Injection/UIC Data

As with CUP pumping data, the same wellhead data is essential for UIC wells. FDEP provided the most comprehensive wellhead data for all UIC wells, and nearly complete pumping data for the Class I UIC wells. Additional data sources cited to verify comprehensive and accurate ASR wellhead data included several contacts at the SFWMD, the SFWMD on-line permit database, and several technical reports from USGS.

In addition to the WMDs, FDEP, USGS, and USACE, the individual facilities and engineers of record were also contacted to verify wellhead and pumping information during the QA/QC phase, as detailed in a later section.

Additional data sources sited to verify comprehensive and accurate Class I and Class V well head data included FDEP's UIC Program, FDEP's Oil and Gas section (part of Florida Geologic Society (FGS), and GWPC. These data sources verified location, depth, and capacity information. The facilities and engineers of record were contacted for this information during the QA/QC phase, as detailed in a later section.

3.3 Monitoring Well Data

USGS and the WMDs all maintain web-based databases for their monitoring well data. Water level and water quality data was downloaded from these sites. Coordination with hydrologists and GIS personnel at each agency was necessary to expedite the process and ensure accurate data. Monitoring well data were also collected from FDEP, which does not maintain their database online. Other databases maintained by FGS and USACE were consulted to ensure a comprehensive data set. FAS water level and water quality data collected by Tetra-Tech were also used. One set collected by Tetra-Tech included internal water pressures for injection wells. However, no depth or aquifer information was available for these pressures, and it was verified by the FDEP injection well specialist that no reference elevations exist for this data. Therefore, these wells were not included in this data set.

It must be noted that many monitoring wells have more than one interval within a single hole, and many well fields exist with several different holes clustered in close proximity with similar depths and therefore similar transient data. Both scenarios could look like a duplicate at first glance, and each case was carefully scrutinized by database comparison and even verification from a source groundwater expert. Each separate interval, even within the same hole, is listed as a separate well with a unique model ID number. This ensures the appropriate water level data is paired with the correct interval.

3.3.1 USGS Monitoring Well Data

Transient water level data maintained by USGS was downloaded from their National Water Information System, or NWIS. Because NWIS monitoring wells are throughout the model domain, this database was compared to the wellhead databases obtained from the water management districts to eliminate duplication. Duplicate wells were matched by name, USGS ID number, XY coordinates, and depth. Transient data between the duplications was spot-checked to ensure the readings were the same. When a duplicate was found, missing data in one of the databases was filled in using the other database (usually the cased depth), so both databases matched. The larger set of transient data was used in each case. There were a few discrepancies in total depths between NWIS and DBHydro (SFWMD's database). It was confirmed by the SFWMD groundwater data department that NWIS data is more reliable, so depths provided by NWIS were used in these cases.

Assumptions were made for cased depths that were not provided. These assumptions were based on the provided total depths and a probable open hole interval at that depth based on cased depths provided for other wells. The open hole interval assumptions used were as follows:

Total Depth, feet below surface	Open Hole Interval, feet
< 25	2
25 – 99.9	5
100 – 499	20
> 500	100

The assumptions listed in this table were used for estimating cased depths in every monitoring well data set collected, from every data source.

Once the duplicates were removed from the dataset, casing depths assumed, and location accuracy verified by GIS, the corresponding transient data was linked to the wellhead data set.

3.3.2 SFWMD Monitoring Well Data

The SFWMD's DBHydro browser was the main source for monitoring well data from that district. DBHydro is the SFWMD's corporate environmental database, which includes hydrologic (including groundwater), hydro-geologic (including well construction), and water quality data. From the transient groundwater level database, both transient water levels and wellhead information were downloaded. The wellhead database downloaded from the transient groundwater section was compared to the well construction data from the hydro-geologic database. It was confirmed by the SFWMD groundwater data department that the well construction data from the hydro-geologic database was more accurate, so the XY coordinates and depths from this database were used where discrepancies existed.

A different set of wells maintained in a separate database are also included in this data set. They are known to the District as the "POT run", a twice a year snapshot of water-level (and in some cases water-quality) from the Upper Floridan Aquifer. It was determined during the compilation that DBHydro included a few wells that fall within the SJRWMD. Only DBHydro provided transient data for these four wells, and they were also included in the data set.

It is worth noting that a little over 10% of the wellheads listed in DBHydro had transient data recorded during ASR's POR. Only those wells with applicable transient data were included in the data set for this model.

Once the duplicates were removed from the dataset, casing depths assumed, and location accuracy verified by GIS, the corresponding transient data was linked to the wellhead data set.

3.3.3 SJRWMD Monitoring Well Data

Monitoring well data from five different sources was compared for duplication and accuracy and then compiled. These five data sources were: the web-based groundwater monitoring network GIS data (known as the ORACLE DB), the web-based archived groundwater level database (known as the WEB HYDRON), monitoring station records for piezometers in the Floridan and shallower aquifers surrounding the Conserv II facility in western Orange County, monitoring well data collected by Tetra-Tech, and the groundwater data set used in the East Central Florida model. With the exception of the Conserv II data, all the data sets included data on the same wells, each using a different mix of three separate and distinct naming systems. A senior hydrologist at the District provided a groundwater monitoring network list showing all three names for each well, which was used to determine duplicate wells.

Once the duplicates were removed from the dataset, casing depths assumed, and location accuracy verified by GIS, the corresponding transient data was linked to the wellhead data set.

3.3.4 SWFWMD Monitoring Well Data

A complete list of monitoring wellheads and the corresponding transient data was available on the district's web-based database, and was also provided directly to the Corps by a senior hydrologist. Data from the same monitoring wells was also collected by Tetra-Tech.

Once the duplicates were removed from the dataset, casing depths assumed, and location accuracy verified by GIS, the corresponding transient data was linked to the wellhead data set.

3.3.5 FDEP Monitoring Well Data

Some water level data was also provided by FDEP. It was verified that their data sources were the same as listed above; the water management districts and USGS. However, after checking for duplications, a few wells had no matches and were incorporated into the data set.

3.3.6 Correcting Water Levels.

Water levels in DBHydro were converted from pressure in psi to equivalent freshwater head in feet above the well's pressure transducer. This methodology assumes a water density with a standard temperature and salinity within the well. It does not account for actual variations in these parameters. Based on information from SFWMD, the converted heads in DBHydro were very close to what they would be if they had been corrected for density and temperature, for TDS values under 10,000 mg/l. These did not need further correction, and were used as reported.

However, for TDS values over 10,000 mg/l, DBHydro heads did not equal what the water levels would be if corrected for the effects of both temperature and

water quality (salinity). SFWMD provided a spreadsheet containing the appropriate formulas for this density correction. Generally, the water quality (salinity) for the wells are reasonably well known; however, accurate temperature readings were not readily available for most wells. In wells where accurate temperatures were not well known, a temperature of 24 degrees Celsius was assumed based on discussions with SFWMD.

Figure 3.1, below, illustrates the relationships between DBHydro water levels, and the affects of density correction.

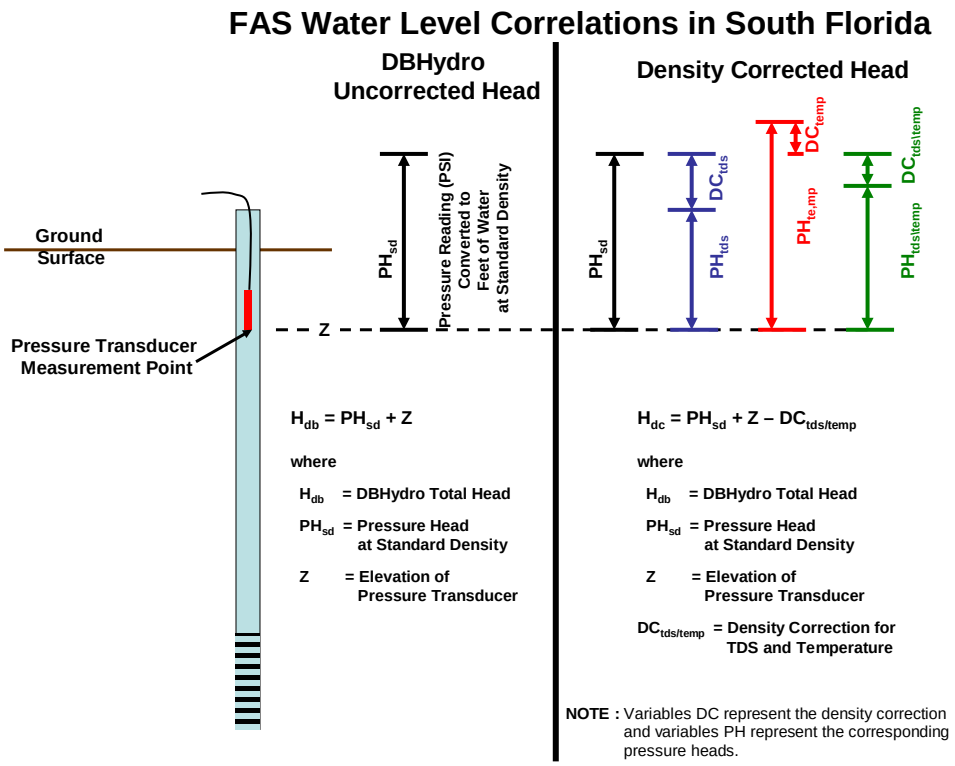

Figure 3.1

The left side shows the ground elevation and transducer elevation in the well. The transducer's reading in psi is divided by 0.4335 to convert to equivalent feet of freshwater (assuming an equivalent freshwater density of 1000.38 kg/m^3), then added to the elevation of the transducer. This is what is reported in DBHydro. Though they are not density corrected, the values are very close to what they would be if density corrected, for TDS levels below 10,000 mg/l. The heads on the right show the relationship between the total heads in DBHydro with and without density correction. The black line shows the unchanged DBHydro values. The blue line shows what the level would be if density corrected only for TDS. The red line shows the water levels for temperature density corrections. The green line shows the water levels after density correction for both TDS and temperature. The black and green lines are equal heads for TDS values below 10,000 mg/l. They are not equal for TDS values above 10,000 mg/l.

Water level data from USGS had not been density corrected and had the same above calculation applied to each reading to give equivalent freshwater heads. However, discussions with USGS verified that their monitoring wells were not deep enough in South Florida to reach water with 10,000 mg/l salinity. This was verified, and the same principles applied.

4.0 Quality Assurance/Quality Control of Pumping Wellhead Data

A large amount of data was collected, all from different sources, all with varying degrees of QA/QC provided prior to dissemination. In short, the data as received included many errors, the nature of which varied by agency. Thus, QA/QC was

required continually throughout the compilation process. Once the pumping wellhead location data was collected, it had to undergo a rigorous QA/QC process before adding the pumping records to it. The following paragraphs describe the compilation QA/QC process.

4.1 Ensure Compatibility

In order for the data to be useful for the model, all wellheads needed to have a location, depth, and either water level, pumping, or water quality data, all with uniform units. Due to the fact that each data source used different nomenclature systems, different reporting requirements of the facilities, and different data management, separate SFWMD, SWFWMD, SJRWMD, DEP, and USGS files were maintained initially. Not only did each agency have a different nomenclature system, but the USGS, FDEP, FDOH, and contractor data overlapped the WMD data, as well as each other. Thus, each file had to be organized identically to easily combine the files later and check for duplicates.

All data had to be in the same vertical and horizontal datum. They are as follows:

Horizontal Datum: NAC 83 State Plane 0901 Florida East, US Survey Foot

Vertical Datum: NGVD 29, US Survey Foot

CorpsCon was used for the horizontal datum conversion, after which the well locations were plotted in GIS to ensure proper conversion and to detect and correct any outliers.

4.2 Eliminate Wells out of the Model Boundary

Wells that fell outside the model boundary were confirmed as having correct location data and omitted. Upon closer inspection, it was found that some wells, though they plotted inside the model boundary, were still in the wrong place. This prompted a more thorough location assessment via GIS.

4.3 Verify Correct Location Data

The remaining wells inside the model boundary were analyzed to determine if the XY locations were correct. Since the ASR and injection well data sets were relatively small (400 wells total), each well could be addressed. However, that could not be done to the 21,000 CUP wells, so a representative number were addressed. The SFWMD CUP well permit numbers were different for each county, so they were plotted by county to determine if their location data was correct. SJRWMD and SWFWMD CUP nomenclature was not by county, so a representative sample of the wells was analyzed individually.

4.4 Eliminate Duplicates

Duplicates were found and eliminated by analyzing multiple wells with the same permit number, owner, well name, depth, capacity, and XY location. All of these parameters were analyzed to make sure it was a duplicate well. Fortunately,

relatively few duplicates were found in these data sets. Most wells with the same permit number and owner had different well names (well 1, well 2, etc.), different depths, well diameters, capacities, or a combination of differences. Some permits with multiple wells provided one XY location for the entire permit; thus the same location for all wells. Each co-located well XY was changed enough to be on the same property, but to avoid being in the exact location of another well (see Section 2.1.2).

The only outstanding issue found was that over 200 wells in the SWFWMD data set were confirmed as all being different wells with different permit numbers, well names, depths, and capacities, yet all having the exact same XY location. The data source was notified of this, and the correct locations were provided.

4.5 Fill in Pumping Gaps

Once the QA/QC procedure for the wellhead data was complete, the product was a comprehensive and corrected pumping wellhead data set. Historic pumping records provided by the WMDs were then added to the respective well heads. It was then determined not only how many wells did not have pumping data, but also how much pumping data did not have a matching wellhead. Phone calls were made to the data sources to discuss the findings and determine appropriate data representation. Again, it was different for each district. The pumping data gaps were handled as follows:

4.5.1 Data sources at one district ensured that their historical pumping data set was complete, and that any "missing" pumping data indicated no pumping at all. A representative sample of the wells was checked on this district's web-based permit data base to confirm the zero pumping for the unreported months. After that, each well was checked individually to confirm that each month of its operation was represented, and that zero pumping was reported appropriately.

4.5.2 Another district provided CUP pumping records for wells for which they previously did not provide wellhead data. There were few of these and it was feasible to look up each permit on the web-based permit database. This procedure provided the permit start date (showing if active during model POR), water source (aquifer name or surface water), how many wells, and the relative location. It was easy to fill in the wellhead information for the pumping records, and determine if it belonged in the model.

4.5.3 Some of the pumping records provided were given in totals per permit, all wells combined. This required a detailed 4-step procedure for properly distributing the provided pumping data, and filling in the gaps. As an example, Bob's Citrus Grove has 6 wells, but only one total pumping value for each month from August 1993 through July 1994.

a. The drill and abandoned dates were noted. Only the wells operating during the pumping dates were used in this process. For example,

wells A, B, and C were drilled in 1978, while wells D, E, and F were drilled in 2000. As a result, only wells A, B, and C can be considered at this point.

b. The capacities of the wells in operation were summed. Well A was 250,000 cfd, Well B was 200,000 cfd, and Well C was 100,000 cfd. A combined capacity of 550,000 cfd was used.
c. For each month, the percentage of the total permit capacity that was pumped was calculated. The total pumped in August 1993 was 20% of 550,000 cfd, 18% in September, and so forth.
d. It was assumed that each individual well pumped at the same capacity percentage, and the monthly percentages were applied to each well. Therefore, well A was reported as having pumped 20% of its 250,000 cfd capacity in August 1993, 18% of its 250,000 cfd capacity in September, and so forth. This was calculated and reported as monthly cfd.

Note from the example that there are no pumping data for any well for the October 2003 through December 2004 POR. The data filling for this period was handled differently.

a. First, the county and the type of well were noted. Bob's Citrus Grove is in Lee County and has all irrigation wells.
b. Another irrigation well in Lee County for which historical pumping records were provided was located. Sunny Groves, also in Lee County, had historical pumping data for both PORs.
c. The monthly percentages were determined for Sunny Groves, as in c. above, FOR BOTH PORs.
d. If the 1993-1994 monthly percentage numbers for Sunny Groves were similar to those of Bob's, it was assumed the 2003-2004 usage percentages were also similar.
e. Sunny Grove's 2003-2004 monthly percentages were applied to Bob's wells for the same POR.
f. If the 1993-1994 monthly percentage numbers for Sunny Groves were NOT similar to those of Bob's, it was assumed the 1993-1994 usage percentages for Bob's may be a more accurate representation of his usage ten years later.

4.5.4 Wellheads with no historical pumping records represented a majority of the pumping data gaps. In this case, only the above steps a, b, c, and e, were followed.

4.5.5 Monthly flow records are not kept for drainage wells. Annual averages were available for two years; 1995 and the 1993-1994 water year. Using the acreages and monthly rainfall totals in the area, calculations were run in an effort to determine a runoff coefficient for each well. A coefficient was determined when the calculated annual average matched the furnished annual average. This process did not provide useful runoff coefficients, as each well had a different runoff coefficient for each year an

average was provided. Thus, the 1993-1994 annual averages (in cubic feet per day) were used for monthly drainage flows for that POR. Monthly flows for the 2003-2004 POR were calculated using the same annual average and the total annual rainfall ratio between the PORs. The 1993-1994 annual average dataset was used for the 2003-2004 calculations instead of the 1995 averages for two reasons. The first reason was to maintain calculation consistency. The second reason was that the runoff coefficients calculated for this POR more closely resembled expected runoff coefficients for the land use types and soil type of the surrounding area. Monthly and annual rainfall totals were retrieved from NOAA and the water management district web sites.

4.5.6 For CUP wells in which the annual average was reported as the capacity, monthly flows were calculated by multiplying the annual average by a flow/annual average ratio computed for a nearby well of the same use type with furnished capacity and flow data.

4.5.7 The capacities calculated for the domestic wells were also used as monthly averages.

4.5.8 Since there were only about 400 UIC and ASR wells, it was feasible to call each owner, lead operator, or engineer of record, and obtain any missing data. During this process, the locations, depths, capacities, and drilled and abandoned dates were double-checked, and any wells that were drilled after 2004 were noted for later modeling.

5.0 Quality Assurance/Quality Control of all Monthly Pumping Data

Once every wellhead had pumping data paired with it for each month it was in operation, the second QA/QC process was initiated. For this, a highly objective approach was necessary. A procedure was established, listing what to look for, but not denoting methodology. Some of the QA/QC steps required were already performed, but it was assumed that an objective party completing the same tasks using a different method may find more mistakes. This proved to be the case. Below are the steps the objective QA/QC team followed:

<u>Pumping locations</u>.

1. Check for duplicates.
2. Check for units. All pumping capacities should be in cfd.
3. Check for possible order of magnitude problems (i.e., if most are in the order of 10,000, but one is on the order of 10).
4. There should be no zeros. If depth or location data are not provided, space should be left blank.
5. Make sure all columns contain data consistent with the heading, and that headings are consistent with guidelines.

<u>Pumping data.</u>

1. Ensure each well had a reported pump rate (including zeros) for every POR month in existence.
2. Check to see that actual pumping rates reported are consistent with the pump capacities. Some reported pumping rates were a magnitude of 10 or more too high. These values were changed to be similar to appropriate pumping rates in other months for the same well.
3. Make sure all pumping data are reported in cfd.
4. Make sure all columns contain data consistent with the heading, and that headings are consistent with model needs.
5. There can be zeros reported in the pumping, which indicate it was recorded that no pumping occurred that month. Spaces indicate no data available.

Once this was completed, the wellhead and pumping data were ready to be included in the model. At this point, the water level and water quality data could be addressed.

6.0 Quality Assurance/Quality Control of Water Level Data

The water level data underwent a similar QA/QC process as the transient pumping data. A majority of the time was spent ensuring the accuracy of the location and depths of the well heads, and verifying accurate intervals, well fields, and corresponding transient data. Careful attention was given to check wells with multiple names, multiple wells with similar depths in close geographic proximity, and wells with multiple intervals. As with the pumping wellheads, all locations were converted to NAD83 State Plane XY coordinates, and every depth was converted to feet below ground surface. Every water level was given in feet, NGVD. Wellheads were mapped in GIS to determine gross outliers and eliminate those out of the model boundary. GIS was also used to help determine duplicate wells.

The transient water level data was handled differently than the monthly pumping data. One major difference is that the daily recorded water levels were used instead of monthly averages. Though daily records for each and every monitoring well was preferred, if data was not recorded for every well, it could not be assumed. The QA/QC process for the transient water level data involved ensuring all water level data available was collected, and paired up with the right wellhead, at the right interval. Many wells had several sets of the same water level data from different projects; only the largest set was included in the data set.

7.0 Quality Assurance/Quality Control of Water Quality Data

The water quality data underwent a QA/QC process similar to that of the transient water level data. It was not necessary to ensure the accuracy of the monitoring well head locations and depths, as water level readings had been

collected from the same monitoring wells, and this step had already been completed..

The transient water quality data was compiled in a similar manner to the water level data. Daily recorded samples, which were infrequent, were used. Though data for each monitoring well is preferred, data cannot be assumed for a well with no records. The QA/QC process for the transient water quality data involved ensuring all water quality data available was collected, and paired up with the right wellhead, at the right interval.

After compilation of TDS, Chlorides, and Specific Conductance data was all complete, the TDS data was analyzed for comprehensiveness. Only the TDS data was needed for the model. However, since it was known that there are large water quality data gaps, both spatially and temporally, the other two species were collected to be converted to TDS to fill any data gaps. However, if the TDS data was comprehensive enough, the conversion of Chloride and Specific Conductance data would not be necessary. This turned out to be the case, and only the original TDS data was used in the model.

The intent of this updated MSR is to augment the original strategy document (submitted via MSR in December 2004), outline the current status and plan for the ASR modeling, identify documents for future review, and anticipated review dates for upcoming work products. See following summary of ASR modeling Tasks.

Task 1 - Literature Search and Data Compilation:

The ASR Regional Study encompasses a large study area extending from Orlando in the north to the Florida Keys in the south. Over the years a considerable volume of geotechnical, geological and hydrogeological information has been collected by governmental agencies and private companies. The existing data types are many and varied. The purpose of this task is two fold. The first component is to assemble, review and evaluate computer model related data. Both published and un-published hydrogeologic and modeling reports concerning the Floridan Aquifer are of interest. The second component is to collect and compile existing data for the calibration of the ASR Regional and Inset Models. Existing databases such as the Florida Geological Survey well database and the SFWMD DBHYDRO database will be of particular interest.

Task 1A: Literature Search

This task included the compilation and organization of existing groundwater modeling efforts to support development of a large regional model as well as several high-resolution inset models that will simulate the Floridan Aquifer System in response to the proposed CERP ASR program.

Status: This task was completed by CH2MHill in December 2005 and a report generated. (Sub-Task No. 3 – Groundwater Numerical Model Development Support and Data Collection Report).

IMC Review: Not Performed

Task 1B: Data Compilation

This task will provide the data sets necessary for numerical model development and calibration tasks. Data will be compiled into a spreadsheet or a database, evaluated and "scrubbed" in order to expedite development of model data sets and graphical output. The main scope of the task will be to synthesize the data into coherent data sets and graphical displays. Three primary data sets will be compiled: groundwater pumping, hydraulic head, and concentration in TDS. Data compiled from this task will assist with the development of the overall Floridan Aquifer System hydrogeologic framework.

Status: This task is currently underway. Data compilation is anticipated to be complete by the end of September 2008. A summary report documenting the data compilation efforts is anticipated by December 2008.

IMC Review: To be performed upon completion of the Data Compilation Report. Anticipated review date 01DEC08.

Task 2 - Bench-scale Modeling Study:

In order to balance the needs of the project with the current technical capabilities of software and hardware, the model development team recommended the development of a bench-scale model to evaluate various model codes and approaches in order to aid the model code selection task. The primary objectives of the bench-scale modeling effort were:

- Provide an improved estimate of model run times
- Provide a preliminary understanding of model development issues relating to resolution requirements, boundary types, and starting conditions
- Uncover model limitations and short comings
- Aid in determining what class of model (constant density standard flow and transport, uncoupled density-dependent flow and transport, fully density dependent flow and transport) is required to address CERP ASR issues
- Provide comparison performance metrics for various bench marked codes including relative accuracy, and model stability and run-times
- Aid in the evaluation of hardware needs & pre/post processing requirements

The four codes were selected in a collaborative fashion among members of the modeling sub-team of the PDT. These codes included:

- MODFLOW and MT3DMS using equivalent freshwater heads to represent saltwater boundaries (e.g., standard flow and transport model)
- MODFLOW using SWI package (Salt-water intrusion package)
- SEAWAT (fully density-dependent)
- WASH123 (fully density-dependent)

Each model included a model boundary consisting of a 40-mile by 40-mile square box with vertical layers representing the Surficial Aquifer System (SAS), Hawthorn Group confining unit, and the Floridan Aquifer System (FAS). Weighing all of the factors and considering improvements that could be made to the model grid or mesh for future models, it appears that both the SEAWAT and WASH123 codes are appropriate to utilize for the ASR Regional Study model development effort.

Status: This task was completed and a final report (ASR Regional Study – Benchscale Modeling) published in July 2006.

IMC Review: The work product from this task was reviewed by IMC and comments were incorporated into the final report.

Task 3 - Hydrogeologic Framework Studies:

Numerous reports and papers documenting the hydrogeologic framework used in the models and testing of various hydrogeologic theories have been performed to date. These include:

- "Preliminary Hydrogeologic Framework Report", Reese and Richardson 2004.
- "Synthesis of the Hydrogeologic Framework of the Floridan Aquifer System and Delineation of a Major Avon Park Permeable Zone in Central and Southern Florida", USGS Scientific Investigation Report 2007-5207.
- "Lineament Analysis South Florida Region", Fies 2004.
- "Using Density-Dependent Numerical Models To Evaluate Regional Ground Water Flow Patterns In South Florida", Bittner et all. 2007.

These reports and papers document the data and approach to be used in the Phase II ASR Regional Model calibration.

Status: These tasks have been completed; however, updates are planned in some cases as the modeling proceeds.

IMC Review: IMC has not reviewed these documents to date. However, subsequent to the17APR08 meeting with IMC, it was determined that a limited review of these documents would be appropriate. This review should focus on the applicability of the data presented and revisions or suggestions to facilitate the development of the Phase II model.

Task 4 - Regional Screening Model:

This task will focus on the development, calibration, verification, and documentation of a regional screening-level numerical computer model of the FAS. The regional screening-level numerical model is intended to be a peninsular size model with low grid/mesh resolution in areas outside the focus of the model which would be north of Lake Okeechobee, adjacent to the C-43 reservoir, and along the Florida lower east coast. In the model focus areas, grid/mesh resolution would be increased to provide greater accuracy in simulating groundwater heads and salinity. The intended use of the screening model is to aid the PDT in evaluating the feasibility of the proposed CERP ASR program. The model will simulate the changes in flow and head within the FAS resulting from various plan scenarios. Performance measures will be developed related to maximum aquifer pressures, hydrofracturing, and others. Model output will be compared to these various measures to determine feasible plans. The intent of this regional screening model is to evaluate the regional impacts of CERP ASR clusters, not to evaluate local scale impacts of individual wells.

Due to the complexity of the FAS and the large scale of the modeling to be undertaken, this regional modeling effort will be divided into the phases described below.

Task 4A (Phase I):

The Phase I model was a coarse test bed for the more refined Phase II model.
Specific goals of the Phase I model were to:

- Identify model boundaries and test model boundary parameters
- Identify regional flow and salt migration pathways
- Identify the timing of salt water intrusion
- Evaluate model run times and model sensitivity to time step sizes
- Test hydraulic and transport parameter sensitivity
- Compare WASH123D and SEAWAT results

The Phase I effort included regional conceptualization, estimates of hydraulic and transport parameters, density dependent 3-D groundwater model construction, gross comparisons to head and concentration data, evaluation of flow and transport patterns, and sensitivity analyses to several model parameters. Each of these tasks and analyses provided a greater understanding of the flow and transport system that makes up the majority of the Florida subsurface. This increased understanding provided a platform on which to build in the additional complexities of the Phase II model.

Status: Task was completed and a draft report (Draft ASR Regional Study Phase I - Groundwater Modeling) published in December 2006.

IMC Review: The work product was not reviewed be IMC, since it was considered to be an interim work product. However, subsequent to the 17APR08 meeting with IMC, it was determined that a limited review of this document would be appropriate. Since this model was not calibrated and several key hydrogeologic features (such as groundwater pumping) were not incorporated into

the model, this review should focus on the revisions or suggestions to facilitate the development of the Phase II model.

Task 4B (Phase II):

The Phase II model will consist of several parts. First, a comprehensive data review will be completed to ensure that all available head, concentration, and groundwater withdrawal data is incorporated (See Task 1B, above). Phase II model construction will accompany the data review since the model construction will depend heavily on data availability and data requirements. Once the Phase II model is constructed, a flow only calibration will be performed. For the flow-only transient calibration, concentration values and transport parameters will be held constant. Flow parameters will be adjusted until the computed heads reasonably match observed data. Once a satisfactory flow-only calibration is obtained, full transient calibrations, with variable flow and concentration data, will be completed. Regional model calibration data will encompass flow and water quality data in approximately 200 monitoring wells in multiple geologic units. Regional model calibration will be performed where computed and observed data are correlated over a duration of approximately 1 year (2003-2004). Flow and water quality data for a different 1-year time period (1993-1994), representing a different hydraulic condition, will be used for model validation. The goal of this effort is a fully-calibrated Phase II Regional Model. The calibrated Phase II model will ultimately be used in the evaluation of proposed ASR project alternatives.

Status: Task has been on hold pending the completion of the data collection effort. Although the data collection work defined in Task 1B is not yet complete, the Phase II model construction has begun. It is anticipated that the first level (flow-only) calibration will be completed in January 2009 and the Phase II model calibration will be completed in September 2009.

