Executive Summary

This report has been prepared for the U.S. Army Corps of Engineers (USACE) to convey the results of a technical review of numerical groundwater models, a review of the Preliminary Hydrogeologic Framework document, and a carbonate aquifer dispersion database study in support of the Comprehensive Everglades Restoration Project (CERP).

A document entitled *Preliminary Hydrogeologic Framework, October 4, 2004*, is an interim work product for the Aquifer Storage and Recovery (ASR) Regional Study. The report synthesized major regional works on the Floridan aquifer system (FAS) into a single comprehensive view of the hydrostratigraphy and hydraulic properties of the FAS from Orlando to Key West. It included 770 hydrostratigraphic picks from 392 wells. Eight cross sections were prepared from wells located in central to south Florida that had appropriate drilled depths and adequate geophysical logs for the purpose of this study. This document identified a newly recognized permeable zone in the FAS.

The USACE selected eight models from a list of 32 models submitted by CH2M HILL. The selected models provided an adequate coverage of the area of interest between Orlando and the Florida Keys. The models were evaluated and summarized for general areas corresponding approximately to the northern and southern regions of the Florida peninsula. Model similarities and differences were described. In addition, the models were compared to the hydrogeologic framework previously established through other studies conducted by the USACE, the South Florida Water Management District (SFWMD), and the United States Geological Survey (USGS).

As stated previously, a dispersion research study was conducted under the Subtask 3 scope of work for the USACE. The goal of this research effort was to provide dispersion data from sandstone and carbonate aquifers with a focus on technical sources from Florida and other similar geologic environments from the United States and the world. Based on the USACE's scope of work, technical papers, reports and other sources available to and obtained by CH2M HILL were reviewed and dispersion values were tabulated. In addition to the dispersion data, which were typically presented as longitudinal dispersivity, other pertinent information (where available) was also tabulated in the database for comparative purposes. These supplemental aquifer data include transmissivity, storativity, transverse dispersivity, molecular dispersivity, and aquifer name, matrix, thickness, and type.

Based on the data reviewed, CH2M HILL recommends construction of a 14-layer model to be run using finite-element groundwater modeling software. Of these 14 layers, seven layers will be used to simulate permeable zones. Three of these zones are identified to be studied further for development of potential ASR systems.

SECTION 1

Introduction

This report has been prepared for the U.S. Army Corps of Engineers (USACE) Jacksonville District and the South Florida Water Management District (SFWMD) in support of the Comprehensive Everglades Restoration Project (CERP). The scope of work for this report is based on Subtask 3 of the Aquifer Storage and Recovery (ASR) Test Well Work Plan Development and Model Data Collection (revised June 10, 2005; Contract No. W912EP-05-D-004). The final purpose of the study is to provide the USACE a baseline of conceptual model recommendations to build an initial Florida Peninsular model. This tool will be used to model the potential regional effects and aquifer behaviors of the CERP ASR implementation plan.

The purpose of this report is to convey the results of a technical review of eight numerical groundwater models selected by the USACE and compare this information to the known hydrogeology of Florida. The eight models were selected by the USACE from a list of 32 models prepared by CH2M HILL. Table 1 provides the list of models. The selected models provided an adequate coverage of the area of interest between Orlando and the Florida Keys. The model review areas correspond to the northern and southern regions of Florida, which are generally north or south of Lake Okeechobee, as shown on Figure 1. The reviews describe the similarities and differences between these models, both individually and regionally, and provide key information for USACE's consideration for future development of a peninsula-wide groundwater numerical model from Orlando to the Florida Keys. Table 2 presents a comparison of the reviewed groundwater model layering schemes. Recommendations on numerical model layering are provided in this report based on the model reviews included in Appendices A and B of this report with comparison to the *Draft-Final Report -Task 3.0. Define Preliminary Hydrogeologic Framework, October 4, 2004*, prepared by Ron Reese (USGS – Project lead) and Emily Richardson (SFWMD – Task lead).

Within Subtask 3, the USACE required the development of a groundwater dispersion database. A separate TM has been prepared and is included in Appendix C to document the results of a literature search and development of the groundwater dispersion database. The goal of this research is to provide dispersion data on primarily sandstone and carbonate aquifers with a focus on technical sources from Florida and other similar geologic environments from the United States and the world.

SECTION 2

Hydrogeologic Framework Document Review

Prepared by the USGS with assistance from the SFWMD, the *Draft-Final Report -Task 3.0. Define Preliminary Hydrogeologic Framework, October 4, 2004*, is an interim work product for the ASR Regional Study. The report synthesized major regional works on the Floridan aquifer system (FAS) into a single comprehensive view of the hydrostratigraphy and hydraulic properties of the FAS from Orlando to Key West. It included 770 hydrostratigraphic picks from 392 wells. Figure 2 presents the wells reviewed for this hydrogeological framework study. The sources of information evaluated through the study are included in Section 7, References.

The framework report provides a starting point for development of a hydrologic model of the FAS to plan, predict, and evaluate the potential impacts of future CERP ASR implementation. The objectives of the report were to:

1. Identify the differences in aquifer nomenclature and interpretation across the study area.
2. Establish stratigraphic framework through correlation of geophysical logs from key wells.
3. Correlate major aquifers and confining units, north to south, and east to west, across the study area.
4. Map bounding surfaces (top and bottom) of each hydrostratigraphic unit.
5. Classify available hydraulic parameter data according to the identified hydrostratigraphic units.
6. Map transmissivity and storativity for permeable zones, and vertical hydraulic conductivity for confining units

The interpretation of data assumed that the aquifers were continuous even though there appeared to be some question regarding correlation and aquifer continuity between points. For aquifer model development, a similar approach was recommended, but applying more conservative approaches in areas of greater uncertainty.

The report proposed the inclusion of a new informal hydrogeologic unit for the FAS, the "middle Floridan aquifer" (MF). The report concluded that the MF is regionally continuous, present above the Middle Avon Park (MAP) marker bed, that the permeability is associated with fractured dolostone within the Avon Park Formation (but may not be equally developed across the study area), and that the MF lies below the 10,000 milligrams per liter (mg/L) total dissolved solids (TDS) salinity boundary (in parts of the SWFWMD area). Figure 3 shows the relationship of the hydrogeologic units evaluated and the incorporation of the proposed MF.

The report identified several issues that may require additional resolution. These issues were:

1. Confinement between the MF and Lower Floridan Aquifer (LFA) permeable zones as mapped in this study could be poor in some areas of southern Florida.
2. In the western portion of the study area, particularly along the coast, the "Ocala Limestone-Avon Park Formation moderately permeable zone" was identified to have high transmissivity locally, and is used for injection of treated wastewater. In the study, the zone was often not included within the MF, but rather was included in the confining unit between the Upper Florida Aquifer (UFA) and the MF. The UFA extends only down to the top of or into the upper part of the Ocala Limestone in this area. However, in other areas of the state, treated wastewater injection activities are typically conducted in the Boulder Zone, where present, or in portions of the LF1 where seawater exists.
3. Confinement between the UFA and MF as mapped in this study could be poor in some areas of north-central and northeast Florida, especially in the area of the upper Kissimmee River Basin.
4. In the lower west coast area of the peninsula (i.e., Lee, Hendry, and Collier Counties), the elevation of the top of the UFA exhibits considerable variability with many pronounced high and low areas. Development of a map showing the thickness of the basal portion of the Hawthorn Group included in the UFA was recommended as a future task to identify the variations in the elevation.
5. The scale of the project necessitated that the Intermediate Confining Unit (ICU) or Intermediate Aquifer System (IAS) be mapped as a single unit, but they may contain significant aquifers within much of the study area, particularly along the west coast of the peninsula.

2.1 Hydrostratigraphic Units

As previously shown in Figure 3, the FAS is comprised of two major aquifers, the UFA and LFA, which are separated by the Middle Confining Unit (MCU). The MCU is also known as MC1 as defined by Reese (2004). Within the UFA and LFA are significant permeable zones such as the Lower Hawthorn Producing Zone, the MF, and the Boulder Zone (BZ). The following paragraphs describe the characteristics of each of these units as defined by Reese (2004).

2.1.1 Upper Floridan Aquifer

Good confinement is exhibited above the UFA as noted by artesian pressure. During drilling, lost-circulation zones or sudden increases in the rate of penetration often help to define the top of the UFA. However, smaller flow zones can occur above the large flow zone near the top of the UFA, but may not be included in the UFA due to their head, permeability, and position (thickness and degree of confinement provided by the unit separating them from the main flow zone). The top of the UFA often coincides with a formation boundary, but can occur over a wide range within the geologic section (e.g., from

within the lower part of the Hawthorn Group in southwest Florida to the upper part of the Avon Park Formation).

The base of the UFA or top of the MCU (MC1) can be gradational and difficult to define. The base of the UFA often occurs in the Avon Park Formation, but in the western part of the peninsula it commonly occurs near the top of the Ocala Limestone. In order to fill some large data gaps in the Southwest Florida Water Management District (SWFWMD), the elevation of the top of the Ocala Limestone was used as a surrogate for the top of the MCU in 47 wells evaluated in the study.

South of Lake Okeechobee, there is a notable lack of fully penetrating tests in the UFA primarily resulting from poor water quality and the development of the Surficial Aquifer System (SAS) or IAS in this area. In the lower west coast region, there are no fully penetrating tests south of the Caloosahatchee River. Similarly, eastward from Orlando, in the far northeastern portion of the study area, a rapid decline in water quality has discouraged development and therefore testing in the FAS.

Transmissivity (T) in the UFA decreases from coastal areas inland with an area of low T extending down the center of the peninsula from southern central Florida (T less than 5,000 square feet per day [ft^2/d]) to central southern Florida (T less than 15,000 ft^2/d). T in 4 coastal areas (Lee, Miami-Dade, St. Lucie-Martin, and Pinellas Counties) and in Orange County reaches 50,000 ft^2/d or greater. The area with highest T (greater than 50,000 ft^2/d and up to 100,000 ft^2/d) extends from Pinellas County inland across northeastern Manatee County and into northwestern Polk County.

Measured storativity values from 82 Aquifer Performance Tests (APTs) evaluated in the study from the UFA ranged from a low of $4.5x10^{-8}$ to a high of 0.4. Erroneously high estimates of storativity for highly anisotropic media (e.g., most flow from fractured rock, cavernous zones, or narrow bedding plane flow zones) in the very high transmissivity areas may be an artifact of the standard curve matching procedure for APT analysis. Erroneous estimation of storativity is likely due to high flow zones in the fractured or cavernous intervals that violate the assumption of radial flow to the well bore.

2.1.2 Middle Floridan Aquifer

The MF usually occurs within a thick section of the Avon Park Formation composed primarily of dolomitic limestone and sucrosic dolomite. The permeability in the MF is primarily associated with fracturing, but cavernous permeability can also be present. Lost circulation zones encountered while drilling often marks the MF. The thickness of the MF is commonly 300 or 400 feet, but it can be as thick as 500 or 600 feet. It reduces to 50 feet thick or less in the lower southwest Florida area.

Permeability in the MF appears to decline abruptly south of Lake Okeechobee. The MF has not been extensively evaluated south of Lake Okeechobee. The report indicated that it is particularly important to have values in this area because the closest measured values north of the Caloosahatchee River were very high.

In general, transmissivity in the MF has higher values than in the UFA, and has a T of more than 200,000 ft^2/d in four areas. Transmissivity is minimal (less than 5,000 ft^2/d) in most of southern Florida (south and west of Palm Beach County). The area with highest T is in

southwestern Florida, centered on a well in southern Desoto County (ROMP 12), where a T of 1,600,000 ft^2/d was reported. In Pinellas County, transmissivity was recorded as high as 1,200,000 ft^2/d.