IMC Review: The Phase II Regional Model Calibration Report will be reviewed by IMC. The anticipated review date for this report is 30SEP09. However, due to the large and complex nature of this regional model calibration, an interim review of the first level (flow-only) calibration is warranted. This interim review is anticipated to be in the form of a presentation to the PDT in February 2009.

Task 4C (Regional Optimization Simulations):

Upon the successful calibration of the Phase II Regional Model, numerous optimization simulations will be performed to evaluate the impacts of the proposed CERP ASR system. Initially, the ASR configuration and flows from D13R (or the appropriate update thereof) will be simulated. The model output will be compared to a set of performance criteria that are currently under development. If the simulated model output exceeds the performance measures at a particular ASR cluster, the number of ASR wells at that location will be reduced systematically until the simulated ASR configuration successfully meets the performance goals. This effort will be coordinated with other

modeling efforts (surface water, ecological, etc.) to evaluate the regional impacts of the proposed CERP ASR system.

Status: This task will be performed after the calibration of the regional model and is anticipated to be complete in July 2010. However, some D13R simulations will be performed during calibration to ensure reasonable runtimes and model stability when the stress of the ASR systems is incorporated into the model.

IMC Review: The ASR Regional Optimization Report will be reviewed by IMC. The anticipated review date for this report is 30JUL10.

Task 5 - High Resolution Inset Models:

In conjunction with the regional model, smaller scale transient stress-test "inset" models will be developed in the vicinity of operational ASR wells. Data collected during the on-going operations or cycle testing will be used to facilitate the calibration of transport parameters for the regional model. Boundary conditions and hydrogeologic parameters will be assigned based on information obtained during the regional model calibration. The calibration of these "inset" models will be done in two steps. The first step will use data from the first cycle testing of the Pilot Projects. The second step will be performed later, after cycle two of the Pilot Projects has been completed. Once the "inset" models have been calibrated to both sets of cycle test data (as wells as regional well data), optimization simulations will be made to evaluate the performance of the ASR configuration determined in the regional modeling. Since these "inset" models will have substantially greater resolution than the regional model, local scale effects of individual wells within each ASR well cluster can be evaluated.

Status: This task will proceed incrementally. The calibration to cycle test one is planned to be complete in September 2009 and the calibration and optimization to cycle test two to be complete in March 2011.

IMC Review: The calibration and optimization report generated for this task will be reviewed by IMC. The anticipated review date for this report is 30MAR11. However, a review of the interim work product during the September 2009 PDT meeting should also be coordinated with the IMC.

MSR 324, Task 1B

IMC Review Comments

On

Aquifer Storage and Recovery

Phase II Groundwater Model Data Collection

In accordance with Modeling Service Request (MSR) 324, the Interagency Modeling Center (IMC) was tasked to review the well data collection and analysis effort of the project Phase II Groundwater Model Data Collection report. The IMC concentrated its efforts on missing information in the report, methodology accuracy of correlating varying data types into a single database with correct translation techniques, evaluation methods of correlation among the data groups, assumptions used in data correlation, criteria used for removing bad data or data scrubbing, data sets assumptions about inflows and outflow parameters within the aquifer system, sufficiency of the data to prescribe inland boundary conditions for the model, and sufficiency of the data to support model calibration with acceptable accuracy for the project.

The project team conducted a comprehensive data collection of thousands of wells and an analysis of the Floridian Aquifer in South Florida for the Phase II groundwater model as part of the Aquifer Storage and Recovery (ASR) Regional Study. The study area is very large and encompasses an area of about 20,000 square miles from Orlando southward to the Keys. The project team acquired data from the United State Geology Survey (USGS), South Florida Water Management District (SFWMD), Southwest Florida Water Management District (SWFWMD), St. Johns River Water Management District (SJRWMD) and independent contractors. They analyzed the data for accuracy and quality, removed redundancy from the various sources and added required missing well data with respect to location, depth, and well screen under some assumptions. Overall the project team did a monumental job in taking various types of data from thousands of wells, with various types of formats from various agencies, and compiling and combining the data into a single data set.

1. Additional Information

1.1. Section 1.2 of the report defined the water well data requirements for the project. It considers accurate location of wells, the depth from which the data was acquired in each well, and the type of water well (pumping, flowing, injection, and monitoring). The project may also consider acquiring seismology and bore-log data from bedrock investigations that were conducted along major roadway, gasoline pipelines, and pre-construction investigations of highways bridges, high-rise structures, and power stations.

1.2. The collected data will help to increase the geologic detail and accuracy of the Phase II modeling effort. Providing fence-diagrams of the aquifer, showing their

structures, well penetration, and well screen, will assist the reviewers, other modelers that may conduct future modeling tasks for the project, and the engineers that will develop the initial and final design of the project.

1.3. The report discusses very well how the modeling team obtained and analyzed the data. The report could be more useful if it included the data or provided a link for it.

1.4. The report could further help to understand the geologic structure of the model domain and the conceptual flow model if it provided a map for each aquifer layer (geologic unit) showing the location of the wells, with unique symbol and color code for each well category, the location where pumping tests took place, model boundaries, and potential ASR locations.

1.5. The reader could benefit by the inclusion of contour maps in the report showing the elevations of the top and bottom of each aquifer layer, and maps showing the thickness of each aquifer layer, model boundaries, and potential ASR locations. This would increase the understanding of the model domain and decrease error in data utilization.

2. Methodology accuracy of correlating varying data types into a single database with correct translation techniques

The project team conducted rigorous work in acquiring data from different sources and merging them into a single database. The work included downloading the data, verifying database attributes, translating elevations to a common datum, and converting pumping rates to common units. The work was automated by employing database analysis routines and Geographic Information Systems (GIS) tools. The manuscript briefly describes this work. The IMC recommends expanding the document to include the following points:

2.1. Explain in Section 1.1.3 whether the "ASR Regional Groundwater model" and the "Mega Model for 1993-1994" boundaries match/relate for employing the mega model for verification.

2.2. Disclose in Sections 1.2.1 and 3.1.3g the source and the location of the annual average flow data and how data was measured for the "free flowing wells".

2.3. Explain the use of a 20-foot open interval assumption in section 3.1.1a., and expand the discussion on using only one of the two interval depths that were provided.

2.4. Expand the discussion in Section 3.1.1c on how drill depths were converted from/to? NGVD elevation for wells which were cross-referenced in local vicinity and aquifer designation. State all the assumptions employed for this conversion, e.g. was GIS or another tool used to average surface elevation for a given location referenced?

2.5. From Section 3.1.1d.c (Table 3.1) would counties such as DeSoto, Hardee, Highlands, and Sarasota be highlighted in red (95% use deeper than SAS) and require aquifer designations and depths assumed for the well figures listed under the FDOH column? Please revise.

2.6. Provide detailed information in Section 3.2, last paragraph, on how "These data sources verified location, depth, and capacity information."

2.7. Specify in Section 3.3 how "Other databases maintained by FGS and USACE were consulted to ensure a comprehensive data set."

2.8. Specify in Section 3.3 the number SFWMD CUP wells that were used as a sample to verify the correct location of the wells, and how verification of all SFWMD wells was done by using only one sample of wells.
2.9. Discuss the error that could occur in operation such as the one described in Section 3.3.1, namely, "… NWIS monitoring wells … database was compared to the wellhead databases obtained from the water management districts to eliminate duplication." Please include a justification for not using a systemic approach such as using Oracle or a VBA to find the data duplication, which would process all incidences.
2.10. Include a justification in Section 3.3.1 for the statement "It was confirmed by the SFWMD groundwater data department that NWIS data is more reliable, so depths provided by NWIS were used in these cases." It is possible that the SFWMD data for some of the SFWMD wells not used are correct. Thus, though preferring the NWIS database indeed assures proper data analysis for most of the wells, data analysis should be done for each of the wells to reduce uncertainty in model input.
2.11. Detail in Section 3.3.1 how the project derived the probability distribution of the "probable open hole interval at that depth based on cased depths provided for other wells. "
2.12. Explain in Section 3.3.2 how the project assumed the casing depth for the SFWMD wells and provide justification for each assumption.
2.13. Explain in Section 3.3.3 how the project assumed the casing depth for the SJRWMD wells and provide justification for each assumption.
2.14. Explain in Section 3.3.4 how the project assumed the casing depth for the SWFWMD wells and provide justification for each assumption.
2.15. Define in Section 3.3.6 the terms 'standard temperature' and 'standard salinity'.
2.16. Quantify in Section 3.3.6 the term "reasonably well known."
2.17. Provide a synopsis of the discussion with the SFWMD in Section 3.3.6 on well-water temperature and explain the reason for assuming well-water temperature of 24^{o}C when the temperature was not provided in the database.
2.18. Explain in Section 4.3 the reason for elimination of all well data outside the model domain, considering that data from outside and adjacent to the model boundary provided information for proper prescription of boundary conditions.
2.19. List in Section 4.5.1 both the number of wells and their percentage of the total wells used as a sample to confirm that no pumping data represent no pumping. Additionally, the section should discuss how the project conducted the examination.
2.20. Describe in Section 6.0 how monthly pumping data correlate with daily water level data.

3. Evaluation methods of correlation

The IMC commends the project team for their work in correlating data from the various data sets and considers this work to be adequate considering the uncertainty in these records. The correlation included cross-referencing data among the agencies data bases; correlating well-screen depth when necessary from drilling depth, other wells in the same permit and same water use in the same proximity; resolving discrepancies among the agencies' databases; verifying the data in each agency

database; assigning well coordinates, when necessary, based on co-located wells; assigning well pumping capacities, when necessary, based on maximum pumping rates, permits, well capacities of other wells of the same type, diameter, use type, water use and required amounts; resolving interval data issues for monitoring wells; and converting monitoring wells water pressures to water heads.

4. Assumptions used in data correlation

Some assumptions were required in order to perform the data correlation due to incomplete database records and/or insufficient data to verify the entries in some databases. Most of the assumptions employed in this process were reasonable and acceptable. The IMC recommends expanding the document to include justifications and explanations for the following assumptions:

4.1. The project should justify the assumption under Item 3.1.1.a, namely, that when only the drilling depth or the casing depth is provided, the other depth was assumed based on a 20-foot open interval.

4.2. The project should justify the assumption under Item 3.1.1.b, namely, that wells within the same permit were assumed to have similar depths. The report should also quantify the term ‘similar’.

4.3. The project should justify the assumption under Item 3.1.1.c, namely, that in the case where records of a few wells do not have the information in their depth, the project assumed that their depth are the same as other wells in the area. In addition, the project should quantify a unit distance that bounds the other wells to be considered in the ‘area’. Additionally, the document should state the actions that were taken when wells in the ‘area’ do not have the same depth.

4.4. The project should justify the assumption under Item 3.1.1.d to assign a depth for a well.

4.5. The project should justify the assumptions under Item 3.1.2.a, namely, that co-located wells are 10 feet apart and that the coordinates of these wells are always increasing (it could be decreasing) from the location specified in the permit.

4.6. The project should justify the assumptions under Item 3.1.3.a, namely, if a well capacity is not given in the records, it is equal to the highest pumping rate in record.. A well capacity could be determined from the well’s equation for maximum drawdown condition, subject to the maximum capacity of the pump.

4.7. The project should justify the assumptions under Item 3.1.3.c, namely, if a well capacity is not given, it is equal to the capacity of other wells in the area with the same diameter. This assumption could be true only if the wells penetration in to the aquifer is the same, the screen length is the same, and the hydraulic conductivity of the aquifer around each well is the same.

4.8. The project should justify the assumptions under Item 3.1.3.d, namely, if a well’s capacity, use type, and diameter are not given, its capacity equals to its average annual pumping rate. This is especially difficult to justify for wet years, where the average annual pumping rate is less than for dry years. Good engineering design would require that the well capacity be higher than the anticipated pumping rate for a dry year.

4.9. The project team should justify the assumptions under Item 3.1.3.e, namely, if no information about the well is given except its location, its capacity equals to another well for the same use type in the co-location. This argument may be

questionable. For example, in a small sub-division where different contractors were hired to construct irrigation wells, each contractor constructed wells according to their individual contract. Some wells depth were only 60 feet deep with 10 feet casing and pumping from the surficial oleic layer, while other wells were 120 to 160 feet deep with 10 to 20 feet casing, pumping from a limestone layer beneath.

4.10. The document should justify the assumptions used to estimate the total depth of a well in the table of Section 3.3.1.

4.11. The document should justify the assumptions used in Section 3.3.6 when "Correcting Water Levels", using water temperature of 24 degrees Celsius.

4.12. When assuming 24 degrees Celsius, the project could use density of 997.2 kg/m3 instead of 1000.38 kg/m3 according to CRC Handbook of chemistry.

4.13. The same section of the document should explain the value of the conversion factor (0.4335) when converting from psi to equivalent feet (head) of freshwater.

4.14. The document should explain in Section 4.1 the conversion of the vertical datum to "Ensure Compatibility."

4.15. The document should explain in Section 4.5.3 the clause "Fill in Pumping Gaps", bullet 'f'. The project may elect to increase the wells' pumping rates by a percentage based on population growth, instead of assuming no increase in water usage from 1993 to 2004.

4.16. The document should explain in Section 4.5.5 using monthly flow records, were wet vs. dry seasons considered in flows, or were all months of the year averaged together. In addition, the project could explain propagation of uncertainty errors in model predictions under this assumption.

4.17. The document should explain in Section 4.5.6, how "nearby" CUP wells were used to extrapolate missing flow data and how the project considered the distance between the wells in the correlation.

5. Criteria used for removing bad data or data scrubbing

Based on the descriptions in the document regarding the data removal, the IMC considers the methodology used by the project team to remove data from the dataset as appropriate, especially when the data was incomplete or unaccountable. The IMC recommends that the document discuss the procedure for which the well data was validated against construction data in order to determine if a given datum is 'bad.' Furthermore, the document should mention whether the CUP, UIC, and ASR wells have been validated against construction dates.

6. Data sets assumption about inflows and outflow parameters within the aquifer system

The document discusses how the project acquired, merged, and correlated water-well data from the model domain. The IMC recommends including a discussion of the data pertaining to flow along the model boundaries, within each aquifer layer, and among the layers, areas as described below:

6.1. The document should discuss data to support any assumption with respect to leakage between the aquifer units.

6.2. The addition of data in three categories: pumping data, water-level data, and water-quality data as mentioned in Section 1.2 above, should be adequately discussed. The document should also discuss information with respect to aquifer flow and transport parameters. The project team should verify if information gathered during the first phase of the modeling effort and in the current task were sufficient with respect to aquifer conductivity, storativity, and dispersion parameters.

6.3. The primary datasets discussed in the document pertaining to inflows and outflows of the aquifer are ground water pumping and hydraulic head. The document should also discuss whether the hydraulic head accounts for precipitation, recharge, and seepage from rivers, canals, lakes, and reservoirs. If not, the project should discuss how these parameters are addressed.

7. Sufficiency of the data to prescribe inland boundary conditions of the model

The IMC was unable to evaluate whether the data gathered is sufficient to prescribe the inland boundary conditions of the model due to the lack of information described above.

8. Sufficiency of the data to support model calibration with acceptable accuracy for the project

The project has already collected a large amount of information about the geology, hydrology, and operation of the model domain. This information may be sufficient for model calibration. The IMC recommends that the following issues be considered and addressed as the project team continues development of the regional ASR model:

8.1. Determination of the maximum uncertainty for model predictions, considering the project purposes.

8.2. Recognition that a potential for model assumption errors could be the result of assumed well depths. Many regions with numerous local wells do not have "standard" depths per well type. Depths may be varied based upon the drilling company and not the well type.

9. Miscellaneous

The document is written quite well, but could be improved by addressing the following issues:

9.1. Stating the purpose of the data collection effort for the Phase II Groundwater Model.

9.2. Having a caption for each table and figure.

9.3. Defining each of the acronyms at their first appearance.

9.4. Defining each term at its first appearance.

9.5. Careful editing to improve readability, way of expression, correcting all typo and grammatical mistakes, and capitalizing the first letter of a name.

9.6. Grammatical – changing sub-titles of Figure 3.1 from "DBHydro Uncorrected Head" to "DBHydro Density Uncorrected Head" and changing "Density Corrected Head" to "DBHydro Density Corrected Head". Another alternative is to take "DBHydro" out of the two sub-titles and add it to the primary title.

Overall the IMC believes that the project team has successfully conducted a monumental data acquisition task. The project obtained the data from various agencies, removed redundancy, converted the data to a uniform datum and units, assigned values to missing data attributes under careful consideration, conducted a quality assurance program, and employed a quality control protocol. The project team could improve the report by giving a link to the database, providing figures to show the geology of the model domain, conceptual model, and depiction of the location and penetration of the water wells. Further improvement of the report could be achieved by expanding the discussion on how the work was done, listing and justifying all the assumptions used in this work, and addressing the miscellaneous items described above.

Appendix B: Grid Resolution Study

Table of Contents

1.0 Spatial Discretization

The numerical solutions presented as output from SEAWAT or WASH123D merely represent approximations of the "true" solution. The nearness of the model output to the "true" solution (accuracy) is dependent on a multitude of factors, including the validity of the conceptual model, and the density and accuracy of model parameters and boundary conditions. In addition to these factors, the construction of the computational grid (or mesh) and the temporal discretization of the model can have a large effect on the accuracy of the model solution. Temporal discretization will be discussed in the following section.

The selection of the grid cell size (or mesh node spacing) is based on a number of factors:

- The discretization of the grid or mesh must be fine enough to sufficiently define the problem. Since solutions are only calculated at the grid cell centers or mesh node points, these calculation points must be sufficiently dense to describe slopes, changes, topographic features, etc. A too-coarse mesh or grid may result in blocky results that do not accurately describe the conditions of the site.

- The discretization of the grid or mesh must be fine enough to provide stability and convergence for the solver.

- The discretization of the grid or mesh must be coarse enough that the solver can produce a solution on available computers in a reasonable amount of time.

- For transport simulations, the discretization of the grid or mesh must be fine enough to minimize numerical dispersion and unnatural oscillations. The impact of numerical dispersion and solution oscillation is also dependent on the solver used.

Thus, the selection of a computational grid or mesh requires the balancing of several differing needs. The following sub-sections describe the process used to create the SEAWAT grid and the WASH123D mesh as well as testing which indicated that the grid/mesh was sufficient for the use intended.

1.1 SEAWAT Grid Selection and Testing

The SEAWAT grid was designed mainly for sufficient discretization to describe the problem while aiming to keep the computational time manageable. This grid has 232 cells per row, 214 cells per column and a total of 22 layers. Horizontal grid cell dimensions vary from 10000 feet to 2000 feet. The smaller cells are placed near possible ASR sites where greater detail of the results will be required. Because of the structured nature of the mesh, horizontal cell sizes must be carried to the edge of the grid, resulting in bands of smaller cells. The structured nature of the grid also results in a number of inactive cells (those located outside the model area, but within the square grid zone. Nearly 25% of the cells in this grid are inactive. The grid is shown in Figure B1-1. To account for anisotropy and the predominant flow directions, the grid was rotated 38 degrees from north. The layer thicknesses are dependent on the thickness of the hydrogeologic layers. In each case, the number of computational layers was selected

and the hydrogeologic layer was equally divided into the grid layers. See the inset to Figure B1-1 for clarification.

Although this grid is sufficiently fine to describe the features, slopes and changes of the regional model, it was not immediately clear whether this grid was sufficiently fine to result in a stable, convergent, accurate solution. Further, because several of the layers become very thin in the northwest area of the model, aspect ratios become very large, raising fears of inaccuracies and instabilities. Tests were run on a number of grids to determine the possible impacts to solution accuracy that might be caused by numerical dispersion, oscillation or other inaccuracies.

1.1.1 Accuracy Testing Grids

Six additional grids were built for the model area. Identical parameters, starting conditions, and boundary conditions were applied to each grid and the results were compared to determine what grid size was necessary for sufficient accuracy in the result. The six grids are compared in Table B1 and shown in Figures B1-2 through B1-7.

Table B1: Test Grid Statistics

Grid Name	**20k11**	**20k20**	**10k11**	**10k20**	**5k11**	**5k20**
Approximate Horizontal Cell Size (ft)	20,000	20,000	10,000	10,000	5,000	5,000
Number of Rows	69	69	138	138	275	275
Number of Columns	55	55	109	109	217	217
Number of Layers	11	20	11	20	11	20
Number of Cells	41,745	75,900	165,462	300,840	656,425	1,193,500
Number of Active Cells	21,161	39,556	84,027	157,054	333,552	623,477

1.1.2 Steady State Testing

Steady state SEAWAT models were set up on each of the six testing grids. Although the models were similar to the calibration model discussed in Section 4.1 of this report, the tests were run before the final versions of all data were available and before the calibration process had been completed. Starting

conditions for both salinity and temperature changed substantially after this testing process. During the calibration period, some boundary conditions were altered slightly, and parameter values were changed. These changes are not reflected in these testing models and the results are not intended to reflect either reality or the calibrated conditions of the model. The general idea was simply to run six identical models on each of the grids and compare the results.

In these models, the starting conditions for salinity and temperature were developed and included in the model. The model did not compute the transport equation, but simply used the starting concentration and temperature conditions to develop equivalent heads (accounting for density variation due to salinity and temperature) for the calculation of the flow portion of the model. Output heads are point-water heads (the level to which water would rise in a standpipe).

In reality, it was impossible to make each of the models exactly identical. Because of the varying sizes of the grids, interpolations of heads on the surface and around the side boundaries varied slightly. Also, starting conditions for both salinity and temperature varied slightly due to the interpolation to slightly different points. These differences account for some of the variability in the results explained below.

The results were compared in two ways. First, a set of points were selected in the model domain and the heads at the cells covering these points were extracted and compared. Some of these points were set at known points of interest, such as potential ASR sites. Other points were selected simply to obtain good coverage of the model domain. The locations of these comparison points are shown in Figure B1-8. The comparison of solution heads for each of the aquifer systems shown in Figures B1-9 through B1-13 is the absolute value of the difference between the indicated grid solution and the solution on the 5000 ft grid with 20 layers. This grid was selected for the comparison since it has the highest resolution and should therefore have the most accurate result.

In extracting the heads at these points, no attempt was made to interpolate between the cell centers to the exact point. The head reported at the cell covering the point of interest was extracted and tabulated unchanged. This means that the point's proximity to the cell center could affect the reliability of the comparison. Figure B1-14 shows an example of this issue. Point M is shown overlain with each of the three test grids. Images a, b, and c each have a single cell from one of the test grids highlighted for clarity. Notice that the point is near the center of the grid cell for the 20000 foot grid, so the extracted value for that cell would be similar to the expected value at the comparison point. For the 10000 ft grid and the 5000 foot grid, the point is near the edge or corner of the cell, so even a set of highly accurate solutions would be expected to yield slightly different results for the point in question. Some of the differences shown in Figures B1-9 through B1-13 are attributable to this issue.

The second comparison of the results was done by overlaying the contour maps for each of the solutions and observing the spread of the contour locations. These results are shown in Figures B1-15 through B1-24. These contours were computed by interpolating from the cell centers using GMS. On these maps, the results from the 10000-ft grid are shown bolded. This is the size of the largest cells in the ASR production grid (see Figure B1-1).

The results of the steady state test runs indicate that there is very little difference between an 11-layer grid and a 20-layer grid in terms of the head solution when the horizontal discretization is the same. The head differences at the comparison points seldom vary by more than a few tenths of a foot, which is well within the expected accuracy of this large-scale regional model. Further, the contours plotted in Figures B1-15 through B1-24 show almost identical results for solutions from grids with the same horizontal grid spacing. Normally, the contour lines are indistinguishable. One significant exception is the 50-foot contour in the Upper Floridian Aquifer as it crosses Lake Okeechobee and continues northwest-ward nearly parallel to the Kissimmee River (See Figure B1-18). Here the 50-foot contour lines for the solutions to the 10,000-ft/11 layer model and the 10,000-ft/20 layer model can be 3 to 4 miles apart. However, the water table here is flat enough that this makes little difference to the actual head values at the comparison points (see Figure B1-10).

Differences between the 10,000-ft grid solutions and the 5,000-ft grid solutions are also minor in most locations. The differences are generally around 1-2 feet at the comparison points. Contour line locations vary by less than a mile in most cases. The main exceptions to these generalizations occur in the northwest section of the model (near comparison point M) and along some of the boundaries. The differences near the boundaries are most likely caused by differences in interpolation of boundary conditions to grids of different sizes and cells with centroids in varying locations. These differences are caused by the difficulty in assigning exactly identical boundary conditions and are not attributable to solver issues.

The northwest section of the grid generally has the greatest head differences and the largest contour movement. In this area, many of the upper layers are extremely thin and, in reality, pinch out. This means that the use of larger cell sizes can cause aspect ratios approaching 5000.

Differences between the 10,000-ft grid and the 20,000-ft grid are more important. The contours may be located 3 or 4 miles away from the location on the smaller grid, but the head differences seldom exceed 2 feet. As with the smaller grids, the worst variation is found in the northwestern portion of the model where aspect ratios are the highest. In the Lower Floridian (LF1) Aquifer and the Boulder Zone, head differences in the northwest corner of the model, exceed 12 feet.

The test results indicate that for the purposes of a steady state regional model, the 10,000-ft grid is likely sufficient from a solver accuracy standpoint. Differences between the 10,000-ft grid and the 5,000 ft grid are minor in most cases and the additional time and computational effort required for a 5,000-ft grid are not warranted with the minor improvement achieved. The results also show that downgrading the grid to 20,000-foot spacing would sacrifice some accuracy, especially in the northwest section of the model. This sacrifice is caused primarily by the interpolation of data to a coarser grid, which cannot sufficiently describe the data. Errors do not seem to propagate into the interior of the model during a steady state run.

1.1.3 Transient Testing

Once the steady state testing had shown that a 10,000-ft grid was sufficient for an accurate result, the same model was expanded to a transient, 12-month run and the results were compared in similar ways

to determine the effect of grid size on the transient head and concentration results. In this case, the transport equation was calculated for salinity and temperature, coupled with the head calculation from MODFLOW. The model was run on the same six computational grids. Specific storage was set to 1.0 x 10^{-5} to allow for sufficient propagation of boundary condition changes. Computational timesteps were 1 day long and solutions were output at the end of each month.

Only a few of the comparison points were used because of the much larger amount of output data. Point C was used because of its proximity to so many of the proposed ASR sites. Point K was used since it is on the far southeast edge of the model and because it is near some of the proposed ASR sites not directly north of Lake Okeechobee. Finally, Point M was used because it had the worst error in the steady state testing. Comparison of output at this point will indicate whether errors are compounded in subsequent timesteps.

Computed heads at point C are shown in Figures B1-25 through B1-29 as an example. Head changes in the solutions on separate grids track each other very closely although the initial head value is often slightly different. Initial heads were slightly different because of interpolation differences for starting conditions and boundary conditions and some differences in the solution of the steady state model. These figures show that head increases and decreases continued for each model, irrespective of the initial head value. Similar plots could be made for any point of interest in the model, but they are not shown in this report.

The differences among the grid solutions can be shown more clearly and concisely in Figures B1-30 through B1-34. Here, the absolute value of the difference in head between the 5000-ft grid with 20 layers and each of the other grids is plotted. In each case, a different color represents a different comparison point and a different symbol represents a different aquifer system. Figure B1-30 clearly shows that, like the steady state solutions, there is no significant difference in the solutions for the 11-layer grids and the 20-layer grids. A similar conclusion can be drawn by noting the similarity between the plots on Figure B1-31 and Figure B1-32 and the similarity between Figure B1-33 and B1-34. Figures B1-31 through B1-34 indicate that at points C (near Lake Okeechobee) and K (southeast part of the model), the horizontal resolution of the grid makes little difference. However, the difference in heads for the various solutions at Point M (northwest part of the model) is often significant. Comparisons of Figures B1-31 and B1-32 with Figures B1-33 and B1-34 also show that the 20000-ft grid has a greater head difference than the 10000-ft grid.

Another important conclusion from these tests is that the head differences do not compound as the model proceeds. This shows that the errors are probably due to differences in interpolation of starting conditions and boundary conditions and not a result of solver errors or numerical dispersion.

Although not shown, the salinity and temperature for these comparison points were also extracted. They showed almost no difference among the solutions (maximum 700 mg/L TDS and 3°C) and no change in concentration with time (maximum of 150 mg/L TDS and 0.07°C change over 1 year). The differences in among the grid solutions are easily explained by differences in interpolation for starting conditions to grids of differing resolutions.

2.0 Temporal Discretization

Temporal discretization can be as important as spatial discretization. Computational timesteps (times at which the solution is computed) must be placed often enough to allow changes in boundary conditions and to describe output head or concentration slopes, but too many computational timesteps can also substantially increase computational time. Output timesteps (times at which the output is reported) must be sufficient to describe the model output, but, too many output timesteps increases computational time, the size of the output files and the RAM required to view results.

2.1 Temporal Discretization in SEAWAT Model

The SEAWAT model requires the definition of both stress periods and timesteps. The stress periods define periods of constant boundary conditions. For this regional scale model, the stress periods were 1 month long. This means that all pumping rates and boundary heads can only change at the end of each month. Pumping is assumed to be constant for the entire month. If more than one measurement was made at a boundary well during a month, the average head was assigned for the entire month. The flow model timesteps were then set to be 1 day long.