Elimination of extreme values and partially penetrating tests left only 14 data points on which to base storativity. Unlike the UFA, the range and distribution of estimated storativity in the MF exhibits significant difference between fully penetrating and partially penetrating tests. The highest permeability in the MF is associated with a horizon of fractured dolomite. Erroneous estimation of storativity is likely due to high flow zones that violate the assumption of radial flow to the well bore (as previously noted).

2.1.3 Lower Floridan Aquifer

The uppermost permeable zone of the LFA (LF1 as defined by Reese, 2004) is defined as the first major permeable zone developed below the MAP marker, but above the glauconite marker (GLAUC) near the top of the Oldsmar Formation. LF1 occurs in the lower part of the Avon Park Formation in fractured dolostone, but tends to be more dense and massive. In some cases, the MF and LF1 may be separated by only a thin but apparently unfractured dolostone unit, and confinement between the MF and LF1 may not exist in some areas. Confinement can be very good in central and southwest Florida due to the occurrence of pore-filling anhydrite and gypsum.

Outside of greater metropolitan Orlando, where the LF1 is highly utilized for water supply, it is not possible to map the hydraulic properties of this zone with confidence. In Orange and Osceola Counties, transmissivity ranges from a low of 82,000 ft^2/d to a high of 688,000 ft^2/d. East of this area, water quality deteriorates rapidly and the LF1 is generally greater than 10,000 mg/L TDS. As a result, the LF1 production capability has not been tested in this area.

LF1 appears to thin significantly toward the coast in much of the study area. Model derived values for transmissivity of the LFA exhibited a similar eastward decline and a transmissivity of 1,360 ft^2/d was estimated at well BR1217. In general, transmissivity in LF1 is higher in southern Florida (greater than 80,000 ft^2/d). Transmissivity greater than 100,000 ft^2/d and up to almost 700,000 ft^2/d occurs in north-central Florida, centered in northwest Osceola and Orange Counties.

Geophysical logs from the Polk City core hole (POLKC 3_G) and Kaiser injection well (W-11424) in Polk County show little evidence of the high permeability exhibited in the LF (west of Osceola and central Orange County). Lithologic logs from both wells indicated the presence anhydrite infilling of pore spaces and it is assumed there is little to no permeability from that point down to the base of the FAS.

The report indicated that there are no aquifer performance tests in LF1 in southwest Florida (Lee, Collier, Glades, or Hendry Counties). Transmissivity was estimated at a number of wells in the SWFWMD based on the aquifer thickness, from the hydrostratigraphic surfaces generated in this study, and a hydraulic conductivity of 9.6 feet per day (ft/day) (as observed at the South Cross Bayou Injection well, W-17073). The report concluded that there was strong evidence to support poor to non-existent development of permeability in the LFA in SWFWMD, but southward, the LF1 is highly permeable based on observed drilling response, lithologic and geophysical logs. At the South Bay site, the results of an APT of LF1

(72 percent of the permeable zone tested) on the southern end of Lake Okeechobee produced a transmissivity value of almost 70,000 ft^2/d.

There are only two archived values of storativity in LF1 within the DBHYDRO database, with values of $1.2x10^{-5}$ and $2.6x10^{-5}$. In the absence of additional data, use of an average value of $2x10^{-3}$ was recommended.

2.1.4 Boulder Zone

The top of BZ, a zone of very high permeability in the lower part of the LFA, was also mapped in this study. The top of the BZ generally occurs one to several hundred feet below the GLAUC marker in the Oldsmar Formation, although there are some exceptions where the top is slightly above the marker. The BZ is not present in central Florida (north of Lee, Glades, and Okeechobee Counties in central Florida) except along the east coast. Similar to the uppermost permeable zone of the LFA, this zone is not developed along the coast in the northwest portion of the study area. BZ permeability ranges from fractured to cavernous, and both fractured limestone and dolostone can be present. Transmissivity for the BZ is in the order of 10^6 to 10^7 ft^2/d.

2.2 Confining Units

Three confining units were identified: the Middle Confining Unit 1 (MC1), the Middle Confining Unit 2 (MC2) and the Lower Confining Unit (LC). The report provided vertical hydraulic conductivity (Kv) data based on hydraulic well tests of confining units, leakance values determined from hydraulic well test of aquifers and core analysis data.

The MC1 separates the UFA and MF permeable zones. Kv of MC1 increases from the west coast, where it is approximately 0.1 ft/day or less, to the east coast, where it is greater than 1.0 ft/day, but less than 10 ft/day. The wells with core data in MC1 were very limited and were located primarily in the western portion of the peninsula. The MC2 separates the MF from the LFA permeable zones; Kv is lowest along both the east, and west coasts of Florida. Kv values range from less than 0.1 ft/day down to 0.01 ft/day. The LC separates LF1 from the BZ. Kv along the east coast of Florida is generally less than 0.1 ft/day and the data are poorly distributed.

SECTION 3

Numerical Model Review

Research was conducted to determine what models were available for review. The government agencies that assisted in providing information on available models were USACE, SWFWMD, St. Johns River Water Management District (SJRWMD), SFWMD, and USGS. A number of engineering consultant models were previously known or recently identified. Most, however, were not considered for placement on the list because these types of models typically are limited in hydrogeologic calibration outside of study area; limited in geological layering accuracy on a regional scale; and in most cases have not been subject to regulatory peer review. For these reasons, only published models, which were constructed by or for governmental agencies, were listed. The following eight models were selected by the USACE for review from among 32 available models:

- Eastern Tampa Bay Model (Barcelo and Basso, 1993)
- Lee County Model (Bower, et al., 1990)
- Lower East Coast Model (Fairbank, et al., 1999)
- Peninsular Florida Model (Sepulveda, 2002)
- Southern District Model (Beach and Chan, 2003)
- East-Central Model (McGurk and Presley, 2002)
- HydroGeoLogic Model (HydroGeoLogic, 2002)
- SWFWMD District Wide Regulatory Model (ESI, 2004)

The models were divided into two groups for review. The first group included the southwest Florida area. The second model review group included the southeast Florida area. This grouping allowed for better model comparisons in similar areas. These model areas were also compared to the *Draft-Final Report -Task 3.0. Define Preliminary Hydrogeologic Framework, October 4, 2004* document to determine how the model layering compared to actual field information. Two model review TMs were produced, one each for the southwest and southeast areas, and are provided in Appendixes A and B, respectively. The conclusions from these TMs were then also compared to each other and to the *Draft-Final Report -Task 3.0. Define Preliminary Hydrogeologic Framework, October 4, 2004* to provide the study area conceptual model recommendations contained in this report.