2.1.1 SEAWAT Timestep Testing

In SEAWAT, the flow solution is computed and output according to user-defined options. For the transport solution using the standard finite-difference method with upstream weighting, the user has the option to define the transport timestep sizes or allow the model to select them based on a maximum Courant Number. Three tests were run using the 10,000-ft, 11 layer grid as follows:

- Allow the model to select timesteps that will keep the Courant Number below 0.5. (This resulted in timesteps of approximately 0.23 days.)
- Force the model to use 1-day timesteps
- Force the model to use 5-day timesteps

The three solutions were read onto the grid and compared as with the previous tests. One main difference was that since all three models were run on the same grid, problems with interpolation of starting conditions and boundary conditions and the location in the cell of the comparison points were eliminated. Figure B2-1 shows the absolute value of the difference in head at three comparison points for the 1-day timestep run and the model-selected timestep run. (The scale is large to match Figure B2-2.) The maximum difference in head is 0.03 ft, which is well within the expected error of the model and the accuracy of the input data. It is likely that the Courant number is high in a few small areas of the model, forcing the model-calculated timestep to be small. It is also possible that the 0.5 limit for the Courant number was too restrictive. Clearly, the tiny change in the results of the model do not warrant the computational time increase caused by reducing the timestep size below 6 hours.

The comparison between a 1 day timestep and a 5-day timestep is shown in Figure B2-2. This figure clearly shows a nearly 20-foot difference in computed heads in the Lower Floridan (LF1) and Boulder

Zone layers at comparison point M, which is located in the northwest portion of the model. Some error is to be expected at this location where the layers are so thin and the aspect ratio is high. However, even point C (just north of Lake Okeechobee) shows a difference of nearly 6 feet between the two runs.

The differences are also shown in Figures B2-3 through B2-12. These figures are plan view contour maps of each of the aquifer systems, each comparing two solutions. For all aquifers, the comparison between the 1-day and 0.23-day timesteps is so close, the lines are indistinguishable on the map at that scale. The maps showing the 5-day timestep indicate some serious convergence problems. There are numerous unexplained depressions and mounds in the water table and the shapes of the contours are often significantly changed.

Because the 5-day timestep simulation runs significantly faster than the 1-day timestep, calibration was performed using the larger timestep. A sensitivity analysis in Section 5 of the main report shows that when the TVD solution scheme (with timesteps smaller than 1 day) was used, differences in computed head were minor. Although this seems to contradict the conclusion of this appendix, significant changes to the model set up during calibration improved the convergences issues and prevented the need for the smaller timesteps.

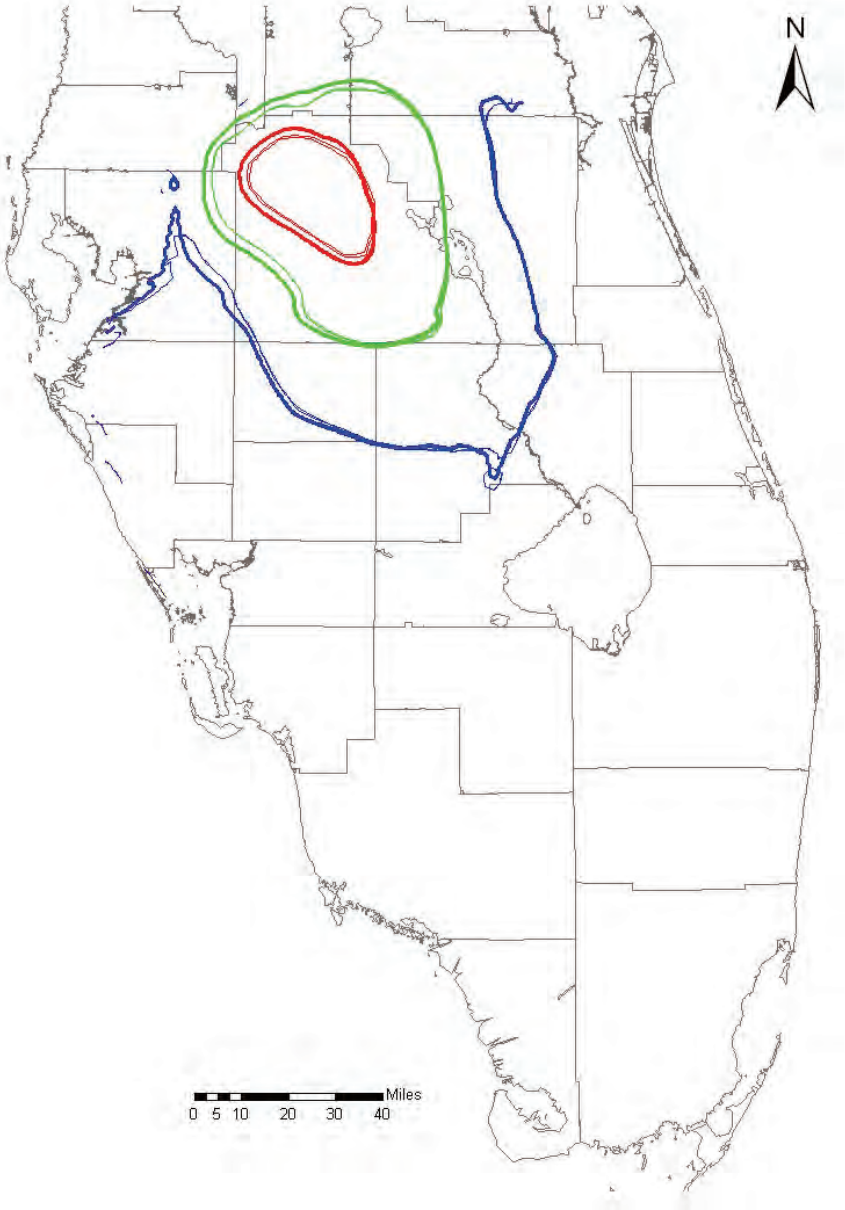
Figure B1-23

October 2010



Legend (Test Grid):

- 20,000-ft grid / 20 Layers
- 20,000-ft grid / 11 Layers
- 10,000-ft grid / 20 Layers
- 10,000-ft grid / 11 Layers

Legend (Head):

- 25 ft
- 50 ft
- 75 ft

Notes:

Solutions from grids with identical horizontal resolution, but differing numbers of layers are nearly indistinguishable at this scale. Here, both are shown, but with the same line type.

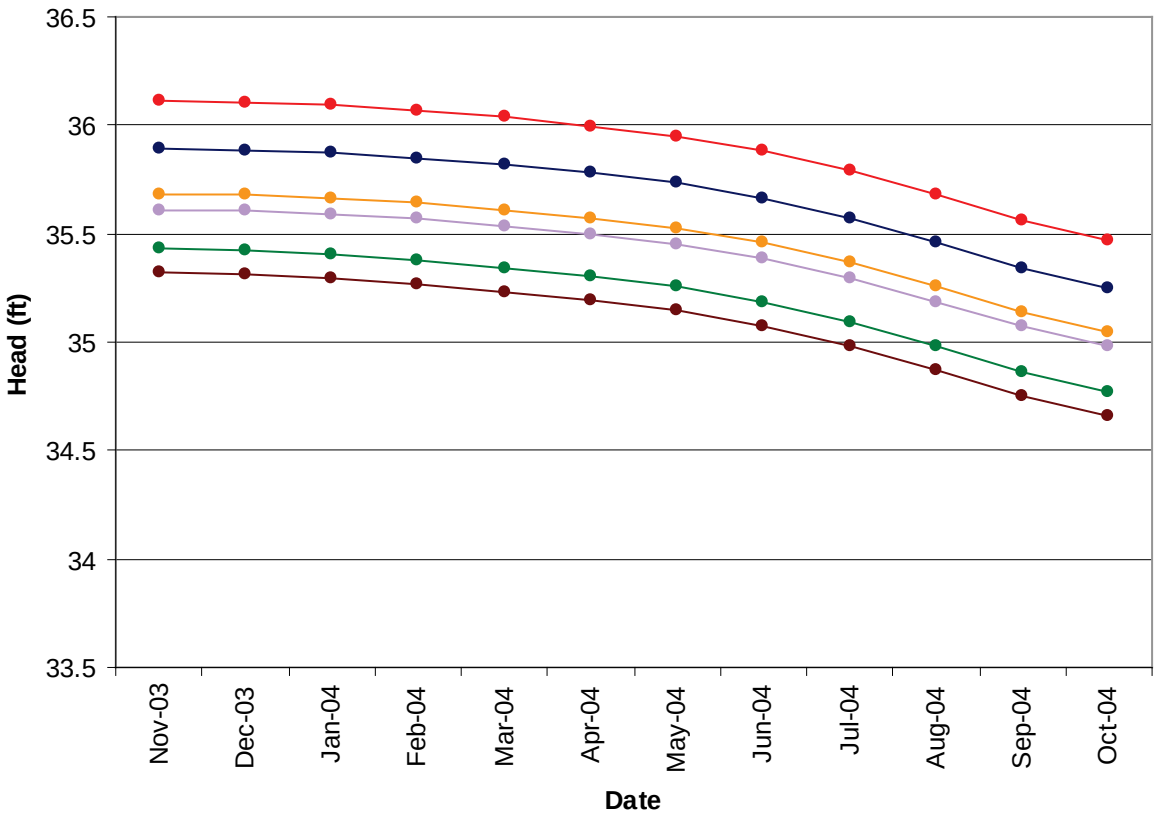
These heads are point-water heads (the level to which water would rise in a standpipe). The model was computed using equivalent freshwater head, which accounts for density variations due to salinity and temperature.

These solutions are from layer 11 of the 11-layer grids and layer 19 of the 20-layer grids.

Steady State Head Solutions for BZ on Test Grids
(20,000 ft grid and 10,000 ft grid)
Final Groundwater Model Calibration Report

Figure B1-24

October 2010



Legend:

Appendix C: Selection of Boundary Conditions

Table of Contents

1.0 Introduction

The selection of appropriate boundary conditions is crucial to the creation of a groundwater model which is both credible and functional. The solutions from SEAWAT and WASH123D models are derived from partial differential governing equations which can only yield unique solutions if the model is provided with a set of boundary conditions.

Suitable boundary conditions must account for any interior stresses in the model. For example, if an extraction well is located near the boundary, its drawdown must be considered in the boundary condition. For a calibration model which is reproducing historic conditions, this is not difficult, provided the data is available. However, in a predictive model, accurately forecasting the drawdown can be difficult and is often the purpose of the model. Ideally, model boundaries coincide with static features that are not affected by internal stresses. Examples include no-flow boundaries occurring at groundwater divides or impermeable boundaries; and specified head boundaries occurring at large surface water features which are directly connected with the groundwater and provide a large source (or sink) of water. Often, these ideal boundaries are either non-existent, or they are too far from the point of interest to be of use. In their absence, modelers must settle for static, estimated boundary conditions at locations far enough from the point of interest to be unaffected by changes in the interior of the model.

Specified head boundary conditions force the model to honor the assigned head values at the boundary cells or nodes. To meet this requirement, the model will remove or add as much water as necessary. This type of boundary is best set at a large surface water body, which can take significant withdrawals or inputs without a substantial change in water level. If it is set at a more arbitrary location with the head based on estimated or measured head values at wells, the user must be aware that the model may be making unacceptable flux changes at that boundary.

Specified flux boundary conditions force the model to honor the assigned flux value – either in or out with no requirement for head. If the flux is too large in the negative direction (out of the model), the stability of the model might be compromised as the model attempts to withdraw water that is not readily available. If the flux is too large in the positive direction (into the model), unreasonably high heads may build up at the boundary.

A no-flow boundary is a specified flux boundary whose flux is set to zero. No water is allowed in or out at this boundary. These types of boundary conditions are often used to simulate groundwater divides, which often occur in unconfined aquifers at ridges where recharge provides an input of water from the surface. Since water must flow horizontally to one side of the ridge or the other, no horizontal flow is expected to cross the divide. No-flow boundaries may also be assigned at impermeable boundaries, which are often assumed to exist on the bottom of a model. When other options are not available, no-flow boundaries are sometimes aligned perpendicular to known groundwater head contours with the assumption that flow will be along the boundary and not across it. This is a dangerous practice since the contours may not be based on sufficient data; interior stresses or seasonal changes may change the shape of the contours; or different hydrogeologic layers may not all have contours with the same shape.

Similar boundary conditions for constituent concentration must be assigned at all boundaries when the model is to solve the groundwater transport equations. For specified head and specified flux boundaries, a concentration is assigned, which the model applies whenever the flux is inward. Fluxes out of the model take the concentration calculated by the model.

1.1 Overview of Head Boundary Conditions for the ASR Regional Model

The ASR regional model has been built to investigate the regional effects of the operation of numerous ASR wells located in the interior of southern Florida. Most of the proposed sites are located along the north and west shores of Lake Okeechobee in Okeechobee and Glades Counties. Additional sites are located in Palm Beach County. Early testing indicated that the proposed flow rates at the ASR sites may have far-reaching effects on the groundwater system throughout southern Florida. The model boundary was designed based on these tests. See Figure C1-1 for the boundary locations.

1.1.1 East Boundary

On the east, the boundary extends to the layer outcrops in the Atlantic Ocean for each hydrogeologic layer. Each layer is cut when it intersects the bathymetry data for the Atlantic Ocean floor and assigned as a specified head boundary. The head value for the boundary condition was based on the monthly mean sea level measured at two tide gauges – one at Virginia Key, near Miami, and the other at Naples, on the west coast of the Florida peninsula. There is some monthly variation in the ocean level, with slightly higher levels in the fall and lower levels in the spring and summer. However, the annual variation of monthly mean sea levels is about 0.5 feet, much smaller than the variation in nearly every other parameter of the model. Since all layers of the model outcrop in the Atlantic Ocean, the ocean is expected to be closely connected, hydraulically, to the groundwater conditions in the model. The ocean is such a large source of water that changes in the interior of the model can be assumed to have no effect on the ocean level. In other words, no amount of pumping in Florida is going to change the level of the Atlantic Ocean!

1.1.2 West, South and North Boundaries

Ideally, the west and south boundaries would also extend out to the locations of the outcrops for each layer in the Gulf of Mexico. However, these outcrops occur nearly 150 miles from the Florida coastline. Extension of the model boundary to these outcrops would add significantly to the model size, RAM requirements and computational time. This would also add a large area to the model which has not been extensively studied and for which there is no significant data regarding heads, water quality or aquifer characteristics. Instead, the west boundary follows the coastline from Tampa Bay down to the north boundary of Collier County. At this point, the model boundary cuts inland and follows a southeasterly line that passes through the Everglades about 10 to 30 miles from the coastline. This section of the Everglades was eliminated from the model because of a lack of data and because of significant surface water, which suggests that ASR pumping is not likely to affect groundwater heads in this area.

The north boundary passes through Brevard, Orange, Lake, Sumter, and Pasco Counties, then cuts down to follow the east coast of Tampa bay down to the Gulf of Mexico. This north boundary was selected to be beyond the area of groundwater recharge in Polk County and the area affected by the ASR wells.

The north, west and south boundaries are located to coincide with available data points. Heads assigned at these locations are based on measured values at wells located on or near the boundary. Although the heads at many of these locations have been measured frequently over long periods of time, the wells are seldom fully penetrating, so they may not represent the conditions in the entire aquifer. Also, heads for cells between well locations must be estimated. Generally, linear interpolations of the measured heads along the boundaries are used for simplicity. Initial testing of the expected effects of the ASR wells indicated that the north, west and south boundaries are well away from the area of impact for the wells. This was later verified with some sensitivity runs on the calibrated model as explained in Section 5.6 of the Groundwater Model Calibration Report.

1.1.3 Top and Bottom Boundaries

The top boundary of the model coincides with the ground surface where recharge of precipitation (less runoff and evapotranspiration) is a primary source of water to the model. In practice, a flux boundary condition is often applied to the surface of a groundwater model to simulate recharge. In these cases, the magnitude of the flux is calculated using a flow budget, subtracting such sinks as evapotranspiration and runoff from precipitation to determine the volume of water seeping through surface soils into the model. This type of calculation is often complicated by land use and soil type variations as well as the typical unavailability of sufficient data. Recharge often becomes a calibration parameter and is varied, along with hydrogeologic material properties such as conductivity and storage, until the model result matches measured aquifer conditions.

For this regional ASR model, the decision was made to assign a specified head to the surface of the model. Although this is an unusual practice, it saves the trouble and inaccuracies inherent in calculation of a recharge value. The use of a specified head at the surface is warranted since the ASR pumping is not expected to affect the heads in the Surficial Aquifer System (SAS), and because there is a wealth of SAS head data in many areas of the model. In the SEAWAT model, the SAS was included as the top layer of cells. In the WASH123D model, the SAS was not included as a model layer but the SAS heads were assigned to the top layer of model nodes. Each surface cell and node was assigned a specified head based on an interpolation of the available head data in the SAS for each month of the calibration and validation periods. See Section 4.0 of this appendix for details on the interpolation process. Since the head was specified in every cell, SEAWAT and WASH123D made no calculations in the top layer of cells or nodes. As explained above, this method allowed the models to calculate the necessary flux in order to honor the user-defined specified head boundary condition. The calculated flux was compared to available estimates on recharge in the model domain and found to be generally similar (See Section 4.1.4 in the main report).

The bottom of the model was set to coincide with the bottom of the Boulder Zone. The exact depth of the bottom of the Boulder Zone is generally unknown and was estimated. The bottom boundary was assumed to be a no-flow boundary. Since the conductivity of the Boulder Zone is so much higher than

the conductivity of the Sub-Floridan confining unit, the majority of the flow in this layer would be horizontal or upward and little, if any, water would flow downward. Thus, it is probably valid to assume no flow through the bottom of the model.

1.2 Equivalent freshwater heads

Because of the close hydraulic relationship between the aquifers in South Florida and the Atlantic Ocean and Gulf of Mexico, there are significant variations in the salinity of the groundwater. Deep aquifers are almost entirely saline, with the exception of some areas in the north of the model. Surface aquifers are fed more by rainfall, resulting in generally low salinity. These salinity variations can have a marked effect on density and flow. This section describes how these variations were incorporated into the model.

TDS was used as a proxy for salinity in the ASR regional model and the two terms are used interchangeably in this report. TDS data was normalized by dividing each measured value by 35,000 mg/L, a commonly accepted TDS value for seawater. This results in a unitless value of approximately 1.0 for seawater and 0.0 for freshwater.

Comments from reviewers early in the modeling process indicated that temperature variations might also play a significant role in the density and flow conditions in the model. Deeper aquifers are generally warmer, likely due to geothermal effects. Temperature does not have as great an effect on water density as salinity, but it is included in the model and treated as another constituent concentration.

Both SEAWAT and WASH123D can solve the flow equations with density dependence, calculating flow and transport simultaneously. Both models require the user to enter head boundary conditions and initial conditions as observed head based on local density, or the water level measured in a well. The models then use the temperature and salinity to calculate the *equivalent freshwater head*, which takes into account both TDS and temperature to determine the potential energy at a given location. The flow equations are solved based on equivalent freshwater heads and then the solutions are converted back to observed heads for viewing and analysis.

Because model results are reported as observed heads, the solutions sometimes appear to show unusual flow patterns. When there are significant changes in salinity, flow may appear to be moving "uphill." Since the equivalent freshwater head is actually the potential energy of the water at a given point, fluid flow would be expected to occur from locations of high equivalent freshwater head to locations of lower equivalent freshwater head. If the salinity is markedly different between two points, high observed heads may not correspond to high equivalent freshwater heads.

Equivalent freshwater head is calculated by first calculating the observed density, using Equation C1:

$$\rho_{obs} = \rho_{fw} + m_{tds}\left(TDS - TDS_{ref}\right) + m_{tmp}\left(TMP - TMP_{ref}\right) \qquad \text{Equation C1}$$

where:

ρ_{obs} = Observed density
ρ_{fw} = Density of water at the reference TDS and temperature
m_{tds} = Slope of the assumed linear relationship between density and TDS

TDS = Total dissolved solids in the water (proxy for salinity) normalized by dividing by 35,000 mg/L
TDS_{ref} = Reference TDS
m_{tmp} = Slope of the assumed linear relationship between density and temperature
TMP = Temperature in the water (°C)
TMP_{ref} = Reference temperature

Once the observed density has been calculated, the equivalent freshwater head can be directly calculated by using Equation C2:

$$EFH = \left(\frac{\rho_{obs}}{\rho_{fw}}\right)h_{obs} - \left(\frac{\rho_{obs} - \rho_{fw}}{\rho_{fw}}\right)Z \qquad \text{Equation C2}$$

where:
EFH = Equivalent freshwater head
ρ_{obs} = Observed density (calculated using Equation C1)
ρ_{fw} = Density of water at the reference TDS and temperature
h_{obs} = Observed head
Z = Elevation of point (using NGVD29 as a datum)

The following physical constants were used in the models:

Table C1: Physical constants used for density dependent flow equations

ρ_{fw}	62.25 lb/ft^3
m_{tds}	1.92 lb/ft^3
TDS_{ref}	0.0
m_{tmp}	-0.0166 lb/ft^3/°C
TMP_{ref}	25 °C

Some analysis of Equations C1 and C2 can be instructive in understanding the great effect salinity can have on the pressure and, therefore, the potential energy of the groundwater. The subsurface water temperatures within the model domain generally vary from about 20°C to 40°C, with some small areas having temperatures outside that range. With the reference temperature at 25°C and the temperature/density slope so low, temperature variations can only contribute to a drop in density of about 0.25 lb/ft^3 from freshwater density or an increase in density of less than 0.1 lb/ft^3. Normalized TDS levels in the groundwater vary across the spectrum from 0 (freshwater) to slightly above 1 (seawater). With a TDS/density slope of 1.92, it is clear that salinity variations can contribute to a change in density of nearly 2 lb/ft^3 from the density of freshwater. These variations in both temperature and TDS result in a range of possible observed density from 62.0 lb/ft^3, just below freshwater density (62.25 lb/ft^3), to about 64.25 lb/ft^3.

At maximum, the first term in Equation C2 can result in a value about 103% of the observed head. The greater difference between equivalent freshwater head and observed head is obtained from the second term in Equation C2. Where the elevation is not much below zero, the second term has little effect, but

at significant depths where *Z* is greatly negative, the effect on the equivalent freshwater head can be startling. The Boulder Zone can reach elevations of -3,500 ft, making the equivalent freshwater head approximately 115 feet higher than the observed head if the TDS is high and the temperature is low!

Most of the analysis of the available data described in the following sections was based on the equivalent freshwater heads calculated from the available data. If measured TDS data was available for the well in question, that value was used to calculate equivalent freshwater head. If no data point was available at that location, the interpolated starting condition for the cell containing the point in question was used to estimate the TDS. For temperature, the interpolated starting condition was always used. Section 3.4 describes the development of initial conditions. Depths used in the calculations were the middle of the open interval for the well.

2.0 Aquifer Boundary Heads

Specified head boundary conditions were assigned to all the cells or nodes around the edge of the model domain in each aquifer layer. Sea level heads were applied to the eastern boundary at the layer outcrop location. Layers 2 and 3 were assigned aquifer heads on the western side of the model within the area designated as IA (Intermediate Aquifer) by Randazzo and Jones (1997). No boundary condition (no-flow) was defined outside the IA area. Other aquifers were assigned heads on all sides of the model. Confining units were assigned sea level heads on the east, but were left as no-flow boundaries for the north, west and south sides of the model.

Early iterations of this regional ASR model followed conventional modeling practice in the application of boundary conditions. For the side boundaries, this process involved gathering available head data at the boundary and linearly interpolating the heads for all cells between the data points. The team found that some of these methods were not applicable to the ASR regional model either because of lack of data, special conditions or the density dependent calculations planned. Here, we present a short explanation of some of the shortcomings of linear interpolation of aquifer boundary heads along the edges of the model.

- Interpolation of observed head data near the edges of the model domain in an aquifer occasionally resulted in sudden, large head variations, which are troublesome for the model's solver routine. This is generally a result of the simplification of the geology in the model. For example, the model includes a hydrogeologic unit referred to as the Upper Floridan aquifer. Many researchers divide this aquifer into the Suwannee and Ocala aquifers in some areas of the domain. Sometimes a Suwanee well and an Ocala well are placed near each other and have significantly different observed heads or TDS measurements, but in the model, both are considered part of the Upper Floridan aquifer. Simple linear interpolation of the heads at these wells can lead to steep head slopes like those shown in Figure C2-1a. Since the model aims to reproduce field conditions on a regional scale, some averaging of nearby well heads often helps smooth out these boundary conditions.
- Sparse data, especially in the lower aquifers, led to different flow conditions in deeper aquifers than in shallow aquifers. For example, both the Upper Floridan aquifer and the Avon Park

Permeable Zone of the Upper Floridan aquifer show high heads in Polk County compared to surrounding areas, due to extensive infiltration of precipitation. This high head is also shown in the wells along the model boundary, which makes it possible for the model to reproduce field conditions. There are very few monitoring wells in the Lower Floridan aquifer and none along the model boundary in this recharge area. A simple linear interpolation of existing data for use as a boundary condition would not include a high water table at this point (Figure C2-1b). However, TDS data (Section 3.4.1) shows very low salinity in the deep aquifers of Polk County, indicating that the source of the groundwater is recharge and the mound in the water table probably extends to the deeper aquifers. This problem can be remedied by adding synthetic points to the boundary that help shape the boundary conditions according to knowledge of the site.

- Combinations of head distributions, TDS distributions and temperature distributions may result in equivalent freshwater head distributions that contain sudden changes or unexpected flow conditions, which pose a challenge to the model solver (Figure C2-2). This problem can be remedied by performing the interpolation on the equivalent freshwater heads and then using site conditions to back out the observed head for assignment as boundary conditions.

The following subsections describe the process, which was developed to address the concerns listed above, and was used to assign boundary conditions to the edges of the layers.

2.1 Using an Azimuth Angle to Plot Data

A common issue with 3-dimensional modeling is the difficulty in viewing, displaying and analyzing 3-D data and results using a 2-D sheet of paper or computer screen. Generally, model images are displayed by viewing contours of a single layer or cross-section cut through the 3-D model. For boundary conditions, the cells or nodes can be colored by the assigned head value and viewed one layer at a time, but this prevents the user from observing subtle changes and slopes. It also makes it difficult to compare heads in different layers.

In reality, the selection of boundary conditions for the side (vertical) boundaries of this model was a 1-dimensional interpolation process of assigning head values to points along a line, which is arranged in a closed loop around the model. To make the analysis of the boundary conditions easier, the line around the model was stretched out along the x-axis of a data plot, which is termed an azimuth plot in this report. The points were arranged by calculating the east-based azimuth between the cell or node in question and a center point. Each cell or node, then, is assigned an angle between 0° and 360°, where 0° (and 360°) correspond to points directly east of the center point; 90° corresponds to a point directly north of the center point, with the angle increasing in a counter-clockwise manner around the model. Head, TDS, temperature, elevation and equivalent freshwater head for boundary cells can then be plotted on the y-axis. Figure C2-3 shows the location of the center point and indicates the angle measurements at various locations around the model. The center point was selected to provide a unique angle value for each cell by preventing any boundary cells from being collinear or nearly collinear with another boundary cell and the center point.

For clarity, Figure C2-4 shows an empty azimuth plot. These plots were used extensively in creating the boundary conditions for the regional ASR model. It is important that the reader fully understand these plots before continuing to read other sections of this appendix. Figure C2-4 includes a small inset map of the Florida Peninsula with a few key cities labeled. These same cities are labeled on the azimuth figure with vertical lines. Beginning from the left of the plot, points represent locations along the eastern (Atlantic) coast of Florida beginning just south of Vero Beach and continuing north toward Cocoa Beach. From 90° to about 120°, the points on the plot represent locations between Cocoa and Orlando drawn from east to west. Points on the plot continue counter-clockwise around the model, passing down the western coast, through the Everglades and then up through Miami, West Palm Beach and Port St. Lucie and back to where it started. The points shown at 360° should have the same values as the points shown at 0° for any given data set as they represent the same location on the map.

All of the azimuth plots in this appendix will be laid out in this manner with the inset map and the vertical city labels on the plot.

This type of display allows us to clearly see trends along the boundary of the model and we can compare heads in different layers simultaneously. It also allows us to more easily compare estimated values with measured values and recognize statistical outliers.

2.2 Selection of Data Points

Most of the data points used to construct the specified head boundary conditions for each aquifer were selected from the database of well data provided by SAJ. The database included a table containing information on the horizontal location of the well and the open interval of each well. This table was used with the interpolated geologic data to determine which of the hydrogeologic layers were expected to provide water to the well. A second table in the database presented water level measurements for each well during the periods of interest: October 2003 through December 2004 (calibration period) and August 1993 through July 1994 (validation period). Data for a few additional wells (not provided in the SAJ database) was obtained by NAP using databases such as DBHYDRO (SFWMD), WMIS (SWFWMD), the SJRWMD Hydrologic Data and the USGS NWISWeb Water Data, all of which are available online.

The wells listed in the database were separated into groups based on the hydrogeologic unit represented, using a database query. To be categorized with a given hydrogeologic unit, the query required that at least 90% of the open length be within that unit. Wells were generally assumed to be on the boundary of the model if they were within 10,000 feet of the boundary (using a GIS selection by location). Since the largest model cells (elements) in the SEAWAT (WASH123D) models are 10,000 feet wide, this corresponds to about 1 cell width from the boundary. On occasion, when data was sparse, additional wells were added to the group even if less than 90% of their screen was in the specified unit or if they were located more than 10,000 feet from the boundary.

Once all of the boundary wells had been compiled, average monthly heads were calculated and the available data was examined to determine which wells had sufficient data for the two time periods of interest. It was important that the head distributions in the boundary conditions for different months be similar. The deleterious effect of missing data is illustrated in Figure C2-5. Here, the available data

for April and May 2004 at three monitoring wells is shown. Since April and May generally have similar heads, the 30-foot difference at ROMP 101 AVPK is unexpected and caused only by the lack of data in April at this well. This problem was prevented in the boundary conditions by ensuring that data was provided for each well in every month of the modeling periods. If a certain well was missing only a few months of data, statistical comparisons could be used to estimate the heads in months with no available data (see Section 2.3 below). If the well was missing data for numerous months, estimating the missing data became a risky process. To prevent the introduction of this level of uncertainty, wells with insufficient data were removed from the group and not used for developing boundary conditions for the model. This determination was generally made if there were less than about 5 unique months of data available in the calibration time periods. Additional wells were removed if they were clearly impacted by local pumping or if other local conditions (such as TDS) made them unsuitable for use in a regional model. Table C2 lists all of the wells extracted from the database and provides explanations for those that were removed.