3.1 Southwest Florida Region Model Review

The area of focus for four of the five models in this group is generally the SWFWMD jurisdictional area. The fifth model (Sepulveda, 2002) includes most of the Florida peninsula. The five models reviewed for the southwest region of Florida were:

- Eastern Tampa Bay Water Use Caution Area Model (Barcelo and Basso, 1993)

- Peninsular Florida Model (Sepulveda, 2002)
- Southern District of SWFWMD (Beach and Chan, 2003)
- HydroGeoLogic Model (HydroGeoLogic, 2002)
- SWFWMD District Wide Regulatory Model (ESI, 2004)

As presented previously, Table 2 provides a comparison of the reviewed groundwater model layering schemes. The TM prepared for the review of these five models is provided in Appendix A. A brief summary, general observations, and any limitations for each model are provided below.

3.1.1 Peninsular Model (Sepulveda, 2002)

This model is a compilation of 17 local numerical models. The purpose of the Peninsular Model was to: (1) test and refine the conceptual understanding of the regional groundwater flow system; (2) develop a database to support sub regional groundwater flow modeling; and (3) evaluate effects of projected 2020 groundwater withdrawals on groundwater levels. The four-layer model was based on the computer code MODFLOW-96, developed by the USGS. The top layer consists of specified-head cells simulating the SAS as a source-sink layer. The second layer simulates the IAS in southwest Florida and the ICU where it is present. The third and fourth layers simulate the UF and LFA, respectively. Steady-state groundwater flow conditions were approximated for time-averaged hydrologic conditions from August 1993 through July 1994 (1993-1994). This period was selected based on data from UF wells equipped with continuous water level recorders. The grid used for the groundwater flow model was uniform and composed of square 5,000-foot cells, with 210 columns and 300 rows.

The active model area, which encompasses approximately 40,800 square miles in peninsular Florida, includes areas of various physiographic regions classified according to natural features. Hydrogeologic conditions vary among physiographic regions, requiring different approaches to estimating hydraulic properties for different areas. The elevations of water levels for the SAS and heads in the UFA, for time-averaged 1993-1994 conditions, were computed by using multiple linear regressions of measured water levels in each of the physiographic regions. The model documentation should be consulted for additional explanation of the regression technique.

Groundwater flow simulation was limited vertically to depths containing water with chloride concentrations less than 5,000 mg/L. Groundwater flow in areas where chloride concentration exceeds 5,000 mg/L was not considered to be part of the flow system in this study. Flow across the interface represented by this chloride concentration was assumed to be negligible.

The groundwater flow model was calibrated using time-averaged data for 1993-1994 at 1,624 control points, flow measurements or estimates at 156 springs in the study area, and base-flow estimates of rivers in the unconfined areas of the UFA obtained by using a generalized hydrograph separation of recorded discharge data. Transmissivity of the IAS, UFA, and LFA; leakance of the upper and lower confining units of the IAS, the ICU, the MCU, and the MSCU; spring and riverbed conductances; and net recharge rates to

unconfined areas of the UFA were adjusted until a reasonable fit was obtained. The active model area encompasses approximately 40,800 square miles in peninsular Florida from Charlton and Camden Counties in Georgia to near the Palm Beach County – Martin County line in south Florida. The west-to-east extent of the study area spans approximately 200 miles from the Gulf of Mexico to the Atlantic Ocean.

3.1.2 Southern District Model (Beach and Chan, 2003)

The Southern District (SD) Model simulates ground-water flow in the major artesian aquifers of the southern half of the SWFWMD, which covers all or parts of 16 counties in west-central Florida. The model is based on the finite-difference, numerical code MODFLOW. The SD Model described here is calibrated to 1993, annual-average, steady-state conditions with a specified-head water table. A verification of transient response was made with a transient simulation for monthly conditions for the period January 1992 through December 1993. The SD Model represents an enlargement of the Eastern Tampa Bay (ETB) Model that was developed to assess groundwater resources within the Eastern Tampa Bay Water Resource Assessment Project (1993) area of southern Hillsborough, Manatee, and northern Sarasota Counties. The ETB Model was also used by the SWFWMD for analysis of groundwater resource conditions in the Southern Water Use Caution Area (SWUCA), which was comprised of all, or parts of the eight counties in the southern half of the SWFWMD. The SD Model is designed specifically to simulate groundwater resource conditions in the SWUCA, thereby overcoming the major limitations of the ETB Model, particularly with respect to boundary conditions.

3.1.3 Eastern Tampa Bay Model (Barcelo and Basso, 1993)

The ETB Model includes all of Manatee, Hardee, Sarasota and Desoto Counties and parts of Hillsborough, Pinellas, Polk, Charlotte, Glades and Highlands Counties. The ETB Model is an earlier version of the SD Model (Beach and Chan, 2003), which was previously discussed. The SD Model extends beyond the boundaries of the ETB Model to include Pasco and Hernando Counties to the north and Lee County to the south. Groundwater in the study area occurs in three principal aquifers: the SAS, the IAS, and the UFA. The aquifers are separated by clay confining units that restrict the vertical movement of water. Recharge to the UFA primarily results from rainfall that infiltrates the land surface and percolates downward through the SAS and IAS. Leakage occurs across the semiconfining beds that separate the IAS and SAS, and the IAS and the UFA. Although the UFA has two major producing zones, the aquifer is conceptualized as a single hydrologic unit. Regional groundwater flow in the UFA occurs predominantly in the lower permeable zone (LPZ). The IAS and UFA are simulated as single layer isotropic mediums with groundwater moving in horizontal planes. Horizontal flow in the confining beds is negligible compared to horizontal flow in the adjacent aquifers. Storage of water in the confining beds is negligible. Movement of the saltwater interface is assumed to have little effect on calculated heads. Heads in the SAS are assumed insensitive to changes in stress in the underlying aquifers.