Modeling the IAS (Intermediate Aquifer System) presented unique challenges for this regional scale model. In reality, the IAS, as its name suggests, is actually a system of poorly defined aquifers interspersed with less conductive materials. Because of the lack of good conceptual data for this system, this ASR regional model lumps the entire system into a single layer of the model. If the data is also lumped into a single layer, the sudden, erratic changes in head cause difficulties for the model solver. Figure C2-6 is an azimuth plot showing the average monthly head for the months of concern (calibration and validation periods only) for the IAS layer. It clearly shows that there are wells located very near each other, which have starkly different heads. The head differences are most likely a result of adjacent wells being open in different flow zones and do not represent the system on a regional scale. The sudden head changes caused by strict linear interpolation of the available data can be difficult for the model to resolve. However, a comparison of the monitoring data and the screened elevations for each well (Figure C2-7) indicates the presence of several different conductive units with unique hydraulic signatures. Consider, for example, the data for wells with Model ID 131440 and 131449. (Model IDs were assigned to each well in the SAJ database.) These wells are located only 1,000 feet apart, but the head at 131440 is consistently 5 to 6 feet higher than at 131449, indicating that they might be tapping different units. This theory can be solidified by an analysis of their open hole intervals, which shows that at 131440, the open hole is more than 200 feet deeper than the open hole at 131449. The well names do not always help with this type of analysis, but in this case, knowing that well 131440 is called ROMP TR 5-1 TMPA and well 131449 is called ROMP TR 5-1 TAMIAMI makes us confident that these two wells belong in separate flow units.

The same process was followed for the rest of the IAS well data to determine if other wells could be separated in this manner. The final division of the wells is indicated by a set of red lines on Figure C2-8. Generally, wells open at higher elevations have lower average monthly heads. The lines on the figure separate the two groups. Clearly, the separation is not perfect. Wells 101348 (City of Sarasota 27th Street Well) and 101344 (Whitaker Bay Well near Sarasota, FL) have rather large screens that span both sub-sections of the aquifer. They are included with the upper group because their head data is more consistent with that group. Conversely, Well 100700 (L-1635) has a head distribution that matches

more closely the upper group of wells, but its screen is so deep, that it remains with the lower group. This causes an area of rather steep slope on the boundary of the model, but since no information was available to eliminate the data from that well and since the open hole is so deep, it was left with the deep well group. Figure C2-9 shows the two separate groups of wells on an azimuth plot. When compared to Figure C2-6, it shows an improvement in the smoothness of the data. The upper section was assigned to Layer 2 of the SEAWAT model the second layer of nodes in the WASH123D model. The lower section was assigned to Layer 3 of the SEAWAT model and the third and fourth layers of nodes in the WASH123D model. It is likely that the models will more easily come to a solution and that the results will be more accurate because of the removal of a simplification that was not warranted by the data.

This comparison of head data and open hole elevations was also critical in determining where nearby wells could be merged for simplification of the boundary condition. Wells were merged for one of two reasons. First, there were often two wells near each other with very similar vertical locations and head data. In some cases they were determined to be duplicates in the SAJ database, but other times, they were simply similar wells in close proximity. Combining the two wells by averaging their data was an easy way to fill in missing data in one well and resulted in simplification of the boundary conditions. The second reason for combining two nearby wells was to average out starkly different head conditions in the same model layer. The actual geology of every layer in the model is more complicated than the model and can often contain sub-aquifers or small areas with different hydrogeologic conditions. Averaging the heads is a good way to ensure that the model accurately represents regional conditions, but does not require the modeler to make a decision as to which of the different heads is more "accurate." (Figure C2-1a.) Table C2 indicates which wells were combined and presents criteria for each decision.

In addition to the monitoring well points around the boundary of the model, two additional points were added to the data set to enforce the ocean boundary on the east boundary of the model. These points were added to the outcrop location for each layer, one point at the northeast corner of the model where the outcrop line intersects the north model boundary, and one point at the southeast corner of the model where the outcrop line intersects the south model boundary. Because the heads are interpolated linearly along a line circumscribing the model, this will ensure that each cell at the ocean boundary is given the head obtained from tide gauge data.

2.3 Filling in Missing Data

Table C2 also indicates the availability of data for each well in the database, which was selected for use as a boundary well. While the water levels at many wells are regularly measured, others have extremely sparse data. As described above, wells with data available for less than about 5 unique months of the periods of interest (calibration and validation periods), were removed early in the process. For the remaining wells, missing data was estimated using one of two methods described in this section, to ensure that the boundary conditions for all periods of interest had similar head characteristics and incorporated seasonal changes. All estimates of missing data were made after the observed head had been converted to equivalent freshwater head as described above and presented in Equations C1 and

C2. Use of the equivalent freshwater head ensures that the TDS and temperature data are taken into account (Figure C2-2).

2.3.1 Using Seasonal Trends to Estimate Heads

The first method was used for filling in missing data for a given month, when the database provided data for same month in a different year. We will use a UF well, ROMP 90 OCAL, as an example to illustrate the method for filling in the missing data. This well is located in Dade City, in the county of Pasco. The SAJ database contained monthly head data from September 1993 through July 1994 and daily head data from October 2003 through December 2004. This is consistent with the SWFWMD website, which indicates a monthly monitoring program beginning in 1994 and continued until daily monitoring became available beginning December 1, 1997. The daily head data for each month in the calibration period (October 2003 – December 2004) was averaged to obtain a single average head value for each month of concern. All months of the calibration and validation periods are accounted for, except August 1993, when no water level value is available for this well.

To ensure consistency between the months of concern, the August 1993 data point was estimated by calculating a linear correlation between all other boundary wells with August 1993 data and August 2004 data. There are a total of 39 such wells. Using the Excel SLOPE and INTERCEPT functions, the following correlations were obtained:

$$WL_{93} = 0.977WL_{04} - 1.073$$ Equation C3

$$WL_{04} = 1.015WL_{93} + 1.377$$ Equation C4

where:

WL_{93} = Water level measured in August 1993

WL_{04} = Water level measured in August 2004

Correlation coefficients (r^2) values for both equations were 0.992, well above the minimum level for statistical significance. The two correlations are not exactly identical because Excel uses a vertical offset least squares linear regression instead of a perpendicular offset to determine the best-fit trendline. This causes slight differences when x and y are reversed. To account for this difference, which is more unsettling than inaccurate, the two equations were solved for WL_{93} and the slopes and intercepts were averaged to obtain a single equation that can be used to estimate the August 1993 head value for any well which has August 2004 data available. This equation is listed below as Equation 5:

$$WL_{93} = 0.981WL_{04} - 1.215$$ Equation C5

where:

WL_{93} = Water level measured in August 1993

WL_{04} = Water level measured in August 2004

Since the August 2004 average monthly head at ROMP 90 OCAL was 70.9 ft, the August 1993 average monthly head at this well can be estimated to be 68.4 ft.

The months of October, November and December appear three times in the periods of interest. When data was available for two of the years, the above process was followed once for each available year, resulting in two estimates for the missing month. These two estimates were then averaged to obtain a single value for use in the model. When data was available for only one of the years, it was used as the basis for estimating heads for both missing years following the procedure outlined here.

This process was followed for every missing data point with available data in the same month of a different year. The correlation was always very good, with r^2 values normally above 0.990. The only exception to this rule was for the comparison between October 1993 and October 2004 data sets when the r^2 value was a substantial 0.988.

The r^2 value is not always the best way to quantify the quality of a regression analysis. Additional investigation of the quality of the regression was done by using the regression equation (Equation C5) to calculate the heads for wells which had measurements for that month. For example, in the August 1993/August 2004 data sets, there were 40 wells with data for both months. (These were the 40 wells used to compute a regression equation.) For each of these wells, the 1993 head was calculated from the 2004 head using Equation C5. This calculated head was compared to the observed head for that month to obtain a residual between calculated and observed heads. Because of the nature of the least squares analysis with a vertical offset, the average of these residuals was 0.0. But when the absolute value of the residuals was averaged, the result was 2.2 feet. This means that, on average, this method of estimating the missing data results in a head that is erroneous by just more than 2 feet. The root mean square (RMS) is calculated by squaring the residuals, averaging the results and then taking the square root. This method gives greater weight to large residuals. For the August 1993/ August 2004 regression results, the RMS was 2.5 feet. Both of these statistics are well within the calibration error expected in a regional model of this scale. All of the other pairs of months show similar regression quality. The worst correlations are between October 1993 and October 2004 and September 1993 and September 2004, where the mean absolute error was 2.2 and the RMS was 2.8.

2.3.2 Estimating Heads Using Similar Wells

The process for estimating head values for wells with a few missing months of data is described in section 2.3.1 and was used successfully to fill in nearly all the missing data for the boundary wells. Seven of the wells, however, were missing a given month in every year of the data set and a second method was developed to handle them. As before, we will illustrate the process by using an example, FMB-MZL. This is an APPZ well located in Lee County. The SAJ database provides daily water level measurements at this well from 19 May 2004 through 8 December 2004. From this data, we can average the measurements in each month and obtain average monthly heads for May through December 2004. Using the process described in section 2.3.1, the heads for the missing months of October through December of 2004 and August through December of 1993 can be easily estimated. The remaining months with no available data, then, are January through April of 1994 and the same period in 2004.

A linear regression was used as before, but this time, the regression correlated the monthly average data from other wells, which have a full data set. It would have been appropriate to select a few nearby

wells in the same aquifer for the correlation, but often there are no wells particularly close and the open interval is seldom the same. So, a comparison was made between the well in question and all other boundary wells in the data set. The five wells with the closest correlation (measured using the r^2 value) were used to estimate the missing data points, even if these wells were located far away or in different aquifers. In the case of FMB-MZL, the correlation coefficients for all the boundary wells varied from 0.001 (the average of ROMP TR 3-3 SWNN and ROMP TR 3-3 OCAL) to 0.888 (IWA-MZL). As would be expected, the best correlation is obtained from a nearby well in the same unit: IWA-MZL and FMB MZL are located about 11 miles apart and their screens are only about 50 feet different in elevation. The five wells with the best correlations were compiled for use in filling in the missing data. For FMB-MZL, the five best correlated wells are:

- IWA-MZL,
- USGS Cocoa D Well near Narcoossee, FL
- USGS Palm Lake Drive Well near Windermere, FL,
- ROMP 85 AVPK, and
- BICY-MZ1

These wells are not all located near FMB-MZL, nor are they all in the APPZ layer, but statistically, they have the best correlated data sets. Figure C2-10 shows these five data sets along with the available data for FMB-MZL. The hydrogeologic layer for each well is indicated in the legend and an inset map shows their locations. The five best-correlated data sets were averaged and then, the correlation between the average and FMB-MZL was used to construct a linear relationship to fill in the missing data. The linear equation is shown in Equation C6 below:

$$WL_{FMB-MZL} = 1.366 WL_{avg} + 37.366 \qquad \text{Equation C6}$$

where:

$WL_{FMB\text{-}MZL}$ = Water level measured at FMB-MZL for a given month

WL_{avg} = Average of the water levels measured at the five most statistically correlated boundary wells for the same month

Equation C6 fit the available data with an r^2 correlation value of 0.889. The estimates for the missing data are added to Figure C2-11. The correlation coefficients (r^2) for the other wells whose data sets were completed using this method varied from 0.46 to 0.93.

As with the regression presented in Section 2.3.1, the residual between measured and calculated heads was calculated for each month and then the mean absolute error and RMS were calculated. For the regression on the data at FMB-MZL, the mean absolute error was 0.3 feet and the RMS was 0.4 feet. The worst RMS for the wells correlated in this way was 1.7, found for the combination of two Boulder Zone wells: OR0613 and the USGS Cocoa C (Zone 1) Well near Bithlo, FL.

Although the r^2 values seem to indicate that these estimates are less trustworthy than those determined by comparing months across years, the residual statistics show that these errors are clearly within the expected calibration error.

2.4 Interpolation

Once the data sets had been cleaned by removing sparse data, removing data with local effects, combining wells located near each other and filling in missing data, the azimuth plots were used to analyze the available data. The interpolation process described here was repeated for each month of the calibration and validation periods.

Figure C2-12 shows the equivalent freshwater heads for October 2003. All data points are connected with straight lines. Where the head is marked with an open circle symbol, there is at least one head measurement available at that location for the month of October 2003. Wherever there is a change of slope in the connecting line without a circle symbol, the head value at that location has been estimated using one of the two methods described in the previous section. Open circles that appear offset from the line indicate that heads at two or more wells in the same area were averaged. Several observations of the data can be drawn from Figure C2-12.

- The highest heads in the Upper Floridan and Avon Park Permeable Zone aquifers are found in the area between Orlando and Tampa. This is known to be the main recharge area for the region and high heads in this area are not surprising. (Low salinities in this area in the Lower Floridan and Boulder Zone indicate that the recharge is likely affecting the deeper aquifers. There are no head data points in this area in the deep aquifers.)

- Between Tampa and Venice, where the boundary follows the coast line of the Gulf of Mexico, the equivalent freshwater heads are low, often lower than the ocean level, indicating flow from the ocean into the model domain in this area.

- Equivalent freshwater heads increase somewhat in the area between Venice and Everglades National Park. This increase is probably caused by movement of the boundary inland, where salinity may be lower and observed heads may be higher.

- From about 100° (just east of Orlando) until about 160° (just south of Tampa), the IAS, UF, APPZ, and LF have very similar equivalent freshwater heads, indicating very little vertical movement and close hydraulic connections between the different layers.

- Along all coastlines, there is a great difference between the equivalent freshwater heads in the different layers. Generally, the highest equivalent freshwater heads are found in the deepest layers, indicating upward movement.

- The points at 50° (east of Cocoa) and 285°(east of Miami) are the locations where tide gauge data was used to set the boundary conditions. On the model, all areas between Cocoa and Miami will be assigned this same observed head value, although variations in salinity, temperature and depth can alter the equivalent freshwater head. The slope of the equivalent

freshwater head on Figure C2-12 towards these points can indicate the direction of water exchange between the ocean and the inland groundwater. For the Boulder Zone and the Lower Floridan Aquifer, these lines slope inland, indicating movement of ocean water into the main section of the model. For the Upper Floridan and Avon Park Permeable Zone layers, these slopes are directed seaward, indicating movement from the peninsular groundwater outward to the ocean. This observation combined with the previous one supports the idea that ocean water enters through the deeper layers, flows upward and then back out towards the ocean.

An examination of these plots also shows that a linear interpolation between the available data points is not sufficient. This is most apparent in the area between Orlando and Tampa. Both the Upper Floridan and Avon Park Permeable Zone aquifers show a distinct increase in head of over 200% around Orlando followed by a precipitous drop in head towards Tampa. The head in the Lower Floridan appears to be following the same trend, but then cuts across the other lines to meet its next data point, near Naples, skipping the high heads in Polk County. The Boulder Zone data follows a similar trend, but with no data points available between Orlando and Miami. It is believed that these anomalies are the result of using a linear interpolation scheme on excessively sparse data. If wells were drilled in the deeper layers between Orlando and Naples, their heads would be expected to more closely follow the trends exhibited in the upper layers. The low salinity found in the Lower Floridan and Boulder Zone indicate that precipitation which recharges the upper aquifers also reaches the deeper layers of the system.

A number of synthetic points were added to the data sets to form the head signatures to the expected shape. Figure C2-13 shows the October 2003 azimuth plot with these synthetic points indicated with small x's. The majority of the synthetic points are added to the Boulder Zone and Lower Floridan lines, and result in a peak in equivalent freshwater heads between Orlando and Tampa and a low point between Tampa and Venice. The upward gradient has been enforced in most places outside the Polk County recharge zone. A few minor changes have been made by adding points to the Avon Park Permeable Zone or Upper Floridan layers.

Since SEAWAT and WASH123D require that boundary conditions be entered as observed head values, not equivalent freshwater heads, the points on Figure C2-13 had to be converted to observed head using forms of Equations C1 and C2. The first step in a SEAWAT model, though, is to convert user-supplied observed heads to equivalent freshwater heads. In this conversion, the user-supplied TDS and temperature initial conditions are used. In order to ensure that the model calculated equivalent freshwater head matches what was developed in Figure C2-13, the conversion back to observed head needed to be done using the TDS and temperature extracted from the initial conditions, not the actual measured values, when available. In most cases, these two values were similar, but on a few occasions, the TDS measured at a well was determined to represent a local phenomena and the measurement was not used in the development of the initial conditions data set. (Section 3.4.1 and 3.4.2)

The resulting observed heads were used to interpolate the specified head boundary condition to the grid. The azimuth angle was used as the basis for the interpolation by calculating the angle from the center point to the center of each cell on the boundary. Heads at cells between each pair of neighboring

boundary data points (and synthetic data points) were linearly interpolated using the following equation:

$$h_{cell} = h_{obs1} - \frac{(\theta_{obs1} - \theta_{cell})(h_{obs1} - h_{obs2})}{(\theta_{obs1} - \theta_{obs2})}$$ Equation C7

where:

h_{cell}	=	The observed head to be assigned to the cell in question
θ_{cell}	=	The azimuth angle of the center of the cell in question
h_{obs1}, h_{obs2}	=	Observed head at two data points (or synthetic data points), which bound the group of cells to be interpolated
θ_{obs1}, θ_{obs2}	=	Azimuth angles of two data points (or synthetic data points), which bound the group of cells to be interpolated

2.5 Additional Data Tweaking

Although SEAWAT and WASH123D require the modeler to provide boundary conditions as observed heads, the model immediately converts the observed heads to equivalent freshwater heads using the user-provided TDS and temperature initial conditions. The model calculations are then made using the equivalent freshwater heads.

As a final check of the boundary conditions, the cells along the boundary were extracted from the grid and the observed head, TDS, temperature and elevation of each of these boundary cells was tabulated. Microsoft Access was used to calculate the equivalent freshwater head at each computational cell or node just as SEAWAT and WASH123D would do at the start of the model run (see Equations C1 and C2). Figures C2-14 through C2-19 show the observed head assigned as a boundary condition and the equivalent freshwater head calculated at each boundary cell. As with other figures in this report, the cells are plotted using their azimuth angle calculated from the same center point. These equivalent freshwater heads are the boundary conditions seen by the model.

Some locations on these plots seem to have “wavy” equivalent freshwater head changes. An example of this phenomenon is the Upper Floridan Aquifer heads (Figure C2-16) between the angles of 240 and 270 degrees. Here, the applied head boundary condition is linear (with a slope change at the data point), but the calculated equivalent freshwater head is “wavy.” This unusual shape to the plot is caused by the different methods of interpolating each of the data sets that affect the final equivalent freshwater head and should not cause a problem for the model since the variations are very small. The TDS, temperature and elevation data sets are interpolated in 2 dimensions using a linear or natural neighbor scheme. Contours may be perpendicular to the boundary, but more often, they touch the boundary at some angle or may even be approximately parallel to the boundary. Conversely, the head assigned to the boundary is interpolated in 1 dimension along a line circumscribing the model. This means that when all the data sets are combined, the contours may be peculiar.

An example of this issue is shown in Figures C2-20 and C2-21. These two figures show the pertinent data sets for calculating the equivalent freshwater heads for a set of 13 boundary cells located near the

southwest coast of Florida, just north of Everglades National Park. Figure C2-20a shows the temperature distribution as a plan view contour plot and as subset of an azimuth plot. Here, the contours on the right half of the section intersect the boundary at nearly a right angle. This results in a relatively smooth azimuth plot. In Figure C2-20b, the TDS distribution is displayed in the same manner. These contours are nearly parallel to the boundary and so sharp declines in the TDS for each cell occur when the boundary moves to the next column of the grid. The layer elevation is presented in Figure C2-20c. These contours are much closer to parallel with the boundary and so the jump in elevation that occurs as the boundary moves to the next column is much more pronounced than with the TDS plot. Figure C2-21a shows the assigned observed heads for these boundary cells. Notice that the lines in the azimuth plot are perfectly straight due to the linear interpolation of the cells by the azimuth angle. The slope change at 237° is caused by a synthetic well point which was added in an effort to smooth out the boundary condition. (This process is explained in Section 2.5.) Figure C2-21b presents the calculated equivalent freshwater head in each cell (See Equations C1 and C2). Because of the sudden changes in TDS and especially elevation which occur when the boundary moves to the next column, the azimuth plot appears to be oscillating. A few rough contours have been added to the plan view image for Figure C2-21b to show that the apparent oscillation is a product only of the azimuth plotting method. Therefore, these unusual line shapes with small oscillations in head can be disregarded in the examination of these equivalent freshwater head azimuth plots.

For each of the Floridan aquifers (Figures C2-16 through C2-18), there are multiple lines indicating the calculated equivalent freshwater heads. Boundary heads, initial TDS and initial temperature are all constant across the layers of any given aquifer. So, for the Upper Floridan Aquifer, each cell along the boundary in layer 5 has exactly the same specified head, initial TDS and initial temperature as the same cell in layer 6, 7, 8, 9 and 10. The only difference between the cells is the elevation of the centroid, which is used in the calculation of the equivalent freshwater head (See Equation C1 and C2). Thus, where the lines are further spread apart on the equivalent freshwater heads plots, the cells are thicker, leading to more divergent elevations and, therefore, equivalent freshwater heads. Note also, that if the observed density is close to freshwater density (low salinity and temperature close to 25°), the elevation differences become less important. This is why the lines always plot on top of each other in the areas between Orlando and Tampa. Salinity is low and so the observed head is nearly equal to the equivalent freshwater head.

Figure C2-22 shows the equivalent freshwater heads calculated for all aquifer layers of the model on one plot. They are overlain with x's showing the calculated equivalent freshwater head at each monitoring well used in the interpolation. Occasionally, the x symbol does not fall close to the line. This occurs either because the TDS of the data point differs from the initial condition TDS or because the elevation of the center of the open section of the well differs from the center of the cell.

Figure C2-22 also highlights an additional problem with this method of assigning the boundary heads. In some cases, there are unusual or unexpected shapes to the lines, beyond what can be explained by the interpolation issues ("wavy" sections) discussed above. These variations are generally the result of assuming that all the pertinent data sets (TDS, temperature and elevation) are linear within the zones of

linear assigned heads. Some of these problems, such as the dropping of the Avon Park Permeable Zone EFH below the Upper Floridan EFH at around 60° can be resolved.

Additional break points were added where nonlinearities in the TDS or elevation data sets caused unusual results in the equivalent freshwater heads. (Non-linearities in temperature rarely caused these types of anomalies.) At each breakpoint, a value for equivalent freshwater head was selected to smooth the plot. Then, the assigned head was back-calculated using the TDS, temperature and elevation at that location. Figures C2-23 through C2-26 show the effect of these breakpoints on the boundary condition expressed as observed head and equivalent freshwater head. No breakpoints were added to the IAS layers. The locations of the breakpoints are obvious from the plots because the new observed head line (solid red) varies from the previous observed head line (dashed red). In each case, the breakpoints smoothed the equivalent freshwater head and removed unexplained anomalies.

It is important to stress that despite the apparently arbitrary nature of some of these edits to the data sets, the applied head boundary condition still matches the measured head at each monitoring well – except where nearby wells were averaged as shown in Table C2. The measured head values for all aquifers are shown as red dots on Figures C2-23 through C2-26.

2.6 Final Results

The resulting equivalent freshwater heads for all aquifer layers of the model are shown together on an azimuth plot in Figure C2-27 for October 2003. The flow directions are preserved much better now that break points have been added. Except for the area between Orlando and Tampa, the flow is generally upward. There is a close communication between upper and lower aquifer layers between Orlando and Tampa. The x's on the figure indicate that there is a close correlation between the measured heads (converted to equivalent freshwater heads) and the applied boundary conditions. The actual head values applied to the model for October 2003 are shown in Figure C2-28. These are observed heads, not equivalent freshwater heads. Notice again that the applied heads match the available data at all locations. Figure C2-29 shows plan view images of each aquifer with the October 2003 specified heads indicated in each cell with a colored circle. The same process was followed to create side boundary conditions for the aquifers for each month of the calibration and validation periods.

3.0 Surficial Aquifer System Surface Heads

As described in Section 1.1 of this appendix, the surface of the model was given a specified head boundary condition. This type of boundary condition sets the required head for each cell and the model adds or removes any amount of water necessary to achieve that head. This imitates the water flux caused by rainfall and evapotranspiration cycles, but does not require exhaustive data analysis and large assumptive leaps to come up with the flux values. This type of boundary on the surface of the model is only valid because there is significant shallow head data available in the Surficial Aquifer System (SAS) and because we are not actually concerned with the flow through this upper layer. None of the forces applied to the final model (ASR well pumping) are expected to have effects on the SAS. The heads applied to the SAS cells directly impact the addition (and removal) of water through the surface to the Intermediate Aquifer System (IAS) layers.

Early iterations of this regional ASR model followed conventional modeling practice in the application of boundary conditions. For the SAS surface head boundaries, 2-dimensional interpolation was used to convert discrete head measurements to an array of head values, one for each surface cell. The team found that some of these methods were not applicable to the current situation either because of lack of data, special conditions or the density dependent calculations planned. Here, we present a short explanation of some of the shortcomings of previous methods of assigning boundary conditions. Two-dimensional linear interpolation of observed head data in the SAS sometimes resulted in unacceptable interactions with the topography, such as:

- The interpolated head was above the ground surface where no surface water was expected, or the interpolated head was below the elevation of the bottom of the SAS. This was often caused by interpolation across an area of sparse data where topographic changes were not linear. (See Figure C3-1a)
- The interpolated water table did not rise underneath hills and ridges in known recharge areas. This was due to monitoring wells being found in river valleys, not at higher ground levels. (See Figure C3-1b)

The following sections describe the process that was designed to avoid those problems and create a smooth, accurate distribution of head in the SAS layer.

3.1 Selection of Data Points

The heads assigned to the upper layer of the model were based on available data for wells open in the Surficial Aquifer System (SAS). The data for these wells was provided by SAJ in a database. Wells were assumed to represent the heads in the SAS layer if the top of their open interval was in the top layer of the model and if the bottom of their open interval was in the first or second layer of the model. These were extracted using a query in Microsoft Access. The measured data for each well was averaged for each month in the calibration period (October 2003 to December 2004) and the validation period (August 1993 to July 1994). The query also extracted the x and y locations, ground elevation and open interval elevations.

Wells with obvious errors or local phenomena were removed from the data set. These errors include:

- Wells with water level more than 10 feet above the ground surface elevation (flooded areas)
- Wells with water level lower than the level of the ocean (affected by pumping)
- Wells with data errors such as the cased elevation below the drilled elevation or the ground surface elevation exactly 0.0 ft.

Additional analyses were used to remove duplicate wells and to remove upper wells in a nested set. This was done by gathering all wells located within 25 feet of each other. In each set of wells only the well with the deepest open interval was used. This deeper well would be expected to better represent

the head conditions which directly affect the IAS layers. This method also removed duplicates in the database.

3.2 Filling in Missing Data

As with the aquifer boundary wells (Section 2.3), it was important to have the same set of points for each month to ensure uniformity among the months. Because many of the wells were not measured in every month of the calibration and validation periods, a procedure was developed to estimate the heads for the months with missing data. The procedure was nearly identical to that described in Section 2.3 for the aquifer boundary heads.

In the first step, a regression of head measurements for the same month in different years was used to estimate many of the missing head values. All r^2 values were above 0.992 indicating a close linear correlation. The quality of the head estimates was also calculated by comparing the available data values to those that would be calculated using the regression equation. The residual between the computed and estimated value for each month was tabulated and the mean absolute error and root mean square error were calculated. The largest mean absolute error was 1.76 for the comparison between June 1994 and June 2004. The largest root mean square error was 3.34, calculated for the November 1993 and November 2004 data. These errors are within the error expected on the calibrated model.

At this point, wells with sparse data were removed from the data set. Sparse data wells were defined as those that had less than five months of data before this regression step or less than ten months of data after this regression step. The removal of sparse data was important for the reliability of the final step in the process of estimating missing data.

The second step to filling in missing data was to correlate the monthly average heads for each month still missing data with five wells whose data was statistically most similar. The similar wells were determined by calculating the r^2 value and the regression line slope for each pair of wells. The r^2 values were ranked and the five highest values which corresponded to positive slopes were assumed to be the most similar wells. The data at these five wells was averaged and the result was compared to the well with missing data using the Excel SLOPE and INTERCEPT functions to determine a linear relationship which could be used to estimate missing data. The r^2 values for the comparison between the average of the five best wells and the well of concern varied from very good (0.99) to rather poor (0.5). The worst r^2 value of 0.5 was found for the well G-2063 located in Broward County. As before, additional comparisons were made for each month with available data for both the well in question and the average of the five best wells. The regression equation was used to estimate the head and this estimate was compared to the actual data with the calculation of a residual error. The mean absolute error and root mean square (RMS) error for these comparisons was less than the expected calibration quality. The worst mean absolute error was 1.57 ft and the worst RMS was 2.1; both occurred at the SWFWMD well MBWF X-1 UPL SURF located in Hillsborough County.