The ETB Model is based on the numerical, finite-difference code MODFLOW, which was developed by McDonald and Harbaugh (1984 and 1996). Both steady-state and transient conditions were simulated by the model. Average groundwater resource conditions for the

year 1989 served as the target for the steady-state model. For the transient simulations, the model was calibrated to hydrologic conditions from October 1988 through September 1989.

The SD Model is divided into three layers:

- Layer 1: SAS
- Layer 2: IAS
- Layer 3: UF

The model grid is oriented along the north-south axis with uniform grid spacing of 2 miles x 2 miles, and consisting of 56 rows and 60 columns.

3.1.4 HydroGeoLogic Model (HydroGeoLogic, 2002)

The HydroGeoLogic Model is based upon the SD Model (Beach and Chan, 2003) discussed previously and an uncalibrated, saltwater intrusion model that was developed by Waterstone Environmental Hydrology and Engineering, Inc. (Waterstone). The domain of the HydroGeoLogic Model includes the southern half of Hillsborough County and all of Manatee and Sarasota Counties. The HydroGeoLogic Model is a smaller subset of the SD Model in terms of geographic area. The simulated area coincides with the domain of the Waterstone Model. Hydraulic properties and boundary conditions were assumed from the SD Model, while the model domain, grid spacing, and layer thicknesses were assumed from the Waterstone Model.

The hydrogeologic framework for this model is the same as discussed in the SD Model. The local groundwater flow system is comprised of three, vertically sequenced aquifer systems and their intervening semi-confining units. In descending order, these aquifer systems are the unconfined SAS, the confined IAS, and the confined UFA. Like the SD Model, the LFA is not considered because it contains highly mineralized groundwater and is not utilized for water supply.

The hydrogeologic framework was conceptualized as 10 layers in the HydroGeoLogic Model. In order to simulate density dependant flow and transport, intervening semi-confining layers must be explicitly modeled rather than using arrays of leakance. Hydraulic conductivity and thickness must therefore be specified for each aquifer and semi-confining unit. The Suwannee Limestone, Ocala Limestone, and Avon Park Formation are subdivided into two, three, and five finite-difference layers, respectively. These layers explicitly simulate permeable units and semi-confining units that have been identified in the three formations. The uppermost formation in the HydroGeoLogic Model is the Suwannee Limestone. Only the UFA was simulated in the HydroGeoLogic Model. Rather than explicitly incorporating the SAS and IAS/ICU into the density-dependant model, vertical flow through these aquifers is simulated by specifying a general-head boundary condition at the top of the upper permeable zone (UPZ) within the Suwannee Limestone. Hydraulic heads for the SAS and leakance values in the SD Model were used to calculate the general-head boundary conditions.

3.1.5 SWFWMD District Wide Regulatory Model (ESI, 2004)

The goal of this modeling effort was two-fold. First, develop a District-Wide Regulation Model (DWRM), which is a modified version of the USGS model of the IAS and FAS in Peninsular Florida (Sepulveda, 2002) covering the entire SWFWMD plus a buffer area surrounding the SWFWMD. The USGS model developed by Sepulveda is known as the Peninsular Model and was described previously. The second goal was to develop a modified telescopic mesh refinement (TMR) technique that would streamline the SWFWMD's review of Water Use Permits.

The DWRM approach was to use the Peninsular Model as a starting point and activate the SAS layer, which the USGS treated as an array of constant heads. The boundary of the new model was the SWFWMD boundary plus a buffer area of approximately 10 miles so that permits at the edge of the SWFWMD boundary could be evaluated. Because the original Peninsular Model did not extend fully to the southern boundary of the SWFWMD, 22 rows were added to the DWRM. The southern boundaries of the DWRM were made to coincide with the SD Model.

The hydrogeologic framework is the same as the Peninsular Model. The SAS is the uppermost water-bearing hydrogeologic unit. The SAS extends throughout most of the study area, except where the UFA is unconfined. The IAS underlies the SAS and extends throughout most of southwest Florida. Confining beds that overlie the UFA and underlie the SAS limit the vertical extent of the IAS in west-central Florida.

The FAS is a thick sequence of limestone and dolomitic limestone of Oligocene and Eocene ages with highly variable permeability. The FAS is divided into two aquifers of relatively high permeability, referred to as the UFA and the LFA. These aquifers are separated by a less permeable unit called the MCU in west-central Florida and in the northwest part of the study area, and the MSCU in east-central Florida. The top of the UFA coincides with either the top of the Suwannee Limestone or the top of the Ocala Limestone, depending upon location. Rather than a single-low permeability unit separating the UFA and LFA, several units of regional extent separate the UFA from the LFA. Any of the regionally extensive low-permeability units may contain thin layers of moderate to high permeability. These confining units are not continuous and do not necessarily consist of the same rock type everywhere.

The conceptual ground-water flow system is the same as the Peninsular Model except that the SAS (Layer 1) is actively simulated in the DWRM. In the Peninsular Model, the SAS was simulated as an array of constant heads. The SAS, IAS (or ICU in areas where the IAS is absent), the UF and the LFA were designated layers 1 through 4, respectively. Confining layers were simulated by using vertical leakance arrays. Model-simulated groundwater flow occurs horizontally within the aquifers and vertically through the confining units.

The IAS (Layer 2) in was simulated as a single active aquifer bounded above and below by arrays of leakance values. Because this model is restricted to simulating the movement of freshwater within the aquifers; areas where the IAS, the UFA and the LFA (Layers 2, 3, and 4) contain water with chloride concentrations exceeding 5,000 mg/L are considered inactive. Recharge to or discharge from the IAS is assumed to occur through the upper or lower confining units of the IAS.