3.3 Regression/Interpolation

The boundary condition for the top of the model was designed to imitate recharge by allowing the model to calculate the flux required to duplicate the measured heads in the SAS layer. This was implemented by assigning a head value to every cell on the surface of the model. This interpolation process was repeated for each month of the calibration and validation period. Initially, the cell heads were determined using an interpolation scheme to convert the occasionally sparse well data to individual cell values. For simplicity's sake, a linear interpolation scheme was selected; however, the density of the data points can have a great effect on the resulting head values. Figure C3-1 shows two examples of how linear interpolation can cause unexpected results when the data points are too sparse to correctly define the water table surface. To account for these and other problems, the following process was designed:

First the model area was divided into five zones based on topography, presence of water and data availability as follows:

1. Ocean areas, placed visually using a map;
2. Lake Okeechobee, placed visually using an areal photo and map;
3. Ridge peaks where linear regression was not consistent with the majority of observed data, based on the zones labeled as Lake Wales Ridge, Winter Haven Ridge, Lakeland Ridge, Bombing Range Ridge, Orlando Ridge, Mount Dora Ridge, Brooksville Ridge, Marion Upland and Deland Ridge in Figure 2 of Sepúlveda, 2002;
4. Dry land areas with a reasonable linear relationship between measured head and ground surface elevation;
5. Remaining dry land where observed data did not fit the linear regression equation developed for Zone 4.

Figure C3-2 shows the zones designated for the model domain. Specified heads were assigned differently in each zone. The cells in the ocean areas and Lake Okeechobee were assigned a specified head according to the mean monthly ocean level and lake level, respectively. The remaining inland areas were assigned a specified head by using either a linear regression or linear interpolation. Figure C3-3 shows the wells used for creating the linear regression (696 data points) and the wells used for linear interpolation (616 data points). For the the inland area (the area shown in green in Figure C3-2), data could be fit to a linear regression which correlated the observed head in the SAS wells to the ground surface elevation at that well. The upper plot on Figure C3-4 shows all of the water level data used to develop the SAS boundary condition for October 2003 plotted against the ground surface elevation at each well, overlain with a linear trend line. From this plot it is apparent that the water level data in the upper elevations does not correlate well with the ground surface elevation. These locations correspond to the ridges. Here, the water surface is much deeper because of the steepness of the ridge slopes. The inclusion of these wells in the regression tended to skew the slope of the regression line downward, so they were removed and categorized in Zone 3. Similarly, wells near the southeast and

southwest coastlines did not appear to follow the general regression of the data. These wells were also removed from the regression and categorized separately (Zone 5) for the development of SAS boundary condition. The lower plot on Figure C3-4 contains the wells used for the regression analysis (Zone 3 and 5 wells removed) for October 2003. The wells in this data set (Zone 4) show a reasonable correlation between the observed water level and the ground surface elevation. Since the water levels varied throughout the year, a separate regression equation was created for each month, using the same set of wells. Plots of head versus elevation for all monthly data sets are similar. R^2 values for all months vary between 0.975 and 0.984, and the root mean square error (RMS) ranges from 3.72 in September 2004 to 4.54 in May 2004, indicating that the data is well correlated in all months. Once a regression equation for each month was developed, this equation was used to calculate a head value for each cell in the SAS layer of the model based on the ground surface elevation assigned to that cell in the model.

Once heads had been assigned in each zone according to the process outlined below, the heads were checked against the ground surface elevation and the elevation of the bottom of the SAS. Heads were required to be at least one foot above the bottom of the SAS (to prevent dry cells) and no more than 10 feet above the ground surface (to remove some anomalous data points).

3.4 Final Results

The final set of specified heads applied to the surface of the regional model is shown in Figure C3-5. As expected the heads trend with the ground surface elevation. Higher heads are seen in Polk County and surrounding areas where ground surface elevations are high and significant recharge occurs. The water table gently slopes down towards the flat areas of the peninsula, south of Lake Okeechobee. The heads assigned in coastal areas are at or close to sea level.

4.0 Differences in Assigning Boundary Conditions for SEAWAT vs. WASH123D

The processes described in Sections 2 and 3 generally refer to the assignment of boundary conditions to the SEAWAT grid. This model was built first and so, was used exclusively while the process was being developed. The same process was also applied to the WASH123D model, except that interpolations were made to mesh node locations, which were not the same as the grid cell centers used in the SEAWAT model.

IAS	101326	USGS 271137082284503 ROMP TR-20 UP HTRN	175302.03	1042549.06	One head data point for the 93/94 calibration period (May 1994) and two head data points for the 03/04 calibration period (May and Sept 2004) were provided by SAJ. No additional data was found by NAP	None	Removed – sparse data

Table C2: Description of data availability and decisions for inclusion in the definition of side boundary conditions for aquifer layers (not including Surficial Aquifer System).

Layer	SAJ Model ID	Well Name(s)	X	Y	Water Level Data Availability	TDS Data Availability	Boundary Head Decisions
IAS	101322	USGS 271118082285301 OSPREY WELL 9	174632.39	1040597.03	Daily head data points for the 93/94 calibration period were provided by SAJ. Head values for the 03/04 calibration period were estimated using least squares analysis comparing the measured heads in the same month for different years.	None	Used in definition of boundary conditions (layer 3). Averaged with 131440.
IAS	131440	ROMP TR 5-1 TMPA	184118.67	1021400.75	Daily head data points for the 93/94 and 03/04 calibration periods were provided by SAJ	Available	Used in definition of boundary conditions (layer3). Averaged with 101322.
IAS	101285	USGS 270808082270503 ROMP TR-20 UP HTRN	184118.67	1021400.75	Two head data points for the 93/94 calibration period and two head data points for the 03/04 calibration period were provided by SAJ (May/Sept).	None	Removed – sparse data

Table C2: Description of data availability and decisions for inclusion in the definition of side boundary conditions for aquifer layers (not including Surficial Aquifer System).

Layer	SAJ Model ID	Well Name(s)	X	Y	Water Level Data Availability	TDS Data Availability	Boundary Head Decisions
IAS	131449	ROMP TR 5-1 TAMIAMI	184124.06	1021397.66	Daily head data points for the 03/04 calibration period were provided by SAJ. Head values for the 93/94 calibration period were estimated using least squares analysis comparing measured heads in the same month for different years	Available for well called ROMP TR 5-1 INTERMED. (determined to be the same well based on location and open interval)	Used in definition of boundary conditions (layer 2). Averaged with 101279 and 131411.
IAS	101279	USGS 270542082261801 VENICE 35	200661.13	987978.05	Daily head data points from 8/1/93 through 10/7/93 and single points for 5/94, 5/04 and 9/04 were provided by SAJ. A few additional months' values were estimated using least squares analysis comparing measured heads in the same month for different years.	Available	Used in definition of boundary conditions (layer 2). Averaged with 131449 and 131411. This well is probably the same as 131411. The data from SAJ match the USGS data, but not that for 131411.

Table C2: Description of data availability and decisions for inclusion in the definition of side boundary conditions for aquifer layers (not including Surficial Aquifer System).

Layer	SAJ Model ID	Well Name(s)	X	Y	Water Level Data Availability	TDS Data Availability	Boundary Head Decisions
IAS	131411	VENICE 35 INT	188539.04	1006263.41	One to four head data points for each month in the 93/94 and 03/04 calibration periods were provided by SAJ.	Available	Used in definition of boundary conditions (layer 2). Averaged with 131449 and 131411. This well is probably the same as 101279. The data from SAJ match the DBHYDRO data, but not that for 101279.
IAS	131465	ROMP TR 4-1 UP INT	187066.86	992964.48	Daily head data points for the 03/04 calibration period provided by SAJ.	Available	Removed – the TDS value at this well is unusually high and may indicate a data error or an anomaly not accounted for in the model.

Table C2: Description of data availability and decisions for inclusion in the definition of side boundary conditions for aquifer layers (not including Surficial Aquifer System).

Layer	SAJ Model ID	Well Name(s)	X	Y	Water Level Data Availability	TDS Data Availability	Boundary Head Decisions
IAS	101276	USGS 270240082235701 ROMP TR 4-2 TAMPA	200661.13	987978.05	Two head data points (May and Sept) for the 03/04 calibration period provided by SAJ. NAP obtained additional daily head data points for the 93/94 calibration period from USGS. Heads for additional months in the 03/04 period were estimated using a least squares analysis comparing the same month in different years.	Available	Removed – this is the same well as 131441
IAS	131441	ROMP TR 4-2 TMPA	200635.54	987954.10	Daily head data points for the 93/94 and 03/04 calibration periods provided by SAJ	Available (well called ROMP TR 4-2 SWWN)	Used for definition of boundary conditions (layer 3). Averaged with 101275.
IAS	101275	USGS 270137082235301 MANASOTA DEEP 14	201113.03	981792.50	Daily head data points for the 93/94 and 03/04 calibration periods provided by SAJ	Available	Used for definition of boundary conditions (layer 3). Averaged with 131441.

Table C2: Description of data availability and decisions for inclusion in the definition of side boundary conditions for aquifer layers (not including Surficial Aquifer System).

Layer	SAJ Model ID	Well Name(s)	X	Y	Water Level Data Availability	TDS Data Availability	Boundary Head Decisions
UF	101346	USGS 272127082323801 CITY SARASOTA 23RD AND COCONUT	154944.20	1102349.83	Daily head data points for the 93/94 and 03/04 calibration periods (except missing 8/93) provided by SAJ.	None	Removed – this well appears to be located in a small local area affected by pumping.
UF	131452	ROMP TR SA-1 SWNN	154331.80	1098420.68	Daily head data points for the 03/04 calibration period provided by SAJ. Heads for the 93/94 calibration period were estimated using a least squares analysis comparing the same month in different years.	None	Used in definition of boundary conditions
UF	131467	ROMP TR SA-3 UP FLDN	165884.36	1098967.02	Daily head data points for the 03/04 calibration period provided by SAJ. Heads for the 93/94 calibration period were estimated using a least squares analysis comparing the same month in different years.	None	Removed – open section of this well is very deep, possibly in the MC1 layer. If it is in the UF, it represents a deeper section of that unit, which is not accounted for in the model.

Table C2: Description of data availability and decisions for inclusion in the definition of side boundary conditions for aquifer layers (not including Surficial Aquifer System).

Layer	SAJ Model ID	Well Name(s)	X	Y	Water Level Data Availability	TDS Data Availability	Boundary Head Decisions
UF	131447	ROMP 20 OCAL	175321.94	1042551.86	Daily head data points for the 03/04 calibration period plus 5 head data points for the final two months of the 93/94 calibration period were provided by SAJ. Heads for the remaining months of the 93/94 calibration period were estimated using a least squares analysis comparing the same month in different years.	Available	Used in definition of boundary conditions
UF	131439	ROMP TR 5-1 SWNN	184128.69	1021407.71	Daily head data points for the 93/94 and 03/04 calibration periods provided by SAJ.	Available	Used in definition of boundary conditions
UF	131468	ROMP TR 4-1 SWNN	187110.38	992895.30	Daily head data points for the 03/04 calibration period provided by SAJ. Heads for the 93/94 calibration period were estimated using a least squares analysis comparing the same month in different years.	Available	Used in definition of boundary conditions

Table C2: Description of data availability and decisions for inclusion in the definition of side boundary conditions for aquifer layers (not including Surficial Aquifer System).

Layer	SAJ Model ID	Well Name(s)	X	Y	Water Level Data Availability	TDS Data Availability	Boundary Head Decisions
UF	130023	ROMP TR 3-3 SWNN	222843.74	944410.19	Daily head data points for the 03/04 calibration period plus 17 head data points for the final 7 months of the 93/94 calibration period were provided by SAJ. Heads for the remaining months of the 93/94 calibration period were estimated using a least squares analysis comparing the same month in different years.	Available	Used in definition of boundary conditions. (Averaged with 130021)
UF	100272	USGS 265531082194803 ROMP TR 3-3 SUWANNEE	222843.74	944410.19	Four head data points for the calibration periods provided by SAJ (Two points for the 93/94 period; two points for the 03/04 period)	Available	Removed – this is the same well as 130023 and has sparse data
UF	130021	ROMP TR 3-3 OCAL	222846.45	944410.16	One to six head data points for each month in 93/94 calibration period (missing Aug through Sept) and daily head data points for the 03/04 calibration period. Heads for the remaining months of the 93/94 calibration period were estimated using a least squares analysis comparing the same month in different years.	Available	Used in definition of boundary conditions. (Averaged with 130023)

Table C2: Description of data availability and decisions for inclusion in the definition of side boundary conditions for aquifer layers (not including Surficial Aquifer System).

Layer	SAJ Model ID	Well Name(s)	X	Y	Water Level Data Availability	TDS Data Availability	Boundary Head Decisions
UF	112113	IWA-MZU	292806.41	767990.45	Daily head data points for the 03/04 calibration period provided by SAJ. Heads for the 93/94 calibration period were estimated using a least squares analysis comparing the same month in different years.	Available	Used in definition of boundary conditions
UF	112114	FMB-MZU	350747.43	785108.32	Daily head data points from 5/19/04 to 12/31/04 provided by SAJ. Many missing months were estimated using a least squares analysis comparing heads from the same month in different years. The months from Jan to Apr in both years were estimated using a least squares analysis comparing the heads at this well to those at 120311, 130245, 100868, 130556, and 130022	Available (Note: This well screen is very low. The TDS for this well was not used in the interpolation of the starting conditions, but is used here to estimate the effective freshwater head for definition of the boundary conditions.)	Used in definition of boundary conditions

Table C2: Description of data availability and decisions for inclusion in the definition of side boundary conditions for aquifer layers (not including Surficial Aquifer System).

Layer	SAJ Model ID	Well Name(s)	X	Y	Water Level Data Availability	TDS Data Availability	Boundary Head Decisions
UF	100701	USGS 262435081535101 L-1634	362680.26	755935.03	One to two head data points available for most months in both the 93/94 and the 03/04 calibration periods. Heads for the missing months were estimated using a least squares analysis comparing heads from the same month in different years. Feb 94 and Feb04 heads were estimated using a least squares analysis comparing the heats at this well to those at 130557, 130556, 130472, 130524, 100570, and 130552.	None	Used in definition of boundary conditions
UF	112128	I75-MZ2	416556.67	668295.47	Daily head data points for the 03/04 calibration period provided by SAJ. Heads for the 93/94 calibration period were estimated using a least squares analysis comparing the same month in different years.	Available	Used in definition of boundary conditions
UF	112143	BICY-MZ2	554522.19	567147.92	Daily head data points for the 03/04 calibration period provided by SAJ. Heads for the 93/94 calibration period were estimated using a least squares analysis comparing the same month in different years.	Available	Used in definition of boundary conditions

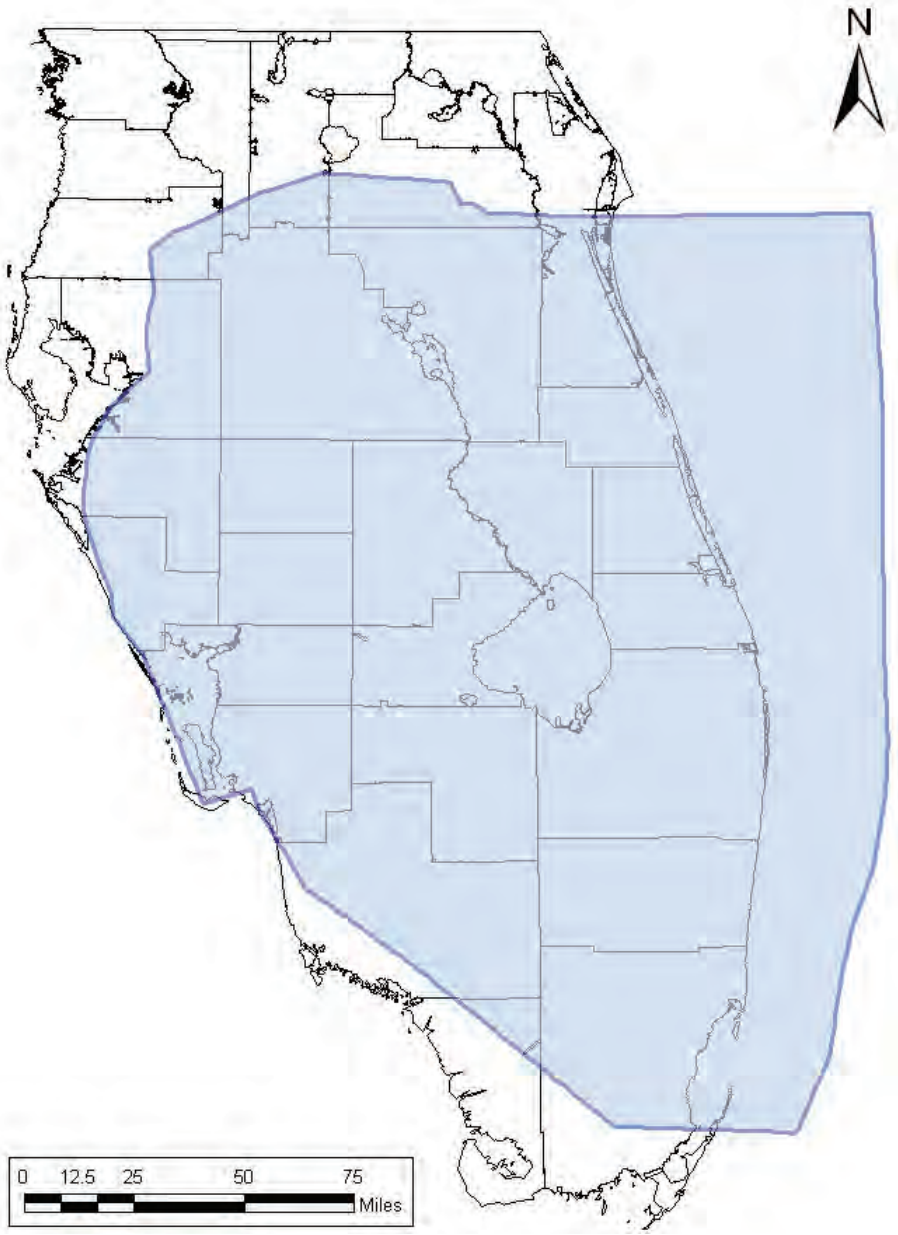
Available. This value is not used for the TDS starting condition interpolation. The interpolated TDS at this location is about 34000. The EFH will be calculated using the measured value of 7620.	Used in definition of boundary condition (averaged with 120053 and 120079)

Table C2: Description of data availability and decisions for inclusion in the definition of side boundary conditions for aquifer layers (not including Surficial Aquifer System).

Layer	SAJ Model ID	Well Name(s)	X	Y	Water Level Data Availability	TDS Data Availability	Boundary Head Decisions
BZ	120079	OR0668	593335.24	1515450.47	Daily head data points for the 03/04 calibration period provided by SAJ. Head values for the 93/94 calibration period estimated based on least squares analysis comparing monthly average heads from the same months, but different years.	None. The interpolated value in the BZ is about 34000. Since this well is actually in the LC, the EFH will be calculate using the interpolated LC TDS, which is 9926.	Used in definition of boundary conditions (averaged with 120053 and 100979)
BZ	120060	OR0465	536035.57	1536998.24	25 head data points covering most of the 93/94 calibration period and all months of the 03/04 calibration period provided by SAJ Head values for missing months estimated based on least squares analysis comparing monthly average heads from the same months, but different years.	None	Used in definition of boundary conditions



Notes:

This model boundary was developed based on bench-scale and Phase 1 modeling.

North, west and south boundaries are placed to pass through convenient monitoring wells.

The east boundary roughly corresponds with the layer outcrops in the Atlantic Ocean floor. Layers above the Boulder Zone do not extend all the way to the pictured boundary, but cut off at the approximate location of the ocean outcrop. The SAS (surface layer) extends only to the coast line on the east coast.

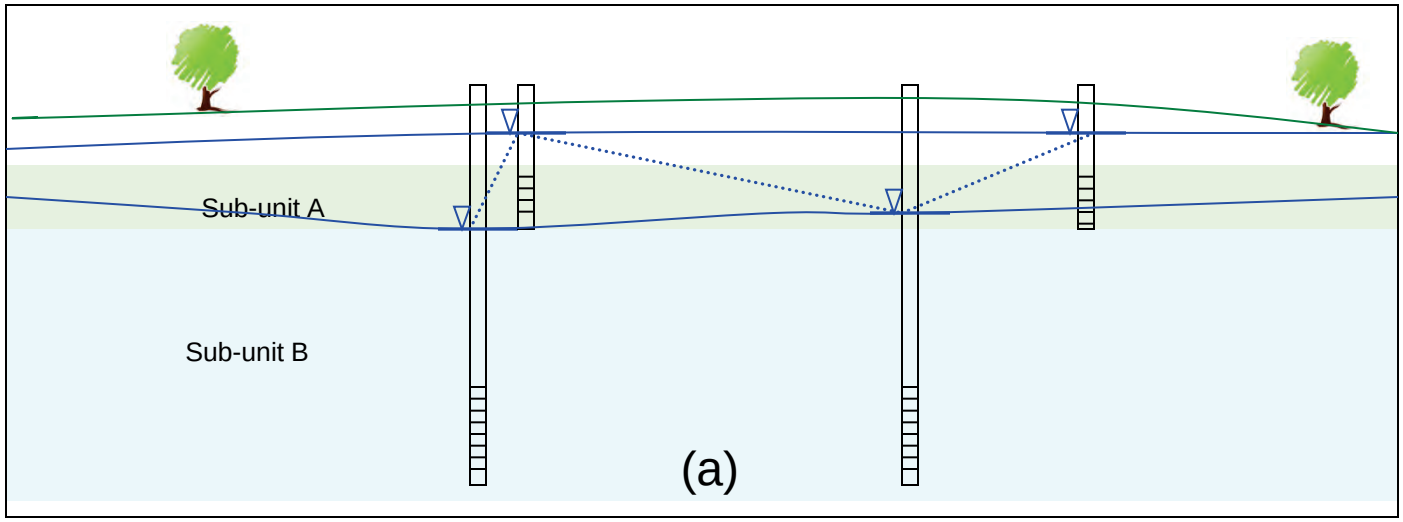
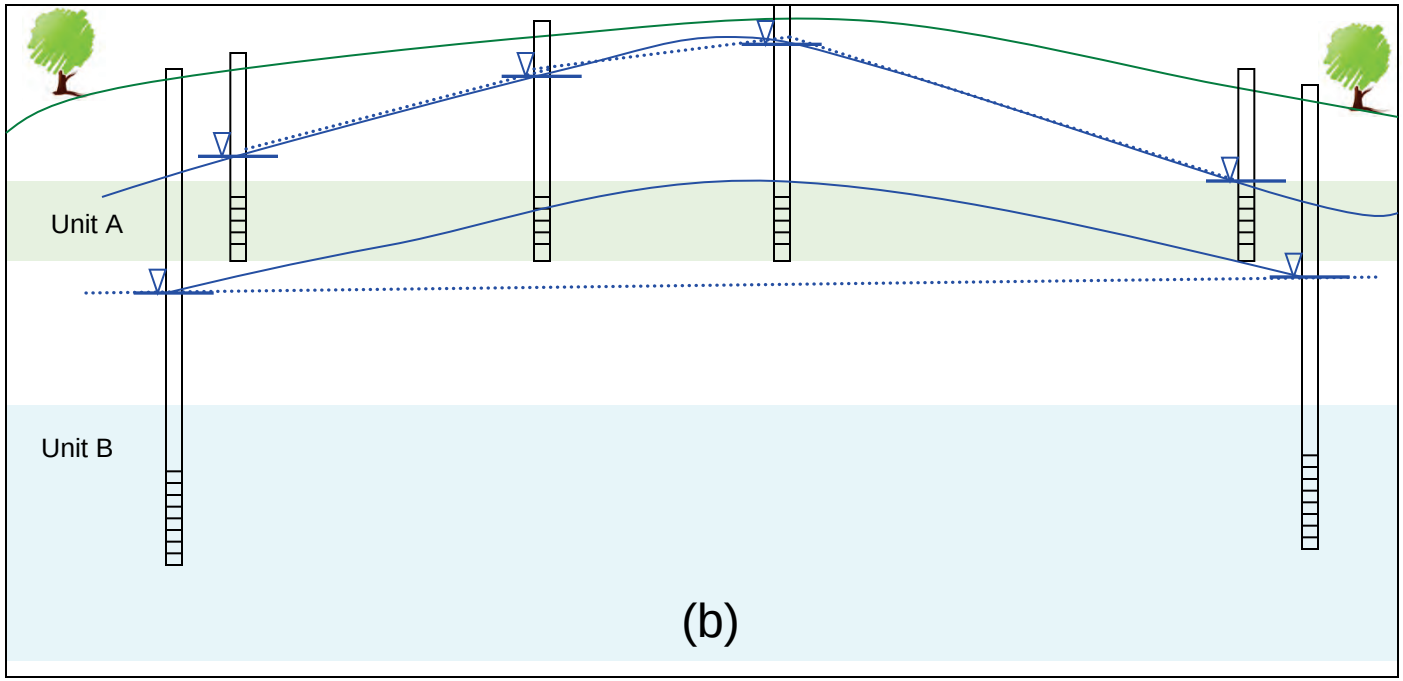
Final Groundwater Model Calibration Report

Figure C1-1

April 2010





Legend

- Ground Surface
- Water Table
- Interpolated Water Table
- Measured Water Level
- Monitoring Well

Notes:

(a) Because the hydrogeologic framework had to be simplified for the regional ASR model, sometimes there are areas where more than one distinct sub-unit is included in a single unit of the model. When wells are screened in separate units and are placed close together, the disparate heads can cause steep slopes in the linearly interpolated heads when all wells are used.

(b) Deeper layers often have sparser data sets. In this example, the center of the image is a recharge area and it affects both shallow and deep aquifers. Because of the sparse data in Unit B, the recharge area is not delineated by the available data. In some cases this can lead to significant differences in the interpolated water tables between deep and shallow zones.

Interpolation Problems for FAS Boundary Conditions

- Monitoring Well

Notes:

(a) In this cartoon, two heads have been measured and a linear interpolation of the measured heads is used to assign boundary conditions to the three cells between the monitoring wells. Because a sudden change in TDS occurs between these wells, the Equivalent freshwater head results in unusual flow conditions between the measured heads. Since the model solves the flow equations using the Equivalent freshwater heads, these steep slopes and slope changes may prove difficult for the solver.

(b) In the second cartoon, the same measured heads have been converted to Equivalent freshwater heads and the linear interpolation was performed using these Equivalent freshwater heads. This makes the flow conditions smooth and regular and will be simpler for the model to resolve. Either condition fits the measured data, but the second will result in a more stable model.

- May 2004 Interpolation

Notes:

This plot shows the heads measured at three wells designated as boundary wells in the Upper Floridan Aquifer. They are located in the north of the model. In May 2004, the water levels in all three wells were measured, showing a higher head around ROMP 101 (Polk County recharge area). Because this well was not measured in April, a strict linear interpolation of the available data does not show this high water level.

Making changes like this to the boundary conditions from month to month can cause difficulties in calibration of the model and may contribute to its instability. In this case, the model would be forced to add nearly 15 feet of water in a single stress period. This is not likely to happen naturally.

For this reason, it is important that data be available for all months of the calibration and validation period for all wells used to develop boundary conditions.

Notes:

1. This figures should be examined in combination with Figure 20.

2. The TDS, Temperature and Elevation data sets on this small set of boundary cells (Figure C2-20(a), C2-20(b) and C2-20(c)) are based in 2-dimensional interpolations of available data to the computational grid.

3. The Observed Head (Figure C2-21(a)) was assigned based on a 1-dimensional linear interpolation of available boundary data around the edge of the model. The slope change which occurs at the third cell from the left is a result of a break point added as described in Section 2.5

4. The Equivalent Freshwater Head (Figure C2-21(b)) was calculated using Equations 1 and 2 presented in Section 1.2.

5. The unusual oscillations of the Equivalent freshwater head are due to variations mainly in the elevations and TDS of the cells. Because the elevation and TDS contours are nearly parallel to the edge of the model in some areas, the blocky nature of the boundary results in these oscillations.

Notes:

(a) In some cases, the ground surface has some variability which is not reflected in the available water level data. If a simple linear interpolation of the available data is used, some areas may appear to have standing water where none is known to exist. The interpolation technique used for assigning heads to the SAS layer did not allow the assigned head to be above the ground surface except in areas where surface water was known to be found.

(b) Sometimes, wells are found near river valleys which are separated by higher ground. In these cases, we would expect the groundwater table to be lower between the rivers where recharge occurs. If no monitoring wells are placed on the higher ground, a linear interpolation will not be sufficient to accurately portray site conditions. The interpolation technique used for assigning heads to the SAS layer used a correlation relationship between head and ground surface elevation to assign heads to high ground areas with sparse data.