The MCU was represented by vertical leakance values that limit water exchange between the UF (Layer 3) and the LFA (Layer 4) in west-central and southwest Florida.

The DWRM is based on the numerical, finite-difference code MODFLOW, which was developed by McDonald and Harbaugh (1984 and 1996). MOPDFLOW96 was the version of MODFLOW used for the DWR Model. Steady-state conditions were simulated by the model. Average groundwater resource conditions from August 1993 through July 1994 served as the target for the steady-state model.

The DWRM is divided into 4 layers.

- Layer 1: SAS
- Layer 2: IAS
- Layer 3: UFA
- Layer 4: LFA

The model grid is oriented along the north-south axis. All model cells are 5,000 feet by 5,000 feet, with 210 columns and 322 rows.

3.2 Comparison of Southwest Group of Models

The Peninsular Model extends from Charlton and Camden Counties in south Georgia to near the Palm Beach County – Martin County line in south Florida. The SD Model encompasses a smaller area, from Hernando County to the north and Lee County to the south and from the Gulf of Mexico on the west to the Kissimmee River on the east. The ETB Model is an earlier version of the SD Model and includes a smaller area, extending from Hillsborough County to the north to Charlotte County in the south, from the Gulf of Mexico on the west to Polk County on the east. The SD Model area includes all of the ETB Model area, while the Peninsular Model includes the areas of both the ETB Model and the SD Model. The DWRM is a smaller subset of the Peninsular Model and coincides with the boundaries of the SWFWMD plus a buffer zone of approximately 10 miles on all sides. The HydroGeoLogic Model is a smaller subset of the SD Model and includes the southern half of Hillsborough County and all of Manatee and Sarasota Counties. Unlike the other models, the HydroGeoLogic Model simulates solute transport and density-driven groundwater movement. All five models are finite-difference models.

Three aquifer systems are present within the area simulated by the five groundwater models. The SAS is the uppermost water-bearing hydrogeologic unit. The SAS mostly consists of variable amounts of sand, clay, sandy clay, shell beds, silt, and clay. The SAS extends throughout most of the study area, except where the UFA is unconfined. The IAS underlies the SAS and extends throughout most of southwest Florida. The unit consists mainly of clastic sediments interbedded with carbonate rocks that generally coincide with the Hawthorn Group. Confining beds that overlie the UFA and underlie the SAS limit the vertical extent of the IAS in west-central Florida. In the absence of significant permeable zones, the IAS is defined as the ICU. The ICU is present outside of west-central Florida, wherever the IAS pinches out. The UFA is considered unconfined in areas where the ICU or IAS is absent or very thin.

The FAS is a thick sequence of limestone and dolomitic limestone of Oligocene and Eocene ages with highly variable permeability. The FAS is generally divided into two aquifers of relatively high permeability, referred to as the UFA and the LFA. These aquifers are separated by a less permeable unit called the MCU in west-central Florida and in the northwest part of the study area, and the MSCU in east-central Florida. The top of the UFA coincides with the top of the Tampa Member, Suwannee Limestone or Ocala Limestone, depending upon location. The bottom of the UF is the top of the shallowest, significant, regional confining unit.

In east-central Florida, the UFA and LFA are separated by the MSCU, a sequence of somewhat permeable, soft, chalky, limestone that locally contains some gypsum and chert and commonly is partially dolomitized. In west-central Florida and in the northwest part of the study area, the UFA and LFA are separated by the MCU, which is composed of gypsiferous dolomite and dolomitic limestone of considerably lower permeability than that of the MSCU in east-central Florida.

Two discrete permeable zones have been defined in the UFA. The UPZ has been identified within sections of the Suwannee Limestone and the Tampa Member of the Arcadia Formation. The LPZ of the UFA has been identified within the lower part of the Ocala Limestone and the upper part of the Avon Park Limestone. The Ocala Limestone occurs between the Suwannee Limestone and the Avon Park Formation and is thought to function as a semi-confining unit between the UPZ and LPZ.

Two discrete permeable zones have been identified in the LFA in northeast Florida. They consist of an upper permeable zone (LF1) and lower Fernandina permeable zone (FPZ). In south Florida, two permeable zones have been identified. The upper producing zone (LF1) is found within the lower portion of the Avon Park Formation below the MCU, while the lower producing zone is found in the Oldsmar Formation. The lower producing zone is known as the Boulder Zone due to drilling characteristics, and is known for extremely high transmissivity.

The Peninsular Model includes four layers: the SAS, IAS (ICU), UFA and LFA. Layer 2 is either the IAS or ICU, depending upon location. The UPZ and LPZ of the UFA are simulated as one layer (Layer 3) given the evidence that there is significant hydraulic connection between the units. Layer 4 is the LFA, which is not simulated in the SD Model or the ETB Model. In west-central Florida where the SD Model and ETB Model are situated, groundwater in the LFA is highly saline. As a result, the LFA is not simulated in those area models.

The SD Model explicitly simulates separate permeable zones found in the IAS in west-central Florida. Permeable zones known locally as PZ2 and PZ3 are simulated as Layers 2 and 3, respectively. In contrast, the Peninsular Model utilizes one layer to simulate the IAS. Layers 4 and 5 of the SD Model simulate the UPZ and LPZ of the UFA. The Peninsular Model utilizes one layer to simulate the UFA. The LFA, which the Peninsular Model simulates, is not simulated by the SD Model.

The ETB Model has three layers, which simulate the SAS, the IAS, and the UFA. The LFA is not simulated nor are multiple zones of permeability in the IAS or UFA. All four models indirectly simulate semi-confining units and confining units with arrays of leakance values.

The DWRM is very similar to and is based on the Peninsular Model. Like the Peninsular Model, the DWRM consists of four layers. Layer 1 is the SAS. Layer 2 is the IAS and Layer 3 is the UFA. Layer 4 is the LFA. Unlike the Peninsular Model, which utilizes constant heads to simulate the SAS, the SAS is actively simulated in the DWRM. Layer 2 of the DWRM simulates PZ3 of the IAS, whereas Layer 2 of the Peninsular Model simulates the average of PZ2 and PZ3 of the IAS. The SD Model simulates PZ2 and PZ3 as separate layers. Another similarity between the Peninsular Model and the DWRM is that the base of the model is the 5,000 mg/L chloride concentration. Strata that contain groundwater with a chloride concentration in excess of 5,000 mg/L are not simulated. In west-central Florida, the LFA is highly mineralized and therefore is not simulated by either model.

The HydroGeoLogic Model is different from the other four models in that it is designed to simulate density-driven, solute transport processes. The HydroGeoLogic Model is based on the SD Model, but covers a smaller geographic area consisting of southern Hillsborough County, Manatee County, and Sarasota County. A notable difference between the two models is that the semi-confining units are explicitly simulated in the HydroGeoLogic Model as separate model layers. The other four models simulate advective groundwater movement and represent semi-confining units with arrays of leakance. The semi-confining units are not directly simulated with model layers. Ten layers are used in the HydroGeoLogic Model to simulate the permeable and less permeable units in the Suwannee Limestone, Ocala Limestone, and Avon Park Formation. The SAS and IAS are not simulated directly in the HydroGeoLogic Model. General-head boundary cells are used instead to simulate the movement of water vertically into the Suwannee Limestone, which is the top of the model. The bottom of the model is the MCU. Two model layers are used to simulate the Suwannee Limestone, while three layers are used to simulate the Ocala Limestone. Five layers are used to simulate the Avon Park Formation. The primary purpose of the HydroGeoLogic Model is to simulate the movement of the saltwater/freshwater interface and the vertical movement of saline water in order to make sound decisions regarding permit applications. Likewise, the primary purpose of the four advective transport models is to simulate potential impacts to the various aquifer systems without consideration of density differences in the groundwater.

3.3 Southeast Florida Region Model Review

The southeast region of Florida generally included the central area around Orange County, southwest Florida around Lee County, and east to Broward County. The area of focus was generally the SFWMD jurisdiction. The three models reviewed for the central and south region of Florida were:

- Lee County Model (Bower, et al., 1990)
- Lower East Coast Model (Fairbank et al., 1999)
- East-Central Model (McGurk and Presley, 2002)

Presented previously, Table 2 provides a comparison of the reviewed groundwater model layering schemes. The TM prepared for the review of these three models is provided in Appendix B. A brief summary, general observations, and any limitations for each model are provided below.

3.3.1 Lee County Model (Bower et al., 1990)

The Lee County Model was created to be used for predictive purposes when evaluating requests for large groundwater withdrawals and to serve as a basis for groundwater management planning in Lee County. The three aquifer systems within the study area are the SAS, IAS, and UFA. The SAS includes the unconfined water table aquifer and the lower Tamiami aquifer. The IAS includes the Sandstone Aquifer and Mid-Hawthorn Aquifer, and associated semi-confining units. The UFA includes the Lower Hawthorn Aquifer and deeper permeable zones.

The Lee County Model extends over 2,000 square miles and consists of seven layers to simulate the SAS, the IAS, and the UFA. Cells in the interior of the model are 1 mile square. Cells on the north and west sides of the model were expanded to reduce boundary effects seen during early calibration attempts.

3.3.2 Lower East Coast Floridan Aquifer Model (Fairbank et al., 1999)

This three-dimensional steady-state model was created for the Lower East Coast (LEC) Planning Area. The LEC Model covers 16,434 square miles and has none layers with a uniform grid spacing of 1 mile. The model simulates three primary flow zones, two within the UFA and a third in the LFA. Flow Zone 1 includes permeable zones at or near the top of the Avon Park Formation and the Ocala Limestone (Layer 3). Flow Zone 2 includes permeable zones within the upper part of the Avon Park Formation (Layer 5). Flow Zone 3 includes the shallowest producing intervals at or near the top of the Oldsmar Formation (Layer 7). Low permeability units between the primary flow zones are included explicitly in this model as individual layers. Additionally, the SAS and the BZ are included as constant head boundaries at the top and bottom of the model. Water quality in the UFA in the area of the model varies, causing density differences which affect groundwater flow. The model utilizes "fresh-water equivalent head values" to account for this water quality variation.

3.3.3 East-Central Floridan Aquifer Model (McGurk and Presley, 2002)

This three-dimensional steady-state model was created, expanding on previous regional models covering all or parts of Orange, Seminole, Brevard, Lake, Osceola, Marion, Polk, Sumter, and Volusia Counties. The East-Central (EC) Model covers 7,568 square miles, has uniform 2,500-foot square cells, and has four layers. The layers corresponded to the SAS, UFA (two layers), and LFA.

In this area, drainage wells provide significant man made source of recharge to the FAS. These injection wells are numerous in the model. Data utilized to create this detailed model came from many sources. Rainfall, surface water data, observation and test well data, groundwater withdrawal data, wastewater treatment plant flows and reuse data were obtained from agencies and reports on previous models and studies.

3.4 Comparison of Southeast Group of Models

The LEC Model utilizes nine layers to simulate the SAS, UFA, and LFA. The IAS is not simulated because it is not present within the model area. Semi-confining units within the LEC Model are explicitly simulated as separate layer, whereas they are implicitly simulated

with leakance arrays in the EC Model and Lee County Model. Two permeable zones in the UFA are simulated in the LEC Model. The LFA is simulated as one permeable zone with one active layer. The EC Model utilizes four layers to simulate the SAS (Layer 1), UFA (Layers 2 and 3) and LFA (Layer 4). As with the LEC Model, the IAS is not present in the model area and is not simulated. The Lee County Model uses seven layers to simulate the SAS, the IAS, and UFA. The LFA is not simulated. In Lee County, the IAS is a significant source of water supply and consists of two permeable zones: mid-Hawthorn Aquifer and Sandstone Aquifer. The SAS also consists of two permeable zones: the unconfined water table aquifer and the confined Lower Tamiami Aquifer. The UFA is simulated as two active permeable zones: Lower Hawthorn Aquifer and the Suwannee Aquifer.