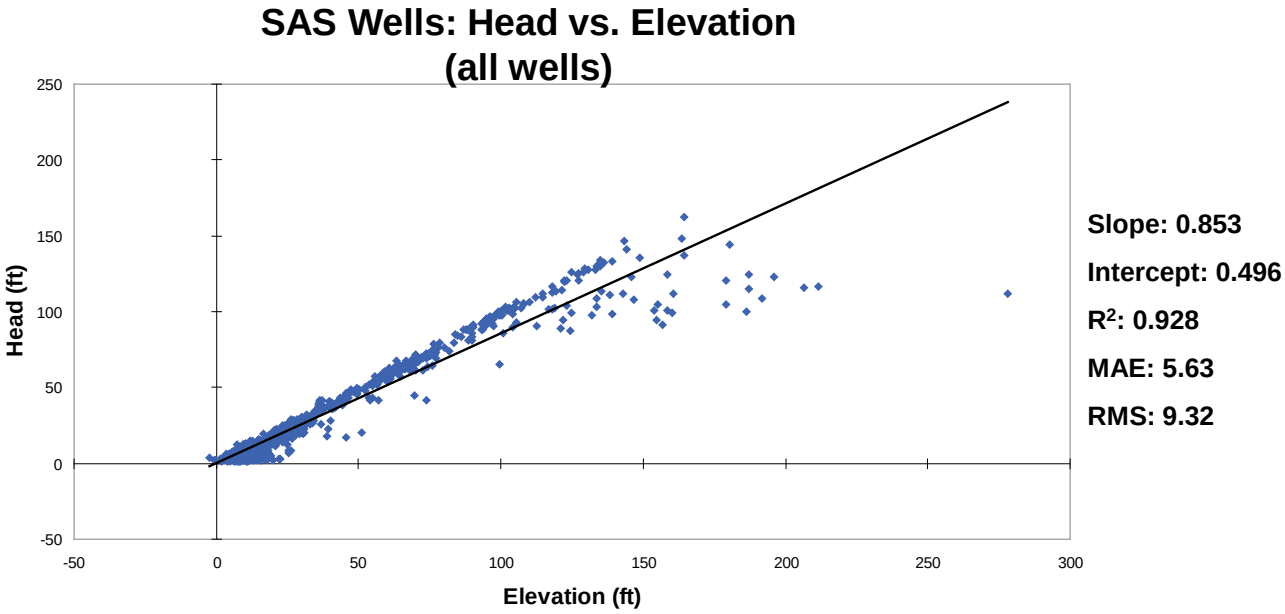
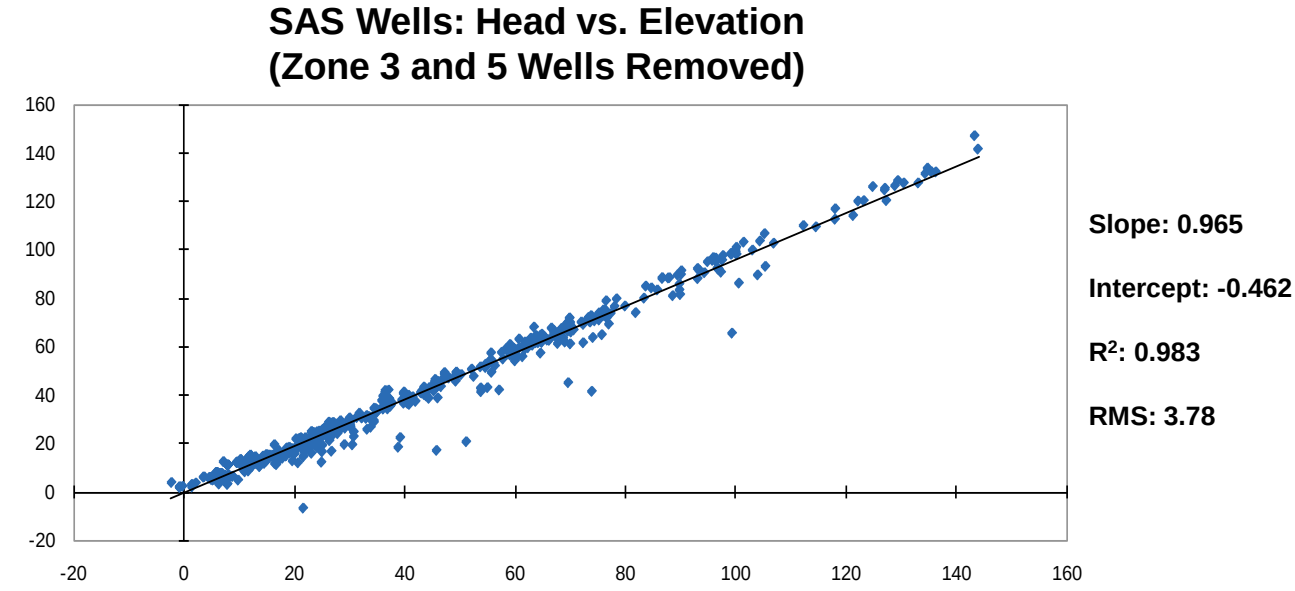
Zones for SAS Regression/Interpolation

Figure C3-3

Final Groundwater Model Calibration Report

October 2010





Notes:

The upper plot shows the correlation between head and ground surface elevation for the month of October 2003 at each well open in the SAS layer of the model. The lower plot is the same, but the points in zones 3 (ridges) and 5 (coastal areas) were removed.

Slope, intercept and r^2 values were calculated by Excel, using the SLOPE, INTERCEPT and RSQ functions to fit the data to a straight line.

MAE (Mean absolute error) and RMS (Root mean square error) were calculated by using the regression equation to estimate the head at each point and comparing this estimated head to the measured head. The MAE is the average of the absolute value of the residual at each well. To calculate the RMS, each residual was squared, they were averaged and then the square root was taken. This gives additional weight to points that have the greatest residual.

The best-fit line on the lower plot has a slope that matches well with the general trend of the majority of the points. This is the line that was used to estimate the head in zone 4. The RMS and MAE values are similar in magnitude to the expected calibration error.

Regressions for other months of the calibration and validation periods had similar statistics.

See Figure C3-3 for zone locations.

Appendix D: Pumping Data Report

Table of Contents

1.0 Introduction

The purpose of the ASR Regional model is to evaluate the large scale impacts of the proposed Comprehensive Everglades Restoration Program (CERP) ASR system on the surrounding groundwater. Prior to using this model as a predictive tool, the model must be calibrated to ensure that it reasonably simulates system responses to historic stresses. For the ASR regional model, these stresses are primarily water removal in water supply and agricultural wells scattered throughout the model domain. As with all inputs to the model, the quality of the data entered has a direct impact on the quality of the final solution. Unfortunately, pumping data is not always uniformly tabulated and collected. There were many pumping wells which provided no pumping data and many that had holes in their data sets.

The Jacksonville District (SAJ) of the Corps of Engineers was tasked with collecting, organizing and providing the pumping data to the groundwater modeling team. An exhaustive search of available data was performed as described in their Data Collection Report provided in Appendix A of the Groundwater Model Calibration Report. In order to correctly represent the pumping in the model, it was important that all wells with missing or incomplete pumping records be assigned an estimate of the pumping for each month of the calibration and validation periods. SAJ also provided the modelers with these estimated pump rates when the data was not available. The methods used to estimate these rates are also described in their Data Collection Report.

The pumping data provided by SAJ was incorporated into the regional SEAWAT and WASH123D models. It should be understood that because SEAWAT and WASH123D calculate the flow equation at their computational points (i.e. cell centers and nodes, respectively), all wells falling on the same computational point are effectively combined. For a regional scale model, this is sufficient, but near-field effects of individual wells are not well-portrayed on a regional scale with coarse resolution like that used in the regional grid and mesh, whose cell and element sizes are as large as 10,000 ft on a side. The methodology explaining how well pumping is assigned to SEAWAT cells and WASH123D nodes is described in Section 2.0 of this Appendix.

The process of model-setup and calibration of the regional model began with a steady-state model representing October 2003. None of the model results for this month caused concern. With October 2003 nearly calibrated, several other months were run to validate the original calibration. With May 2004 and September 2004, a pattern of unusual results began to emerge, indicating a problem with the pumping data. Section 3.0 of this appendix presents an evaluation of the problems and the process used to select and implement a solution.

2.0 Pumping Rate Assignment in the Regional Model

The results of the SAJ data collection effort were several tables of regional pumping data for consumptive use wells, deep injection wells and existing ASR wells. The tables contained well location information including well name, well identification number (Model ID), horizontal coordinates in Florida State Plane 1983 East, aquifer designation, depth from the ground surface to the top of open hole (cased depth), and depth from the ground surface to the bottom of the open hole (drilled depth). The tables also contained transient pumping rate data including well type, pump capacity, date

pumping, pumping rate, and a flag to indicate whether the pumping rate was reported or estimated. This data needed to be reworked into a format that could be incorporated into the SEAWAT and WASH123D models.

The first step was to determine the vertical elevations for the pumping wells. The ground surface elevation was estimated at each pump using the topographic data described in Section 3.1 of the calibration report, and then the given cased and drilled depths were subtracted from the estimated ground surface elevations to determine the open hole cased and drilled elevations. These elevations were compared against the hydrostratigraphic surface elevations for each layer to determine the aquifer(s) where the casing is open. If a pump's open hole interval overlapped more than one aquifer, the pumping rate for that pump was divided among the multiple aquifers based on the percentage of the open hole in each aquifer. The confining units were not considered in this computation. For example, if 15% of a pump's open hole overlapped the Upper Floridan (UF), 50% overlapped the Upper Middle Confining Unit (MC1), and 35% overlapped the Avon Park Permeable Zone (APPZ), then the pumping rate was distributed so that 30% of the rate was assigned to the UF and 70% was assigned to the APPZ. If the pump's open hole interval completely overlapped a confining unit, then judgment was used to determine the vertical location of the pump based on the proximity to aquifers, the pump's aquifer designation, the pump name, well drilling reports, or other available data.

Special consideration had to be given to pumping assignments in the Surficial Aquifer System (SAS) and the Intermediate Aquifer System (IAS) as a result of their geologic conceptualizations, described in Section 3.0 of the main report. Because the SAS has an assigned head, no head computation will occur in the SAS layer so pumping stresses will have no impact on the SAS heads. Therefore any wells found to pump from the SAS were removed from the data set. The Intermediate Aquifer (IA) portion of the IAS only occurs in the western portion of the model in the middle third of the IAS layer. For pumps found to be located horizontally and vertically within the IA, pumping rates were distributed by the percentage of the open hole overlapping the conceptualized aquifer. For example, for an open hole whose open interval was 10% in the SAS, 15% in the upper third of the IAS (ICU), 20% in the middle third of the IAS (IA), 20% in the lower third of the IAS (ICU), and 35% in the UF, the distribution of the pumping rate would be assigned with 54% of the rate coming from the UF and 31% of the rate from the IA. The 15% of the pumping rate in the SAS is removed from the data set. Pumps located horizontally outside the boundary of the IA but located vertically within the IAS were determined to be within the SAS or the UF based on proximity to the SAS or UF, the pump's aquifer designation, the pump name, well drilling reports, or other available data.

Once aquifers were identified for each pump, their pumping rates were assigned to the grid and mesh. The pumping rates were incorporated into the SEAWAT grid using the *Map to MODFLOW* tool in GMS and into the WASH123D mesh using the *Map to FEMWATER* tool. These tools determine the location of the model computational point(s) for each pumping well given the well horizontal and vertical location. For SEAWAT, the location is the center point of the model grid cell containing the well and for WASH123D, the location is the node nearest to the well location. Due to the differences in computational points for the two codes, the pumping rates were applied somewhat differently in the two models.

For the SEAWAT grid, if a pump was horizontally and vertically located within a cell, its pumping rate was applied to the center of that cell. Therefore in the case of a 10,000-foot by 10,000-foot cell, the rates of all wells existing within that cell are totaled and applied to the same computational point. If the pump's open hole overlaps several vertical cells, the pumping rate for that pump is split up among the vertical column of cells in proportion to the coverage of each of the cells by the well open interval. The GMS tool *Map to MODFLOW* totals and applies the pumping rates for each cell automatically.

For the WASH123D mesh, pumping wells must have horizontal coordinates that coincide with its computational points, the mesh nodes, to be assigned correctly with the *Map to FEMWATER* tool in GMS. Thus, the actual horizontal locations of the pumping wells must be manually adjusted to match mesh nodes. This adjustment was made by generating a two-dimensional mesh with horizontal node locations coincidingwith pumps (or pumping centers made up of several pumps) having rates higher than 100,000 cubic feet per day. The remainder of the 2D mesh to the model boundary was filled in with nodes at 10,000-foot spacing. The locations of pumps with lesser rates were moved to coincide with the nearest 2D mesh node. Once each pump was adjusted to coincide with a mesh node, the open hole intervals were evaluated to ensure that each pump's open hole interval overlapped the appropriate aquifer nodes in the 3D mesh. If the pump's open hole interval overlapped several vertical nodes, the pumping rate for that pump was split up among the vertical column of nodes in proportion to the hydraulic conductivity of the elements surrounding the nodes. The GMS tool *Map to FEMWATER* was used to total and apply the pumping rates to the mesh nodes.

3.0 Pumping Rate Problem Identification

During the calibration process, a reasonable preliminary steady state calibration to October 2003 data was achieved (see Figure D3-1). Further, initial testing of a transient model for the period data between October 2003 and December 2004 showed a coarse agreement between calculated and observed heads. However, with the development of steady state models for other months of the period, distinct patterns were computed by the numerical models that were not supported by the existing water level data. Figures D3-2 and D3-3 show examples of these patterns. Figure D3-2 shows the model results of the Upper Floridan aquifer for May 2004, using parameter values developed during the steady state calibration of October 2003. In this figure, distinct cones of depression can be seen northwest of Lake Okeechobee, primarily in Highlands County (within the red box). These cones of depression are relatively widespread and can reach up to 100 ft in depth. Available water level data does not indicate a water table depression of this magnitude in this area. The inset verifies (as expected) that these depressed areas are caused by the presence of wells which pump at high rates. It also indicates that most of the wells at the centers of these cones are irrigation wells. A second example of an anomalously large cone of depression can be seen in Figure D3-3. This figure shows the computed results for the Upper Floridan aquifer for the September 2004 period. During this period the large cones of depression seen in Highlands County are no longer present; instead, a distinct cone of depression in northern St. Lucie County (within the red box) is predicted by the model. Again these water levels were not supported by the available water level data.

The poor calibration achieved for May 2004 and September 2004 when the same parameter values yielded a good calibration for October 2003 indicated a problem with either the data or the conceptualization of the system. The fact that the areas of greatest concern for both May 2004 and September 2004 corresponded with the locations of pumping wells with large pump rates, pointed to a problem with the pumping data. For this reason, a closer look was taken at the pumping data and the methodology used to provide estimated pump rates for wells without a complete pump record. The following sections describe the evaluation performed, the search for a solution and the selection of a path forward.

3.1 Problem Evaluation

Since the pumping was suspected to be the cause of the calibration problems, the modeling team re-evaluated the pumping data provided by SAJ, beginning with the September 2004 period. As shown in Figure D3-3, a significant cone of depression was computed in the vicinity of St. Lucie County. The pumping data provided for September 2004 calibration was compared to the results of an analysis provided in February 2007 by the SFWMD (Center for Hydrology & Water Resources, 2007). The water management district provided this information in response to concerns raised during the initial data evaluation subsequent to the Phase I modeling effort regarding the significant pumping data gaps identified. Although it had been expected that this data would be integrated into the pumping data, some discrepancy still existed between the original data provided by SFWMD and the final pumping data set. The inset figure (right side of Figure D3-3) shows a blow up of the September 2004 St. Lucie cone of depression, as well as the pumping well locations. Data from SFWMD is indicated with an "X" and the SAJ database data is marked with a "DOT." Each pumping location is colored based on the magnitude of the pumping with blue being lower magnitude pumping and red being higher magnitude pumping (up to 250,000 cfd). Remember that the dots indicate the pumping magnitude that was used in the calculation of the head contours shown. The map shows numerous locations where the pumping in September 2004 is significantly higher in the SAJ data set than the SFWMD data set (blue X's over red dots). These locations correspond to the deepest portions of the cones of depression shown. The figure also shows that the overall pumping in the area is much higher in the SAJ data than in the SFWMD data – few of the x's are any closer to the red end of the spectrum than a light blue or green color.

Further analysis compared the September 2004 pump rates from the data base with the October 2003 pump rates. Remember that the October 2003 pump rates yielded a reasonable calibration. In Figure D3-4, the magnitude of the October 2003 pumping is indicated by the color of the "X" marking the well location. Similarly, the September 2004 pump rates are indicated by the color of the "DOT" at the same location. Each pumping location is again color coded by magnitude with blue being lower magnitude pumping and red being higher magnitude pumping (up to 250,000 cfd). The contours shown on this figure are from the September 2004 model run using parameter values which resulted in a well-calibrated October 2003 steady state run. At several locations the pumping reported for September 2004 in the SAJ database is significantly higher than that provided for October 2003 (red dots over blue X's). This higher pumping causes the significant computed cone of depression in September 2004, which does not appear in the October 2003 calibration runs.

Based on this initial evaluation, it appeared that the high magnitude pumping at a few wells in the September 2004 SAJ data set was the cause of the unexpected cone of depression in the St. Lucie County area. Discussions with SFWMD indicated that their pumping data was from an in-depth study of irrigation pumping in the St. Lucie County area. Since the SAJ estimates were based simply on the comparison of known pump rates to the pump capacity or allocation, the SFWMD pumping estimate would be more representative of the actual pumping. Unfortunately, since the SFWMD data is only available in a small area of the model domain, it could not solve the data problem for the entire model domain.

The next step in the evaluation was to determine if the high magnitude pumping observed in the SAJ database was based on reported or estimated data. Reported data consists of pumping rates provided by one of the data sources for each month of the calibration period. For wells where no reported data was provided but there was reasonable certainty that the well was pumping, the rates were estimated. In all cases examined, large pumping rates which caused significant and unexpected cones of depression were the result of estimated pumping data, not reported data. This evaluation also indicated that the types of wells causing this problem were primarily irrigation/farming wells. Notice that Figure D3-2 shows that almost all of the wells located near the centers of the anomalous cones of depression in Highland County for May 2004 are irrigation wells.

The SAJ pumping data (including both reported and estimated pumping rates) indicated that nearly 2000 irrigation wells in the model domain were pumping at 85% or more of their pump capacity in September 2004 (Figure D3-5). However during September 2004, Florida was affected by three major hurricanes (Frances, Ivan and Jeanne). Both Frances and Jeanne caused significant precipitation across a large swath of the model domain, resulting in one of the wettest months in the last 15 years. With so much rain in such a short period of time, it would be unlikely that irrigation needs from the wells would be so high. Figure D3-6 shows the location of irrigation wells listed in the SAJ database with pump rates more than 85% of their capacities. This figure shows that these high pumping rate irrigation wells are in all three of the Water Management Districts covered by the model and many are in the vicinity of the two problem areas already identified in Highlands and St. Lucie Counties (Figures D3-2 and D3-3).

Additional analyses compared the long term trends of the reported and estimated pumping data at wells divided into geographic zones shown in Figure D3-7. These zones were roughly based on similar physiographic and hydrogeologic properties, not necessarily on Water Management District Boundaries. Due to the availability of the SFWMD study of irrigation wells in Zone 1 and lack of major Floridan irrigation pumping in Zone 2, the following evaluation is only presented for Zones 3, 4, and 5. For the October 2003 to December 2004 period, there were 5,669 irrigation wells with reported pump data for all months, 4,206 irrigation wells with reported data in some of the months, and 6,628 wells with no reported data. For each zone the reported and estimated pumping data was normalized by dividing the reported rate by the pump capacity/allocation. The distribution of the average normalized pumping rate for wells with reported data is shown by month (October 2003 to December 2004) on Figure D3-8. Although there are minor variations between the zones, the general trend shows higher pumping in the dry season (spring and early summer) and lower pumping in the wet season (late summer and fall) as expected. When compared to the monthly rainfall data in Polk County, shown in Figure D3-9, a distinct

inverse correlation can be seen, where pumping increases in low rainfall months and decreases in high rainfall months. The data in Figure D3-8 also shows that the reported pumping rate is on average less than 20 percent of the capacity/allocation even in the driest months. This average percentage of pumping capacity is also consistent with the data provided by SFWMD for Zone 1.

Figure D3-10 shows the comparison between the reported and estimated pump rates as a percentage of the capacity/allocation averaged across all irrigation wells in Zone 5. There are two main concerns illustrated in Figure D3-10. First, the estimated data is five to thirty times higher than the reported data when considered as a percentage of capacity or allocation. Secondly, the seasonal variations applied to the estimated data do not match either the reported data or the expected variations. Generally, pumping would be expected to be highest during dry periods when rainfall is not sufficient for the fields and orchards. When rain is abundant, pump rates would be expected to fall. The highest pump rates in the estimated data occur in July 2004. Although Figure D3-9 shows that although July's precipitation is about half of September's, it is quite a bit larger than nearly all other months of data. (This same precipitation trend is repeated in numerous weather stations throughout Florida.) Further, the lowest estimated pumping rates occur in January 2004, which has one of the lowest rainfall measurements of the period. The estimated pumping rates clearly do not correlate with the known meteorological conditions at the time.

The concerns with the methodology for estimating missing pump data are further illustrated by looking at selected individual wells. An example of this can be seen on Figure D3-11 at the irrigation wells in Northern St. Lucie County in the center of the anomalous water table depression computed by the model in September 2004. This figure shows that the maximum pumping rate (94 % of capacity) was estimated in September 2004, which has already been shown to be one of the wettest on record. The pump rates for the entire period seem completely uncorrelated to the precipitation data. It is also suspicious that exact pump rates are repeated for seemingly unrelated months. For example, March 2004 and September 2004 have identical estimated pump rates. Similarly, February 2004, August 2004 and December 2004 have identical rates.

This analysis clearly indicates that the original methodology used to fill gaps in the available pumping data was flawed. When it is totaled up across all the irrigation wells in the model domain, the difference between the estimated and reported pump volumes is on the order of tens to hundreds of millions of gallons of water per day (depending on the month). Clearly, this discrepancy severely impacts model calibration. A new process for estimating missing pump rates was necessary in order to adequately calibrate the model for all time periods of concern.

3.2 Solution

In order to calibrate the regional ASR model, it was necessary to revisit the available pump data and develop a new methodology for estimating pump rates where data was not available. The majority of the problems found in the data set from SAJ were with the agricultural or irrigation wells, so they have been handled separately from the remainder of the wells. This section describes the process used to analyze the data and estimate missing values.

3.2.1 Agricultural/Irrigation Wells

In the SAJ Data Collection Report (provided in Appendix A), the method employed to estimate pump rates for irrigation/agricultural wells with missing data is described. The methodology involved dividing the wells up by county, calculating the average pumping across each county as a percentage of capacity/allocation and then applying this percentage to the wells and months with missing data. Our analysis showed that some errors must have been introduced during the process because those percentages do not hold true for all wells and are significantly larger than the percentages calculated on the wells with sufficient data. The main concerns with this method are twofold. First, it separates the data into groups based on county boundaries, which have no known physical relationship to either water availability or water needs. Secondly, it assumes that pump capacity or allocation is directly related to the water needs of each user. The available data shows that this is not always true. For example, based on the reported pump rates, the average usage for October 2003 was 5.8% of the capacity. But the standard deviation is over 10% and the median rate as a percentage is only 2.4%, meaning that there is a wide spread in the values and 50% of the values are below 2.4%. These statistics indicate that there are a lot of agricultural wells whose reported (not estimated) usage in October 2003 was nowhere near the average usage of 5.8%. These may be permit owners who did not correctly calculate their usage requirements or who have changed their usage since receiving a permit.

The issue is clarified in Figure D3-12, which shows the pumping data for four randomly selected wells from the data set. These four wells all have complete data sets in the SAJ database and are scattered across the model domain. The only one of the four that appears to follow the general seasonal usage which is inversely proportional to rainfall is the Palm Beach Country Club. Aerial photos indicate that this water is most likely used to irrigate a golf course. Water usage at this well is low in August and September when rainfall is high. Conversely, water usage is highest earlier in the summer when rainfall is low. However, although the shape is similar to the average usage seen in the rest of the data set, the percentages of capacity are significantly higher than average. In October 2003, the average usage was 5.8% of the capacity, while this well used nearly 30% of its capacity.

The other three wells all have unusual usage rates. Aerial photos show all of these wells are near farmland which appears to be growing various tree crops such as citrus fruit. The Oak Island Citrus well has low usage rate throughout most of the first year, with a sudden, stark increase in usage during August, September and October. These are the months when evapotranspiration would be expected to be highest, but these are also the months when rainfall was highest. There is also no known explanation for the high usage in December 2004. The Evans Properties and Lykes Block wells have similar unexplainable variations in usage during the period in question. Figure D3-13 presents the same data as a normalized pump rate for all four wells together.

These problems were addressed by first attempting to find a geographic method of separating the wells into groups based on their data or other available characteristics – not on something as arbitrary as the county boundaries. A geographic separation of groups would allow us to assign the wells with no data or very little data to the appropriate group. Making the division based on the available data would assure that the known data in each group could be used to accurately estimate the pump data for the

wells with sparse or non-existent data in the same group. Unfortunately, all efforts to divide the wells into groups based on their data failed, despite analysis of the data as reported pump rates, percentages of capacity, percentages of another month's data, etc. Only about 50% of the wells have data closely correlated with precipitation data. These wells are scattered all across the domain and are interspersed with wells that seem to have no correlation to any seasonal changes. The zones described in Section 2 were chosen somewhat arbitrarily, with some attention to physiographic regions. Although these zones spread across two-thirds of the model domain and include the majority of the wells, there is very little variation in the pump rates when expressed as percentages of the capacity or allocation.

Some effort was expended in looking for a way to divide the wells based on the type of crop being irrigated. Although SFWMD was very helpful in providing extensive information on the methods used to calculate water needs based on crop type, no data was easily available to determine what crop was being served by each well. SAJ was unable to provide this type of data. Land-use GIS coverages indicated only that the land was used for agriculture – not the specific type of agricultural activity. Internet searches yielded little information and well permit applications obtained online did not request information on the use of the water being allocated. It might be possible to use aerial photographs to make assumptions on water use based on the types of fields nearby. However, this would be a time-consuming and likely inaccurate process. Aerial photos might be out of date and the wells might not be located exactly at the field they are irrigating.

Additional work was performed to find a statistically significant correlation between rainfall at the nearest weather station and the pump rate at each well. However, the correlation was weak and not within acceptable confidence intervals.

In an effort to remove the dependence of this methodology on the capacity or allocation of each well, comparisons of pump rates were made between months. However, this analysis ignored nearly 42% of the wells since they had no reported data in the database. Further, an additional 2% of the wells were removed from the analysis because they had only three or fewer months with available data. Using this month-to-month comparison of available data, it was found that nearly 50% of the wells statistically fit into a group in which the May 2004 pumping was approximately three times the January 2004 pumping rate and April 2004 pumping was approximately 22 times the September 2004 pumping rate, for example. Similar ratios were calculated between all other months of the period. Although only 50% of all agricultural wells fit into this group, it was actually 86% of the agricultural wells with sufficient data. And these wells were spread across the entire model domain. Additional groupings of wells were found, but were all very small and none were geographically grouped. Without a geographical grouping, it was impossible to determine the grouping of wells with no data or very little data. For this reason, only the first grouping (including about 86% of the wells) was used to estimate missing pumping data.

Using this month-to-month comparison of pumping rates, missing data was filled in for all wells with a partial data set. If a well had no available data, the average pump rate as a percentage of capacity was used to estimate one month and then the month-to-month ratios were used to calculate the remaining months. The pumping obtained in this way was compared to the pumping obtained using only the average ratio of pumping to capacity for each month (described below). The differences were negligible

– especially on a regional scale. For this reason, the simpler of the two methods was used and is described in detail in the following section.

3.2.1.1 Final Method for Estimating Missing Pumping for Agricultural Wells

The method selected for estimating the missing pumping data for agricultural wells involved comparing the pump rate for each well and each month to the capacity or allocation for that well. Where all the data was missing, the average percentage of capacity being pumped across all the wells was used to fill in estimated pump rates. Where some data was missing, the available data was used to offset the average percentages for filling in the missing months. The method is described in detail here.

1. Reported data was separated from estimated data in the SAJ database. If the flag was zero, the data value was assumed to be a reported value. The exception was for those wells with model IDs between 20000 and 39999 (Southwest Florida Water Management District data). In these cases, if the data value was a zero, it was assumed to be a reported data value regardless of the flag. (See the SAJ Data Collection Report provided in Appendix A.) Values estimated by SAJ were removed from the data and replaced with empty cells.

2. For all reported data values, the fraction of the capacity/allocation was computed by dividing the pump rate by the capacity or allocation. No calculation was made for empty cells (missing data).

3. For each month all of the calculated fractions were averaged by summing them and dividing by the number of wells with reported data in that month. Figure D3-14 shows these averages. As observed above, these averages show an inverse correlation to precipitation (see Figure D3-9 for Polk County precipitation as an example).

4. The ratio between each known pump rate as a fraction of capacity and the average pump rate as a fraction of capacity was computed by dividing the result of step 2 by the result of step 3 for each known data point. For example, if a certain well was pumping 11.6% of its capacity/allocation for the month of October 2003, the ratio to the average would be 2, since the average pumping for October 2003 among known data points was 5.8%. This would tell us that this well was pumping at twice the average when reported as a percent of capacity or allocation.

5. For wells with at least one month of data, the ratios computed in step 4 were averaged for each well. For the example presented in step 4, imagine that in November, the pump rate was 6.9% of the capacity/allocation. Since this is the average rate among all wells, the ratio for November calculated in step 4 would be 1.0. If these were the only two data points, the average for this well would be 1.5 (the average of 1 for November and 2 for October), indicating that on average, this well was pumping 150% of the average when reported as a fraction of the capacity/allocation.

6. Fractions of the capacity/allocation are listed for every well and every month.

a. If reported data is available for every month, the fractions calculated in step 2 is listed.

b. If reported data is available for some, but not all of the months in the period, the fractions calculated in step 2 are listed for the months with available data. For the months with no available data, the fraction is estimated by multiplying the average for the well calculated in step 5 by the average for all the wells for the month in question calculated in step 3. For the hypothetical well mentioned above, the averages for months missing data (December 2003 through December 2004) were multiplied by 1.5 to obtain an estimated fraction. For December 2003, the average pumping for all wells with data was 7.3% of the capacity/allocation. Thus, for this hypothetical well, the fraction for December would be 10.95% (1.5 times 7.3%) of the capacity/allocation.

c. If reported data was not available for any month of the period, the averages calculated in step 3 were assigned to each month.

7. Pump rates were calculated by multiplying the capacity/allocation reported for each well by the fraction calculated in step 6 for each month. Pump rates were not allowed to exceed the capacity/allocation. If the fraction was over 1.0, the capacity/allocation was assumed to be the pump rate for that month.

There were two exceptions to the above process. First, for wells which had a drill date or abandonment date within the calibration period, the zero pumping months before drilling or after abandonment were not included in the average calculated in step 5.

Secondly, initial runs with this pumping data indicated too much pumping in the area just north of Lake Okeechobee (see Figure D3-15). Agricultural wells in this area were separated and their pump rates as ratios to their capacities were averaged separately. The averages were slightly different than the average calculated for the data set as a whole and are presented in Figure D3-15. These averages were used in place of those shown in Figure D3-14 for missing pumping data in this area.

3.2.2 Other Wells

As a result of so many questionable pumping rates estimated for the irrigation wells, the pumping rates for other well types were analyzed to see if their estimated rates appeared to be reasonable. These pumping well types included recreational wells, mining/dewatering wells, commercial/industrial wells, air conditioning wells, domestic/private wells, aquaculture wells, freeze protection wells, Orlando drain wells, injection wells, and public water supply wells. These well types are not generally related to rainfall or meteorological conditions so a comparison to the reported data is the only means of assessing whether the estimated pumping appears reasonable. For each well type, the reported pumping rates for wells of each type were normalized by the well capacity and compared to the estimated values normalized by the well capacity. The results for each well type are summarized below. It should be noted that existing ASR wells are not included on this list. As described in the Data Collection Report, each ASR facility was contacted to obtain daily pumping data during the time periods of interest so none of the existing ASR pumping rates were estimated.

1. Recreational wells (671 wells), Mining/Dewatering wells (90 wells), Commercial/Industrial wells (471 wells) and Air Conditioning wells (5 wells): A comparison of the estimated pumping rates to the reported pumping rates demonstrated that the estimated values are reasonable for these well types. For the recreational wells, all pumping rates within the 2003/2004 time period were reported data and some estimates were required for the 1993/1994 time period using the ratio of reported pumping rate to pump capacity for each well per month. For the mining/dewatering wells, only 2 wells required calculating estimated values. The ratio of reported value to pump capacity used to compute the mining/dewatering estimates is reasonable. For the commercial/industrial wells, only 104 wells required pumping rate estimates to be calculated. The reported pumping rate to pump capacity ratio used to make the estimates is slightly low but the estimated values are not unreasonable. For the air conditioning wells, only one well was completely estimated and 4 wells were partially estimated. The reported pumping rate to pump capacity ratio used to make the estimates is slightly low but reasonable for these minor pumping wells.

2. Domestic/Private wells (10,165 wells): There are no reported values for these well types. These well pumping rates are estimated based on the logical methodology described in the Data Collection Report. These pumping rates are all very low values, as expected for domestic and private wells. The range of values is from a low withdrawal of 0.2 cubic feet per day (cfd) to a high of approximately 2,300 cfd but the majority of the withdrawal rates are in the 40 to 50 cfd range. Because the rates are so low, it is not likely that these rates have a significant impact on the regional model calibration. No adjustment was made to these estimates.

3. Aquaculture wells (20 wells): There are 18 wells that are completely estimated and 2 wells that are partially estimated. The reported values have a maximum pumping rate of approximately 300 cfd. The estimated values were as large as 141,000 cfd and 81,000 cfd at 11 of the estimated wells. These estimates were too high compared to the reported data. It was confirmed by SAJ that these well types were lumped with agricultural well types because the term “farms” was included in the well name. However, these farms are seafood farms and there rates vary differently than agricultural wells. The rates for these wells were revised by normalizing the reported data by the pump capacity and using that ratio to determine the pumping rate estimates. The resulting maximum estimated pumping withdrawal was 1,400 cfd.

4. Freeze Protection Wells (124 wells): There are two general areas where wells labeled “freeze protection” are located: northeast of Lake Okeechobee and southwest of Lake Okeechobee. The maximum reported values provided for these two areas, respectively, was 10,000 cfd and 35,000 cfd. Estimated values provided for these two areas were as high as 76,000 cfd (northeast of Lake Okeechobee) and 200,000 cfd (southwest of Lake Okeechobee). Also the maximum ratio of reported data to pump capacity is 30% while the maximum for the same ratio in the provided estimated data was 80%. These pumping rate estimates were too high. In looking at the data provided, six facilities were identified that have reported pumping rates:

a. Six L's Farms has many pumps that pump all year long. It's possible that these wells are actually used for irrigation rather than freeze protection, since it is expected that freeze protection would only be required during certain parts of the year.

b. Highlands Citrus Grove has reported data and estimated data. The reported pumping rates are approximately 30% of the pump capacity.

c. Southern Grove and LaBelle Grove have rates of 0.0 cfd for each month.

d. A Green's Citrus Grove has reported values of approximately 3% of the pump capacity and is located within Hendry County

e. River Country Land and Cattle – reported pumping in 1993 and 1994 only at rates approximately 6% of the pump capacity and is located within Okeechobee County

Based on the reported rates at these facilities, it was decided that Six L's Farms wells would not be used to estimate pumping rates since it seems likely that these are actually irrigation wells. Also the Highland Citrus Grove reported well rate to pump capacity ratio appeared high for these well types and was used to estimate the unknown pumping rates at Highland Citrus Grove only. The known pumping rate to pump capacity ratio at A Green's Citrus Grove was used to estimate the unknown pumping rates southwest of Lake Okeechobee. The known pumping rate to pump capacity ratio at River Country Land and Cattle was used to estimate the unknown pumping northeast of Lake Okeechobee. With these changes, the resulting pumping rate estimates were considerably lower than the estimates provided. For example, at LaBelle Drainage District, the maximum estimated pumping rate was revised from 200,000 cfd to 16,000 cfd.

5. Orlando Drain Wells (25 wells): All of the pumping for the Orlando drain wells is estimated. Drain wells are used to inject street runoff in the City of Orlando area to the UF aquifer in order to minimize flooding and control lake levels. The estimates provided did not appear to be related to rainfall patterns although it seems likely that months with high rainfall values, like September 2004 as mentioned in Section 3.1 of this appendix, should have the highest injection values. Adjustments were made to the computation of the drain wells estimates described in the Data Collection Report as follows. As part of the study by Sepulveda (2002), these drain wells estimates were made in cubic feet per second per year for the 1993/1994 time period. These estimates were converted to cfd units and the value was adjusted in each month based on the percentage rainfall in that month to the total for the 1993/1994 time period. The rainfall data was collected from the NOAA rainfall gage at Orlando, Florida. To find the 2003/2004 values, the 1993/1994 cfd/year was adjusted by the ratio of the 2003/2004 rainfall over the 1993/1994 rainfall. That new 2003/2004 yearly cfd was adjusted for the percent of rainfall for each month in the 2003/2004 time period. As a result of the changes the maximum estimated injection for the drain well decreased from approximately 75,000 cfd to 16,000 cfd.

6. Injection wells (120 wells): As stated in the Data Collection Report, the pumping rate data for these wells was verified by calling each facility. A few updates were made to these data sets including correcting pumping rates that were not placed in the correct month, changing an assumption that led to very small injection rates instead of a more appropriate rate (for example 0.13 cfd was revised to be 19,295 cfd) and re-contacting a facility to obtain data not previously received. Of the 120 wells, only 4 wells required updated pumping rates.

7. Public Water Supply wells (2,046 wells): Of the well total, there are 385 wells with reported pumping rates, 475 wells with partially reported data and partially estimated pumping rates, and 1,186 wells with all estimated pumping rates. The Data Collection Report states that the public water supply wells were estimated based on the ratios of reported pumping to pump capacity on a per county basis. These ratios were pro-rated by pump use within the county if possible. For example, municipality pump rates tend to be higher than business pump rates which tend to be higher than church pump rates. Questions arose in a backcheck of these assumptions. For a few public water supply wells, reported pumping to pump capacity ratios for irrigation wells were inadvertently used to estimate public water supply pumping rates. The use of nearby similar-use public water supply wells revised the maximum pumping rates from approximately 17,000 cfd to 3,000 cfd. The largest inconsistency was found at the two locations with the highest pumping rates in the model. One is a public water supply well in Kissimmee with a maximum rate of 1.4 million cfd and the other consists of two wells at Reedy Creek Improvement District (RCID) with a maximum pumping rate of 1.1 million cfd each. While the Kissimmee public water supply well and the RCID wells are large pumpers, these estimates are incredibly high. Further investigation revealed that the Kissimmee well rates were doubled compared to an appropriate estimate. The RCID wells were duplicates of other RCID wells already present in the data set for which some reported data was provided. The reported values ranged from 0 to 600,000 cfd.

Notes

Contours are the model results for September 2004 (preliminary calibration).

All pump rates (designated with the color of the markers) are from the SAJ database, which includes reported pump rates and estimated rates.

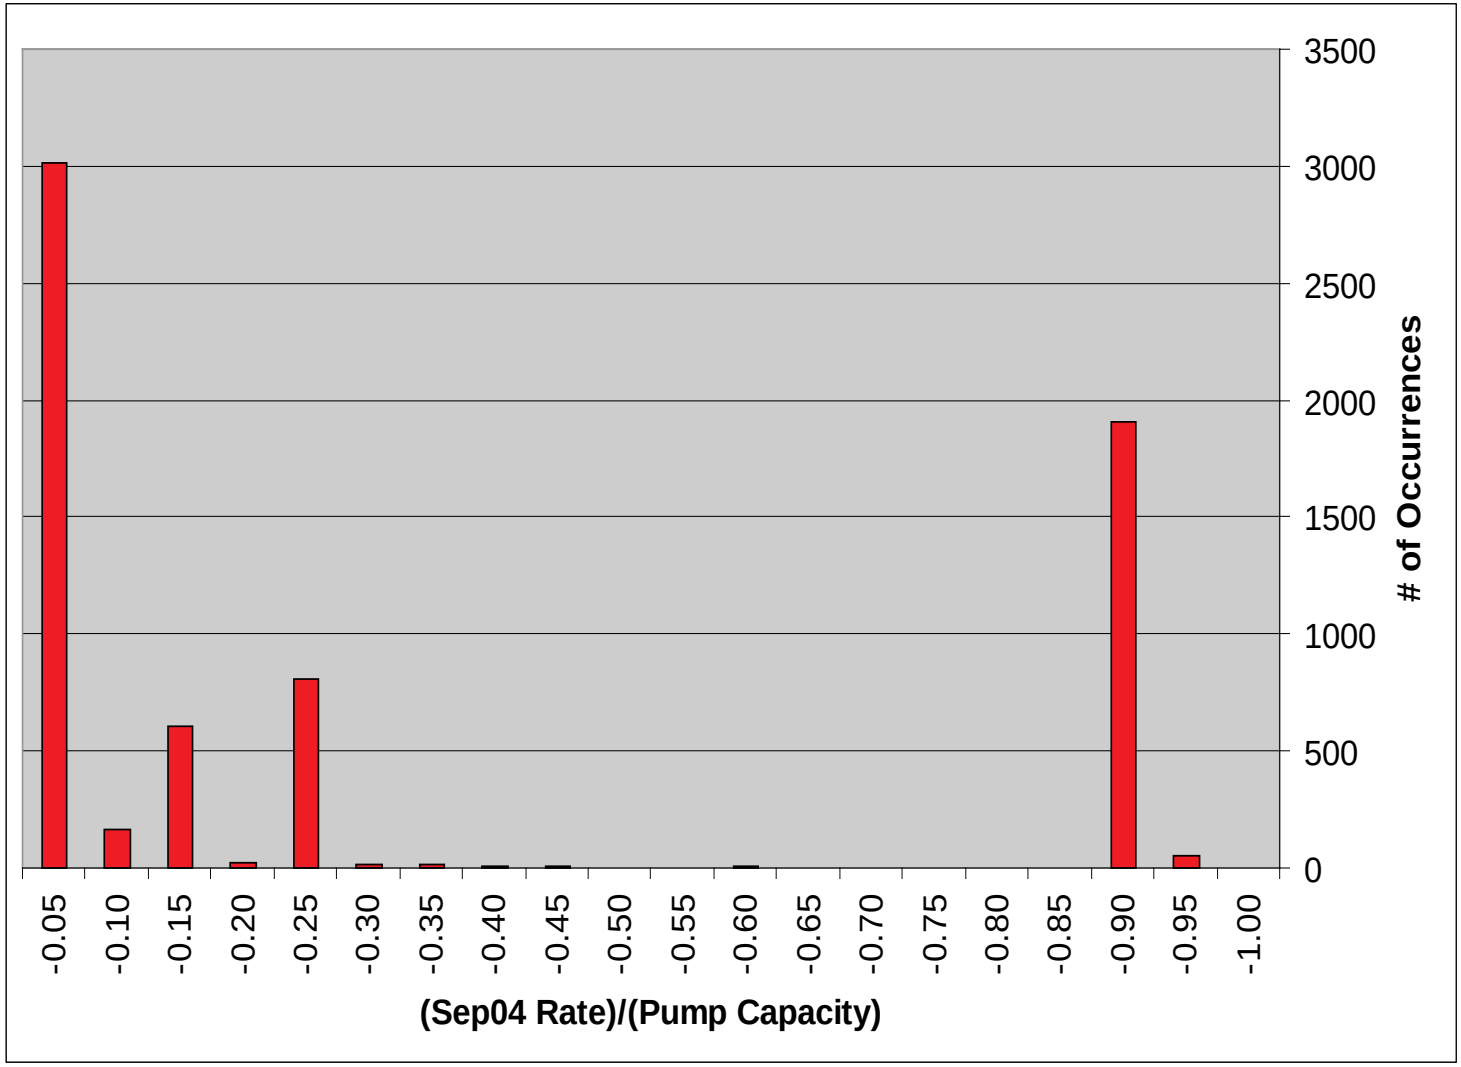
The four wells called out on the figure were selected because they are located near the lowest head in this cone and because their September 2004 pump rates are much higher than the October 2003 rates as reported by SAJ.

Comparison of September 2004 and October 2003 Pump Rates

Final Groundwater Model Calibration Report

Figure D3-4

October 2010



Notes

This histogram shows the distribution of irrigation well pump rates for September 2004 (reported in the SAJ database) as a ratio of the reported pump capacity.

This includes both reported pump rates and estimated pump rates.

The ratios are negative since the pump rates are reported as negative values (for extraction) but the capacities are reported as positive numbers.

- Estimated Normalized Pump Rate

Notes

This figure presents average normalized pump rates for agricultural wells in Zone 5 (see figure D3-7).

Rates are normalized to capacity/allocation data for each well.

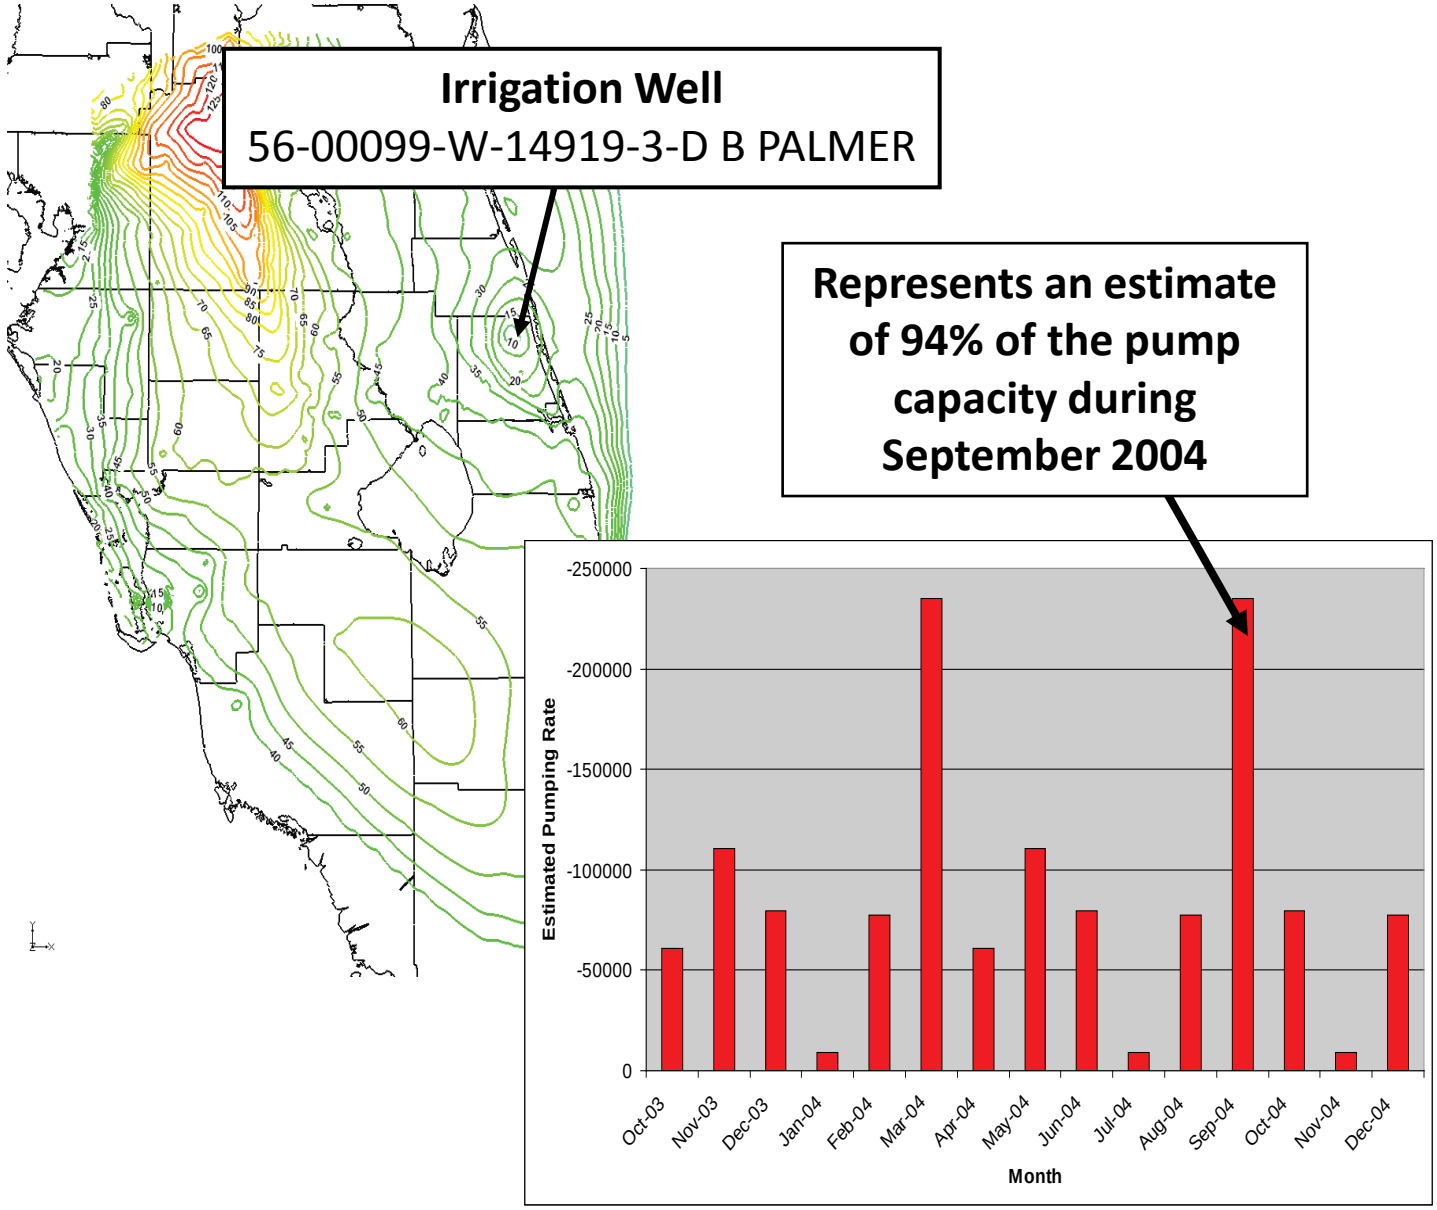
Reported and Estimated pump rates are based on SAJ database.

Normalized Pumping Distribution of Actual and Estimated Data for Irrigation Wells

Final Groundwater Model Calibration Report

Figure D3-10

October 2010



Notes

This is an example of a well with estimated pump rates that are suspicious.

According to the estimates provided by SAJ, September 2004 and May 2004 had identical pump rates at 94% of the capacity of the well. Several other groups of months show exactly equal pump rates, as well.

There is no correlation between the pump rates and the known meteorological conditions. For example, three hurricanes caused significant rainfall during September 2004, so agricultural pumping would be expected to be minimal.

Appendix E: Total Dissolved Solids (TDS) and Temperature Data Evaluation

Table of Contents

1.0 Introduction

Groundwater density variations can affect groundwater heads and regional groundwater flow patterns. The impact of this density effect is magnified as depth is increased. That density affects regional groundwater flow patterns in the Floridan Aquifer System is supported by several studies [Hughes, Vacher, and Sanford (2007), Meyer (1989), Sanford et al (1998), Kohout (1965), Kohout et al (1977)]. The SEAWAT and WASH123D codes were chosen for use in the ASR Regional Groundwater Model study because both codes have the ability to model density-dependent flow based on variations in both salinity and temperature.

To compute the density variations in the model, salinity and temperature values representing two conditions are required: initial conditions and boundary conditions. For the initial conditions, salinity and temperature assignments are required at every computational point in the model domain. These datasets form the salinity and temperature initial condition for the steady state and transient simulations. Because data was sparse in deeper model layers and because data during the calibration time period was often unavailable, available data from the last few decades was evaluated. It should be noted that although current values of salinity and temperature were used to begin the steady state simulation, salinity and temperature are not considered to be in equilibrium. The steady state simulation was used to generate heads that agreed with the current salinity and temperature datasets. The steady state heads were then used as the initial condition heads for the transient simulation.

Boundary conditions for salinity and temperature are required when flow is entering the model at a boundary. When flow is leaving the model at the boundary, the salinity and temperature values are computed by the model. The initial conditions values coincident with the model boundary were assumed to be the boundary conditions. The boundary changes to salinity and temperature in this model are expected to be small given the time scale being modeled. Boundary conditions for salinity and temperature are also required at each well where injection occurs within the model domain, since the injected water quality often differs from that of the native aquifer water quality.

This appendix contains a discussion of the data collection, evaluation, and interpolation used to define the initial and boundary conditions for salinity and temperature.

2.0 Salinity (TDS) and Temperature Data Collection

For this study, reported measurements of total dissolved solids (TDS) are used as proxy for salinity. An extensive TDS and temperature data collection effort was undertaken to identify representative water quality data from the SAS to the BZ. Water quality data for injected water was also gathered. A variety of data sources were used to collect the available data. The primary data source for TDS was the SAJ data collection effort, which is summarized in Appendix A. For temperature, the primary data source was SFWMD. In order to augment this data, additional TDS information was collected from a variety of sources, including USGS Water-Resources Investigations and Scientific Investigations Reports, the SFWMD DBhydro database, databases maintained by SWFWMD and SJRWMD, individual well

completion reports, packer test data, personal communications, and, to a limited extent, data from previous modeling efforts.

3.0 Regional TDS and Temperature Data Evaluation

Once all of the data sources were compiled, the available TDS and temperature data was evaluated to ensure representative data was used in setting the initial TDS concentrations and temperatures in each model layer. Since data was compiled from a variety of sources, the master data file contained duplicate data with different well names for the same well. This often occurred due to the different naming conventions of the agencies collecting the well data. Care was taken to remove duplicate wells from the representative data sets developed for each model layer. Once the duplicate well data was removed, the data was reviewed to determine which water quality values were representative of existing conditions in the FAS. Where possible, water quality data from the beginning of the calibration period (October 2003) was used; however, in areas where data was sparse, reported measurements from other time periods were used to fill data gaps. Since the regional water quality does not change drastically over a period of a few years, this method of filling data gaps was considered to be sufficient.

In some cases, the TDS and temperature data collected was accompanied by an identification of the particular aquifer or confining unit where the data was sampled. Because many of the sources of TDS and temperature data provided only depths of the tested intervals, vertical locations for the data had to be estimated. The ground surface elevation at each monitoring well was approximated from the topographic data described in Section 3.1 of the calibration report. Then the given tested interval depths were subtracted from the estimated ground surface elevations to determine the vertical interval where the water quality was measured. These vertical elevations were compared against the hydrostratigraphic surface elevations for each layer to determine the layer(s) where each measurement was taken. Although each data measurement was taken only in an interval of the hydrogeologic layer, the measurement was assumed to represent the entire vertical column of the aquifer or confining unit. In some cases, the measurement interval straddled two hydrogeologic units. In that case, the TDS and temperature values were considered applicable in both layers.

As the data was reviewed, the time series data indicated that the TDS and temperature at several wells was being influenced by on-going injection or ASR operations. Data of this type was considered to be suspect since the lateral extent of the impacted groundwater quality should be limited to the area very near the injection well. As a result of the sparse data measurements and coarse resolution of the model, the injected water quality applied to the model could impact a much larger area. Consequently, data at or near injection wells was not used if the samples appeared to reflect the quality of the injected water instead of the native water quality. In some cases, TDS or temperature values found in the well completion reports could be used to represent the water quality prior to injection. Examples of locations where well completion TDS and temperature values were adopted are Big Cypress Preserve (BICY), Immokalee Water and Sewer District (IWSD), and I-75 Canal (I75).

Another data quality issue was discovered as the TDS data was processed. Typically, salinity increases with depth throughout the model domain. However, some recorded TDS data from multi-zone wells

were determined to be inverted. This resulted in data in select locations to appear saltier in shallower units in comparison to the deeper monitoring zones. Data at these locations were reviewed in detail and coordinated with the SFWMD. Numerous corrections were made to the TDS database developed for this study to rectify problems with the raw data that had been collected. In these instances, the source of this raw data was contacted and consulted. However, at several locations, the verified data confirmed that more saline water was observed in the UF than the underlying APPZ. This TDS inversion primarily occurred in coastal southeastern Florida. Prominent examples of inversion are located at the SFWMD test wells near City of Oakland Park and the Hillsboro ASR Pilot Project.

The City of Oakland Park wells are located in Broward County near the Atlantic coast. The wells in this location where TDS data are available for the UF are designated BF-1, BF-3, and BF-4S. The recorded TDS for these UF wells varies between 7,500 mg/l and 8,731 mg/l. In addition to these UF wells, there are two wells, BF-2 and BF-4M, that have TDS data for the APPZ. The recorded TDS levels for these wells range from 4,810 mg/l to 5,520 mg/l, which is noticeably fresher than that observed in the UF.

The Hillsboro ASR Pilot Project wells are located in southern Palm Beach County. The wells in this location where TDS data are available for the UF are PBF-10R and PBF-13. The recorded TDS for these UF wells varies between 2,932 mg/l and 6,500 mg/l. The corresponding APPZ well at this location, PBF-11, again has a lower TDS range of between 1,262 mg/l and 3,200 mg/l.

Additional locations along the southeastern coast of Florida have also been identified as having higher TDS levels in the UF than the APPZ. These include the deep injection facility for the Coral Springs Improvement District (CS-M2), the Sawgrass Water Treatment Plant at the City of Sunrise (SUN-BTW), and the reverse osmosis facility at the Town of Jupiter (JUP_RO). A variety of published reports document these areas of known TDS inversion. As shown in Figure 3.18 in the main report, the use of observed data to set the UF TDS distribution resulted in isolated areas of elevated TDS in the UF along the southeast coast.

During the TDS and temperature data evaluation process, close coordination was maintained with the SFWMD to ensure the data used to set the initial distributions in the model were representative of each modeled geologic layer. The lower hydrogeologic units generally contained fewer TDS and temperature data points than shallower units. Table 3.1 summarizes the TDS data and Table 3.2 summarizes the temperature data used for this modeling effort.

The following sub-sections describe how the available TDS and temperature data was used to generate a representative distribution in each geologic layer and also documents any assumptions/simplifications made for this study.

4.0 Regional TDS and Temperature Distributions

The evaluated TDS and temperature data were used to generate representative TDS and temperature distributions in each hydrogeologic layer. For TDS, the interpolation methodology and assumptions to create the final distribution for each model layer can be grouped as follows: the SAS, the aquifers, the

confining units, and the IAS. Interpolation methodology and assumptions for the final temperature distribution in each layer are split into two groups: the SAS and the other model layers. Below is a discussion of each group used to create the final distribution.

4.1 TDS Distributions

4.1.1 SAS Layer TDS Distribution

In the SEAWAT Phase II Regional Model, the top layer (representing the SAS) is set as a constant head boundary condition. Since this layer is shallow and fresh, the density impact on the computed heads in the model is negligible. Consequently, several simplifying assumptions were made in setting the TDS distribution in this layer. These include setting the TDS concentration to 100 mg/l in the land areas and 35,000 mg/l at the ocean. Although some variability does exist in the observed SAS TDS data, this assumption is reasonable for the scope and purpose of this modeling effort. Since the WASH123D model did not include model elements for the SAS, the TDS assumptions for the SAS are only applied to the top layer of nodes in the WASH123D model.

4.1.2 Aquifer Layers TDS Distribution

Once the TDS data were collected and evaluated by the modeling team, GMS was used to interpolate the data to each modeled aquifer in the FAS (UF, APPZ, LF1, and BZ). A variety of interpolation schemes were tested to ensure a reasonable fit with the observed data. Based on the density of available data, the natural neighbor interpolation routine (Sibson, 1981) with a constant nodal function was adopted. For this interpolation the TDS at the ocean outcrops for each geologic layer was set to 35,000 mg/l. As the TDS distribution for each layer was interpolated, it was critically evaluated to ensure that it was reasonable. Numerous error checking routines were used to ensure deeper aquifers were progressively more saline than shallower layers. The primary exception to this guideline was between the UF and APPZ along the southeastern coast of Florida. As previously discussed, the observed data indicates that a TDS inversion may exist in this area. As such, the APPZ was allowed to be fresher in this area so that the model was able to properly account for this phenomenon. Figures 3.18, 3.20, 3.22 and 3.24 in the main report show the TDS distribution adopted for each modeled aquifer in the FAS.

4.1.3 Confining Layers TDS Distribution

For the modeled confining units within the FAS (MC1, MC2, and LC), GMS was again used to interpolate the data to each modeled layer. However, during the evaluation of the confining unit data a high degree of variability in salinity was identified at numerous locations within the confining units. Often a large TDS gradient (generally becoming significantly saltier with depth) was observed within the confining unit. This was particularly apparent at locations where packer test or continuous measurement data was available. It must be noted that the observed TDS in an individual well open within a confining unit may be very dependent on open interval of well, with shallower open intervals generally fresher and deeper open intervals generally saltier. This high degree of variability in observed salinity with depth necessitated a thorough review of the data used to develop a representative initial TDS distribution for the confining units. Wells where significant TDS gradients existed were evaluated individually to prevent skewing of the interpolation. The natural neighbor interpolation routine (Sibson, 1981) with a

constant nodal function was again used to develop the TDS distribution for each FAS confining unit. For this interpolation the TDS at the ocean outcrops for each geologic layer was set to 35,000 mg/l, consistent with the methodology used in the aquifer layers. As the TDS distribution for each layer was interpolated, it was critically evaluated to ensure that it was reasonable. In areas of significant TDS variability, the TDS data, the depth interval of the sample, and data available from underlying/overlying aquifers were used to determine if sampled data was representative of confining unit conditions in a particular area.

Once a representative data set was derived, numerous error checking routines were used to ensure that the interpolated TDS value in the confining units was no fresher than that in the overlying aquifer and no saltier than that in the underlying aquifer. The primary exception to this guideline was again in the area along the southeastern coast of Florida where the UF observations are saltier than those in the APPZ in some locations. In the areas where this TDS inversion was observed, the average of the UF and APPZ was used for the MC1, in the absence of observed data. Figures 3.19, 3.21, and 3.23 in the main report show the TDS distribution adopted for each modeled confining unit in the FAS.

4.1.4 IAS Layers TDS Distribution

Due to the highly variable nature of the hydrogeology in the IAS (inter-bedded aquifers in the west and primarily confining in the east), a separate approach was adopted to determine the TDS distribution in these layers. In the western "aquifer" portion of the IAS substantial data was available, while in the east "confining" portion of the IAS only limited data was available. Accordingly, the TDS distribution for the IAS was developed in two phases.

First, the available data in the "aquifer" portion of the IAS was interpolated consistent with the methodology adopted for the FAS aquifers. In this portion of the IAS, 196 observed TDS data points were available for this interpolation. No attempt was made to vertically differentiate the TDS interpolation in this area, since the observed TDS was generally relatively fresh (less than a few thousand mg/l TDS) and modeled geology is grossly simplified for the purposes of this study. The second step in the process was to develop a TDS distribution in the "confining" portion of the IAS. Since only limited data was available in this portion of the model domain, an average of the assumed SAS and the interpolated UF TDS distributions was used in this portion of the model. As with the SAS, the depths of the IAS layers are relatively shallow. Consequently, the density impact on the computed heads in the model is negligible.

4.2 Temperature Distributions

4.2.1 SAS Layer Temperature

Because shallow density variations have little impact on model results, temperature data in the SAS layer was not evaluated. An average temperature value of 24^{o}C was assumed for the entire layer. For the SEAWAT model, this constant temperature value was applied to the top layer of cells whereas the top layer of nodes was assigned the constant value in the WASH123D model.

4.2.2 IAS and FAS Temperature Distribution

The temperature datasets for each of the other layers (IAS, UF, MC1, APPZ, MC2, LF1, LC, and BZ) were imported to GMS. The 2-D natural neighbor interpolation scheme (Sibson, 1981) with a constant nodal function was used to interpolate the data to each computational point for the grid/mesh for these layers. The temperature on the ocean boundary for the aquifers was approximated by a general temperature-depth of ocean water profile (Middle Latitude Thermocline) compiled by the University Corporation for Atmospheric Research (Figure 3.27 of the main report). Use of this general thermocline to estimate ocean temperatures in the model is supported by measured data from studies of the Floridan Current at latitude 27°N, between Jupiter Island and Grand Bahama Island (Morrissey and Clark, 2009 and Chester, 1989). For the confining units, the ocean boundary temperature was interpolated from the estimates of the aquifer temperature above and below each confining unit.

Temperature data points used in the interpolation of a particular hydrogeologic layer were from monitoring wells with open intervals completely or partly within that hydrogeologic layer. In the shallower model layers, sufficient temperature data was available for interpolation. In the deeper layers, some temperature data points were added from adjacent layers to fill data gaps and smooth sharp variations. For example, the LF1 well, W-17073, in Pinellas County was used in the interpolations for the BZ, LC and LF1. Because the BZ does not exist in this area, the LF1 temperature data value at W-17073 should be representative for all of these layers.

The temperature interpolation in the LF1 layer also included the addition of data points for consistency. The initial interpolation of the LF1 temperature data showed that the layer was cooler than the layers above and below (MC2 and LC) in areas west of Lake Okeechobee and in Brevard County. Several temperature values measured at monitoring wells estimated to be within the MC2 and LC were added to the LF1 interpolation to make the LF1 warmer in both areas.

Although layer interpolations were checked for consistency with layers above and below, it should be noted that no method was employed to ensure that temperature increased or decreased with depth as was done for the TDS analysis. Generally, on the east coast, temperature decreases with depth while on the west coast, temperature increases with depth as shown in Figures 3.28 through 3.36 of the main report.

5.0 Injection Well TDS and Temperature Evaluation

The model requires the assignment of TDS and temperature values for injected water. There are three types of injection wells within the model domain: 1) Drain wells that inject excess stormwater, 2) Class I deep injection wells, and 3) ASR wells. For all three types of wells, the injected temperature was assumed to have a value consistent with the regional water temperature assumed for the SAS, 24°C. For salinity, TDS data was gathered for Class I deep injection wells and ASR wells as discussed in Appendix A. Salinity injected at drain wells was assumed to be 250 mg/l. The drain wells are near the northern model boundary and have negligible impact on the model results.

The injected TDS values provided as a result of the data collection effort were average monthly values. The date range of the injected TDS values did not always overlap the calibration and validation time periods but generally, the average monthly injected TDS data values for a particular well do not vary significantly over time. If the date range of the injected TDS dataset was after the model time period, the first monthly value was used for the entire model time period. Conversely, if the date range of the dataset was before the model time period, the last monthly value was used for the entire model time period. For example, for Cooper City Water Treatment Plant, monthly injected TDS data values were available from March 2005 to December 2005 so the March 2005 value was used for the entire calibration period from October 2003 to December 2004.

Injected TDS data were not available at all injection wells. Consequently, injected TDS values were based on assumptions at some wells. In cases where the injection well is associated with an oil and gas facility, the injected water is brine, so a value of 35,000 mg/l was assumed. In cases where there were several wells pumping for one facility and at least one of the wells had known TDS injection values, the other facility wells were assumed to inject the same TDS. In some cases, injected TDS data from a nearby similar facility could be used to generate a TDS injection dataset where none was available. Table 5.1 lists the wells, their locations, the average injected TDS, the date range of available data, and the applied assumptions.

The injected TDS and temperature have very little impact on the calibration or flow patterns of the regional model. As a result of the coarse model resolution and limited model time period, the impact is only to the model cells where the injection wells are located.

Appendix F: WASH123D and SEAWAT Comparison

Table of Contents

1.0 Introduction

During the model construction process, a WASH123D model was developed for the same domain as that of the SEAWAT model. Calibration models were completed and compared in the Draft Calibration report for the two models. After receiving comments from the Project Delivery Team and the Interagency Modeling Center, the model was recalibrated to produce the final calibration results documented in the final ASR Regional Calibration Report. The final calibration was completed using only the SEAWAT model. The WASH123D model was not recalibrated for two main reasons: 1) It is much more difficult to incorporate heterogeneity of the hydrogeologic parameters into the WASH123D model as described later in this appendix, and 2) WASH123D has fewer solver options. A less accurate but faster solver allows for a coarse calibration in SEAWAT followed by a more refined calibration with its more accurate, slower solver. The WASH123D code has only a more accurate but slower solver resulting in a longer time to develop a calibrated solution.

The draft calibration results are retained in this appendix for both the SEAWAT and WASH123D models to demonstrate their similarity. This similarity supports the reliability of the final SEAWAT calibration results. Sensitivity runs from the Draft Calibration Report that were related to the WASH123D model are also found in this appendix.

2.0 Draft Steady State Calibration

Using the same methodology as described in Section 4.1 of the final report, model hydraulic conductivities for the draft SEAWAT and WASH123D models were varied until the computed heads matched observed heads at selected wells for both October 2003 and February 2004. The goodness of fit to the observed data was evaluated using error statistics, calibration target figures, gradient analysis at well clusters, and comparison to other published information. Only the error statistics and calibration target figures for the draft SEAWAT and WASH123D are retained within this appendix. In comparing these statistics and figures, it can be shown that the model results using the two different codes are very similar.

For the draft SEAWAT model, both trial-and-error and automated methods were used to vary the hydraulic conductivities. Also smooth, interpolated conductivity fields were generated through use of “pilot points” rather than zonal conductivity fields. This process was identical to the calibration process for the final SEAWAT model described in detail in Section 4.1 of the main report.

During the Phase I model study, it was determined that the SEAWAT and WASH123D codes should provide similar results given similar hydrogeologic parameters, initial conditions and boundary conditions. To take advantage of these similarities, the initial hydraulic conductivities used for the WASH123D model were based on the draft calibrated hydraulic conductivities from the SEAWAT model. Using this method allowed for a time savings because only one model (the SEAWAT model) had to be calibrated using both “trial and error” methods and automated methods. Once the draft calibrated SEAWAT conductivities were determined and input to the WASH123D model, adjustments were made to the WASH123D model conductivities by the “trial and error” method.

2.1 SEAWAT

2.1.1 Draft Conductivity Fields

Figures F2-1 through F2-4 show the draft calibrated maps of hydraulic conductivity for all aquifer layers of the FAS. Aquifers are shown with horizontal hydraulic conductivities (vertical conductivities were always 1/10 of the horizontal value). Figures F2-5 through F2-7 show the draft calibrated maps of hydraulic conductivity for all confining units of the FAS. Confining units are shown with vertical hydraulic conductivities (horizontal conductivities were always twice the vertical value).

The IAS layers are shown in Figures F2-8 through F2-10. In reality, this geologic layer is a complex combination of interbedded confining units and sub-regional aquifers. Because of the complexity of this system and because the ASR wells are not expected to impact this layer substantially, the IA and ICU were combined into layers 2 through 4 of the SEAWAT model and Layers 1 through 4 of the WASH123D model. For this modeling effort, the aquifer portions of this geologic system were simplified into a single aquifer layer between two confining unit layers. The aquifer layer was modeled located in the northwestern portion of the model domain in layer 3 of the SEAWAT model and layers 2 and 3 of the WASH123D model. The boundary between the aquifer and aquitard in this model layer is based on a figure in "The Hydrogeology of Florida" (Miller, 1997). All ICU layers have identical vertical hydraulic conductivities in the areas outside of this aquifer zone in both models. (Note that Figure F2-9 shows horizontal hydraulic conductivity, not vertical, so the colors are slightly different.) Variability was allowed between the ICU conductivities overlying and underlying the aquifer portion of the IAS. This allowed for some variation in the source of pumped water in the IA. It is important to remember that these layers are not expected to replicate reality. The model was not calibrated in the IAS and no attempt has been made to correctly simulate flow in this section. These layers act simply as a conduit for recharge water traveling to the UF and discharge water traveling to the surface. The objective was merely to correctly define these flows.

Figures F2-1 and F2-2 show the horizontal hydraulic conductivity values for the UF and APPZ. There was a significant amount of data available for both these layers and the calibration process did not allow model conductivities to vary significantly from what has been measured. The UF (Figure F2-1) shows a zone of somewhat low conductivity along the Kissimmee River, with higher conductivities in the southern portion of the model. It is important to note that the lower conductivities found in the west portion of the model coincide with greater thickness, so the transmissivity does not drop as low as it may seem from this figure. This is also the area where the Hawthorn and Suwannee units are found. This model has combined both of these units into the UF, so the conductivities may vary somewhat from known measurements in either of these units. It is also interesting to note that the Kissimmee River ASR Pilot Project (KASR) is at the eastern side of a small area of high conductivity. The drop in conductivity towards the east is documented, but the exact location and nature of this drop is unknown. The area of lower conductivity to the East of KASR may significantly impact the efficiency of the proposed CERP ASR wells in this area.

The conductivities in the APPZ (Figure F2-2) are lowest along the north-south ridges west of Kissimmee River and reach higher levels on the east side of the model, including an area of very high conductivity directly beneath the low conductivity area in the UF near KASR. The line between the northern dolomite rock and the southern limestone is one of the few sudden changes in conductivity in this model. The location of the interface between the two rocks is based on USGS Scientific Investigation Report 2007-5207 (Reese and Richardson, 2008) though its exact location may be unknown. Suggestions were made to try to soften the conversion from dolomite to limestone. Some sensitivity analyses were run to determine the importance of the placement of that line, but the effects were minor and localized. Since the precise location of this line did not affect the regional calibration, the location of this interface was kept consistent that depicted in USGS Scientific Investigation Report 2007-5207 (Reese and Richardson, 2008).

Figures F2-3 and F2-4 present the horizontal hydraulic conductivity fields for the LF1 and BZ layers of the model. Very little data was available for either layer. The draft calibrated results show generally increasing conductivity to the southeastern portion of the model domain. This distribution is consistent with the current understanding of these deeper aquifers (Reese and Richardson, 2008).

Finally, Figures F2-5 through F2-7 show the vertical hydraulic conductivity values selected for the three confining units in the Floridan system. Although some data was available for these layers, it was used only as a loose constraint on the range of conductivities in each layer. The conductivity values in these layers were valuable tools in the calibration process since the model was highly sensitive to these values.

2.1.2 Description of the Steady State Calibration Quality

Figures F2-11 through F2-20 show the calibration target plots and the error statistics separated by layer and month. The UF steady state head solution and corresponding calibration targets in Figures F2-11 and F2-15 (February 2004 and October 2003, respectively) shows a good calibration. The RMS in both months is 1.9 feet or less with the mean error values very close to zero. The majority of the calibration targets are green, indicating a match within 2 feet of the measured head value. The exceptions are due to steep head gradients, near-well pumping effects or the inability to calibrate both months simultaneously (likely due to errors in the pumping estimates or lack of a local steady state condition).

The statistics and calibration targets for the APPZ steady state calibration are shown on Figures F2-12 and F2-16 (February 2004 and October 2003, respectively). These plots show slightly more error than the UF but with the RMS still less than 2.4 in both months. Most of the calibration points in this layer show a close similarity between calculated and measured heads. A few exceptions, skew the statistics, but do not materially affect the usefulness of the model.

Figures F2-13 and F2-17 show the head solution and calibration information for the LF1, while Figures F2-14 and F2-18 show the same data for the BZ. The unusual shapes in the head contours are due to the influence of density as caused by salinity and temperature and a great depth. At this great depth, there is much less data for comparison, but the figure shows that all data has been matched very closely and the RMS values are impressive at less than 1 foot. Due to the small number of calibration points in the

LF1 and BZ, an expanded calibration was performed in these layers. Figures F2-19 and F2-20 show the head solution and calibration information of the calibration of data from the LF1 and BZ to data that has been collected for these units during a time period other than the calibration period. Since the water level data used for this expanded calibration was not from the modeled period, these figures use a confidence interval of 5 ft rather than the 2 ft interval used in the other calibration plots (i.e. green bars indicate agreement within 5 feet). The error statistics for this expanded calibration are consistent with that seen in the other layers of the model. The reasonable fit of the calibration and expanded calibration in these lower layers of the model indicates that the flow to and from these units into the units more directly affected by the CERP ASR program is reasonable on a regional basis.

2.2 WASH123D Comparison to SEAWAT

The following sub-sections compare the hydraulic conductivities in the SEAWAT and WASH123D models and describe the correlation of the WASH123D draft calibration results to those generated in the SEAWAT draft calibration model.

2.2.1 Draft Conductivity Fields

The initial hydraulic conductivity values for the WASH123D model varied somewhat from the draft calibrated SEAWAT model conductivities. For the SEAWAT model, "pilot points" were used as described in Section 4.1, to provide a smooth conductivity field with a different value at every cell across the domain. In WASH123D, hydraulic conductivity is assigned to each finite element using a material zone. The material zone associates the element properties such as porosity, hydraulic conductivity, and storage coefficient, to each element within the model domain. A different hydraulic conductivity value for each element in this model would require 740,637 material zones, which would be difficult to implement and would tax the memory requirements of the code. To reduce the number of material zones, the draft calibrated SEAWAT conductivities were contoured by layer at contour intervals sufficient to replicate the regional flow fields. Then the contours were used to create zones of similar hydraulic conductivity with one material for each zone. A total of 297 material zones were assigned for the steady state WASH123D model.

The WASH123D heads produced using SEAWAT draft calibrated conductivities resulted in an RMS of approximately 5 feet. Trial and error adjustments were made to the WASH123D material zone shapes, the number of zones, and zone conductivity values, primarily in the confining units, to improve the calibration.

Figures F2-21 through F2-30 show the draft calibrated hydraulic conductivities for the WASH123D steady state ASR Regional Model.

The WASH123D calibrated hydraulic conductivities for the IAS (Layers 1 through 4) are shown in Figures F2-21 through F2-23. A comparison to the SEAWAT conductivities for corresponding Layer 2 through 4 (Figures F2-8 through F2-10) reveals that the values are very similar with minor differences resulting from efforts to reduce the number of material zones.

Figures F2-24 through F2-27 show the calibrated WASH123D Floridan Aquifer horizontal hydraulic conductivities. These values are nearly identical to the SEAWAT aquifer horizontal hydraulic conductivity values (Figures F2-1 through F2-4). Differences are the result of condensing similar values to reduce the total number of material zones. Few changes were made to these layers to establish the draft calibration.

The WASH123D vertical conductivities for the confining units are shown in Figures F2-28 through F2-30. Conductivities in these layers were adjusted to improve the calibration. Even with the adjustments, overall the conductivities are very similar to the values from the SEAWAT model (Figures F2-5 through F2-7). The most sensitive area was the MC2 layer where adjustments of a few hundredths of a ft/d in the southern part of the model had a significant impact on several calibration wells across the model. The MC2 conductivity change from SEAWAT to WASH123D is apparent in the figures where the "bright green" area, indicating a vertical conductivity range of 0.005 to 0.01 ft/d in the SEAWAT model, was adjusted to a "yellow" area of 0.01 to 0.05 ft/d in the WASH123D model. This change resulted in increasing the amount of upward flow from the LF1 to the APPZ and UF in these areas. Minor differences in vertical flow between the two models are to be expected based on based on differences in the way vertical conductivities and initial conditions are applied to the computational points as described in this section and Section 3.4 of the main report.

2.2.2 Comparison of Steady State Calibration

The Floridan Aquifer WASH123D calibrated head contours, error statistics and calibration targets for February 2004 are shown in Figures F2-31 through F2-34 and for October 2003 on Figures F2-35 through F2-38. The WASH123D calibrated head contours are also compared to the SEAWAT calibrated head contours in Figures F2-39 through F2-46. In the comparison figures, the WASH123D contours are colored by elevation and overlay the black head contours from the SEAWAT model.

As found for the SEAWAT model, the WASH123D UF calibration is very good with RMS values for both February 2004 and October 2003 (Figure F2-31 and F2-35, respectively) of less than 1.9 feet. The majority of the calibration locations show results within 2 feet of the observed data. Discrepancies described in Section F2.1.2 for the SEAWAT model also occur in the WASH123D model and for the same reasons. For both February 2004 and October 2003 (Figures F2-39 and F2-40, respectively), the WASH123D and SEAWAT head contours nearly align. The largest contour discrepancies are in the southern part of the model where the WASH123D heads are a foot or two higher than the SEAWAT heads.

The error statistics for the APPZ are larger than for the UF with RMS values of 2.8 ft and 2.6 ft for February 2004 and October 2003 (Figure F2-32 and F2-36, respectively), respectively. Also, the WASH123D APPZ RMS values are approximately 0.5 foot greater than those computed using SEAWAT. Despite the slightly larger error, most of the calibration wells are within two feet of the observed data. The WASH123D APPZ calibration locations with the greatest error are the same as those for the SEAWAT model (Section F2.1.2). The APPZ WASH123D and SEAWAT head contours track closely for both calibration months (Figures F2-41 and F2-42). The heads are slightly higher in the southern part of the WASH123D model.

The WASH123D LF1 RMS values are 1.7 ft and 1.1 ft for October 2003 and February 2004 (Figure F2-33 and F2-37), respectively. The February 2004 WASH123D calibration is similar to the SEAWAT draft calibration for the same month but the October 2003 calibrations differ slightly between the two models. The greatest difference occurs at ROMP 28 in Highlands County where the October 2003 computed head is about 3.5 feet lower than the observed head. Despite the difference at this one point, the head contour comparison between WASH123D and SEAWAT (Figures F2-43 and F2-44) show a close contour alignment throughout the area surrounding ROMP 28. Near the coast, some minor head contour differences are found.

As described in Section F2.1.2, an expanded calibration was done for the deeper units of the FAS (LF1 and BZ). Figures F2-34 and F2-38 show the calibration targets when October 2003 or February 2004 model results are compared to calibration locations that are not from the same date. These figures show head contours from the BZ and have calibration targets that use a 5 ft confidence interval instead of the 2 ft confidence interval used for the other calibration plots. Because the calibration points were not from the calibration time periods, less effort was expended to match the points exactly. The RMS values are between 2.5 ft and 3 ft for both months indicating that the computed heads are within a reasonable range. Comparing the SEAWAT and WASH123D head contours for the BZ (Figures F2-45 and F2-46) reveals that the models are computing similar heads. In the BZ layers of the models, the density impacts from the largest changes in salinity, temperature and pressure are greatest. The compatibility of the head contours in this layer verifies that the two codes are computing the density-dependent calculations in a similar way improving the reliability of the results.

3.0 Draft Transient Calibration

Draft transient calibrations were performed for the SEAWAT and WASH123D models for the time period from October 2003 to December 2004. The quality of the calibration was determined through visual analysis of the computed head variation over time at each calibration point compared to the observed head variation. The results of the 2 draft transient calibrations are very similar, except in the western part of the model domain. Differences between the SEAWAT and WASH123D draft calibrations appear to be due to differences in pumping locations and differences in assignment of specific storage.

Although transport parameters such as porosity, dispersivity, and molecular diffusion coefficient vary over time, their effect was insignificant at the time scale (15 months) of the model. Model sensitivity to these parameters can be found in Section 5.0 of the main report. For transient calibration, the most sensitive parameter was specific storage.

3.1 Specific Storage

Specific storage was varied using “trial and error” and automated methods for the draft SEAWAT transient model. Rather than zonal distributions of specific storage, interpolated “pilot points” were used to generate smooth specific storage fields. This process was identical to that used for the hydraulic conductivity fields for the steady state calibration for the final SEAWAT model described in detail in Section 4.1 of the main report.

Specific storage is not specifically used in WASH123D as shown in Equations 2.5 and 2.6 of the main report. The WASH123D code requires an effective aquifer compressibility to determine the storage term used in the governing equation. The relationship between specific storage and the compressibility parameters is shown in Equation 3.1.1.

$$S_s = \rho_\omega g(\alpha + n\beta)$$ Equation F3.1.1

where

S_s = Specifc storage (L^{-1})
ρ_ω = Density of water (M/L^3)
g = Acceleration of gravity (L/T^2)
α = Compressibility of the aquifer skeleton ($1/(M/LT^2)$)
n = Porosity (L^3/L^3)
β = Compressibility of water ($1/(M/LT^2)$)

In WASH123D, the equation is rearranged by multiplying density and gravity into the parenthesis as follows:

$$S_s = \alpha' + n\beta'$$ Equation F3.1.2

where

α' = Modified compressibility of the aquifer skeleton, $\rho_\omega g\alpha$ (L^{-1})
β' = Modified compressibility of water, $\rho_\omega g\beta$ (L^{-1})

The WASH123D code hardwires the value for the modified compressibility of water (β') at a value of 1.22×10^{-6} ft^{-1}. This is based on an assumed water compressibility of 1.96×10^{-8} ft^2/lbf and cannot be changed without reprogramming and recompiling WASH123D. Using the constant value for modified water compressibility as well as the specific storage and porosity values from the calibrated SEAWAT model, the modified aquifer compressibility values were calculated. Zonal distributions of these values were applied to the model.

In some cases, the SEAWAT specific storage values were so small that the corresponding modified aquifer compressibility was negative. Further discussion related to negative aquifer compressibilities and their negligible affects on the calibration are discussed in Section 4.0 of this appendix.

3.2 SEAWAT

Figures F3-1 through F3-21 show the SEAWAT calibration at a number of observation wells which had significant data available. In each case, the observed and calculated heads are plotted during the 15 month calibration period (October 2003 through December 2004). Note that because of differing ranges of heads measured and calculated at each well, each plot has a different head scale on the y-axis. In order to facilitate the analysis of these plots, every graph has a horizontal grid line at every foot of head. In this way, the reader can tell, at a glance, whether the well has a large swing in heads (many grid lines) or has very little head variation (few grid lines).

Because of the time discretization (constant boundary conditions and pumping for each month) it is impossible for the model to correctly calculate the head every single day. The main purpose of the calibration effort was to correctly calculate the average head during the driest period (usually during the month of June 2004) and the average head during the wettest period (usually late fall 2004).

Because the model can only attempt a calculation of the average monthly heads, it is not surprising that the model will seldom match the lowest measured head (usually during the first few days of June 2004). Further, the time discretization often results in the lowest model-calculated head occurring several weeks after the lowest measured head. During June 2004, the head changes on nearly all observation wells indicate that significant pumping occurred during the first few days of the month and then abruptly stopped, causing a steep rise in water levels. Because of the ASR regional model's time discretization, this high pumping is averaged over the entire month, resulting in the lowest heads being calculated at the end of the month. See for example, the results at ROMP 9 SWNN in Sarasota County (Figure F3-9). The continued pumping during the month of June causes the model to calculate a lower head for the whole month of June, but the measured data shows a sudden, steep increase in head beginning in the first week of June.

In some cases, the October 2003 steady state calculated head differed by a few feet from the measured head at the end of October. In these cases, the transient calibration sought to match the head changes each month, instead of the actual heads. This ensures that the aquifer response to hydrogeologic forces is accurate, even if the initial computed head value is slightly different from that observed. See for example, ROMP 13 SWNN in De Soto County (Figure F3-10). The October 31 calculated head (steady state) is nearly 2 feet lower than the measured head value. However, the difference between the October 2003 heads and the June 2004 heads is 5 to 6 feet in the measured data and just over 6 feet in the model results. Similarly, the head rise between June 2004 and October 2004 is 8 feet in the measured data and about 7 feet in the model output. This indicates that the model is doing a good job of reproducing the effect of temporal changes such as seasonal rainfall changes and pumping effects. Although the steady state model did not perfectly reproduce the heads at this point, the head variation is reasonable.

Similarly, MF-37 on the east coast of Lake Okeechobee (Figure F3-11) was installed during the calibration period. Thus, there was no data available for either the October 2003 or February 2004 steady state calibration. It appears that if data had been available, the model would have underpredicted the head at this well by approximately 3 feet. However, during the transient calibration, it becomes clear that the temporal effects on this well are being correctly reproduced in the transient model. It is important, when viewing Figures F3-1 through F3-21 to mentally move the model calculated heads up or down until the initial value matches the measured value at that time before determining the quality of the calibration.

It is significant that the pumping across the region exerts a much greater effect on the transient head data than the specific storage values. Section 3.5 of the main report and Appendix D present the difficulties in collecting and using the pumping data. A huge percentage of the pumping data had to be estimated based on well type and seasonal averages.

These estimates of pumping caused additional problems during calibration. These are made clear by comparing the results at Edgeville Deep Well 3 in Manatee County (Figure F3-9) and BF-6 in Broward County (Figure F3-14). At Edgeville, the model results indicate a significant reduction in pumping during the last month of the model (December 2004). The measured data at this well do not show such a sudden and large increase in head. This indicates that the pumping in the model in this area is incorrect – likely due to the failure of the assumptions made during the pumping estimated (described in Appendix D). Conversely, at BF-6, there is clearly a reduction in pumping during the months of November 2003 and January 2004, with an increase in pumping during the months of October 2003 and December 2003. In this case, the estimates made in the model appear to closely match reality, as shown by the close similarity of the heads at this well. Pumping estimation errors can also be the cause of the failure of the model to reproduce the low heads in the summer of 2004 or the high heads in the Fall of 2004. As will be explained later in Section 6, the pumping data quality represents the single largest source of error to this model. The estimates made to fill in missing data were planned in order to provide a model accurate enough to make gross, regional-scale estimates of the effects of the CERP ASR program. Because of pumping errors, the regional model cannot be used for near-scale problems or to answer questions requiring high accuracy.

In general, the transient calibration is considered to be of a high enough quality to answer the questions required by the regional ASR model. The model was able to roughly reproduce both the scale and timing of the main head changes during the 15-month calibration period.

The storage terms used in the calibrated transient model are presented in Figures F3-22 through F3-29. Conductivity values were the same as those used for the steady state model (See Section F2.1). Table 4.1 in the main report presents the other transport parameters used in the transient model. These parameters were selected to be similar to generally accepted values. Their sensitivity is discussed in Section 5 of the main report.

3.3 WASH123D