The MF is not simulated in the three models. The Lee County Model simulates two active permeable units in the UFA, whereas the LEC Model simulates two permeable units in the UFA and one active permeable unit in the LFA. The EC Model, like the LEC Model, simulates two permeable units in the UFA and one permeable unit in the LFA. None of the model documentation mentions the MF.

SECTION 4

Dispersion Research and Database

The goal of this research effort was to provide dispersion data on primarily sandstone and carbonate aquifers with a focus on technical sources from Florida and other similar geologic environments from the United States and other areas of the world. Based on the USACE's scope of work, technical papers, reports and other sources available to and obtained by CH2M HILL were reviewed and dispersion values were tabulated. In addition to the dispersion data (which was typically presented as longitudinal dispersivity), other pertinent information, where available, was also tabulated in the database for comparative purposes. This supplemental aquifer data include: transmissivity, storativity, transverse dispersivity, and molecular dispersivity, and aquifer name, matrix, thickness, and type. The dispersion study TM and information database is provided in Appendix C.

Dispersion values for other sedimentary, igneous and metamorphic aquifer matrixes have also been included and may be useful for evaluation of fractured flow through dolomite, where applicable. CH2M HILL was able to obtain dispersion data from primarily domestic technical publications, which were limited in number. To supplement dispersion data from foreign sources, CH2M HILL contracted Nerac, Inc., an outside research service. The combined research effort generated 40 literature sources from which the dispersion data were obtained and tabulated.

Very few of the documents had physical data on dispersivity based on tracer or other in-situ testing. Many of the dispersivity values presented in the cited literature were estimated, established from other sources, or where the results of groundwater model calibration. It was also noted that the differences in the ranges of dispersivity values depended on how the coefficient was being used. The values based on large-scale model calibration were relatively high, while those based on matching results from single-well tracer tests were comparatively low. This illustrates that dispersivity values in the literature are scale-dependent and dependent on their ultimate use in modeling or calculations. Essentially, dispersivity is more of a modeling calibration factor rather than an actual measured aquifer parameter in the available literature. The values in the sited literature appear to depend also on the flow field and the scale at which it is being described.

SECTION 5

Conceptual CERP Model Recommendations

5.1 Common Hydrogeologic Framework

The review of the eight models discussed above indicates that the best approach to simulating the common hydrogeologic framework is to represent the SAS, IAS, FAS and intervening confining and semi-confining layers as discrete layers within the CERP Model. The semi-confining and confining units must be directly simulated via model layers if solute transport processes and density-driven groundwater movement are to be simulated. The following conceptual model is one possibility:

Layer 1 – SAS
Layer 2 – Semi-confining Unit
Layer 3 – IAS ***(potential ASR Zone)***
Layer 4 – Semi-confining Unit
Layer 5 – UPZ of the UFA ***(potential ASR Zone)***
Layer 6 – Semi-confining Unit
Layer 7 – LPZ of the UFA ***(potential ASR zone)***
Layer 8 – MC1 Semi-confining Unit
Layer 9 – MF Middle Floridan Aquifer ***(local potential ASR zone)***
Layer 10 – MC2 Semi-confining Unit
Layer 11 – LF1 UPZ of the LFA
Layer 12 – LC Semi-confining Unit
Layer 13 – BZ Boulder Zone (where present)
Layer 14 – Sub-Floridan Confining Unit

The expected focus of the modeling effort will be to simulate ASR in the UPZ of the UFA and to a lesser extent the LPZ of the UFA, and the IAS. Which permeable zones that are selected will largely depend upon native groundwater quality and the presence of competing groundwater users. Potential ASR zones become less ideal as the TDS concentration increases, which will limit recovery efficiency. Water quality falls within the ideal range for ASR consideration in all three proposed zones depending upon location. With these general criteria in mind, certain layers in the proposed model can be eliminated from consideration as an ASR zone. However, they may still need to be simulated in order to assess potential impacts from ASR activities.

5.2 Potential ASR Storage Zones

The SAS (Layer 1) could be eliminated from ASR consideration due to competing users, the presence of sensitive ecosystems, lack of available storage (i.e., high water table), excellent groundwater quality, and lack of suitable transmissivity and storage volume for ASR. Likewise, the IAS (Layer 3) in west-central Florida can be eliminated for similar reasons. The BZ (Layer 11) can be eliminated from consideration because the transmissivity of this unit is

so large as to preclude development of an ASR storage zone. This unit is also widely used in south Florida as a disposal zone for municipal reclaimed water. Because of these considerations, the SAS, IAS (in west-central Florida), and BZ can be ruled out as potential ASR storage zones.

The UPZ of the UFA is widely used as an ASR storage zone in Florida. It generally coincides with the Tampa member of the Arcadia Formation and the Suwannee Limestone. There are no active ASR systems in Florida that utilize deeper aquifers than the UPZ for ASR storage. There is at least one system in the planning stages that will use the LPZ of the UFA for an ASR storage zone. The LPZ is generally found within the upper portion of the Avon Park Formation. These two zones would be the primary targets for developing the CERP network of ASR wells. Locally in southwest Florida, the Lower Hawthorn Producing Zone (IAS) is currently utilized as a source of groundwater for reverse osmosis water treatment in Lee County and could be utilized as an ASR storage zone. There are few competing users of this zone due to the availability of good quality water in shallower aquifers.

The MF and LF1 of the LFA are not expected to be less favorable potential candidates for ASR system development on a regional scale. Due to formation depth and saline water quality, use of LF1 in central Florida would be precluded because it is a source of good quality water for the Orlando area However, after further investigation, these formations may be found to be locally favorable for ASR development. Elsewhere, the ambient water quality (typically elevated salinity concentrations) in the MF and the LF1 would preclude ASR development. In terms of further investigation, the permeable zones within the UFA should be considered the best candidates for ASR development, followed to a lesser degree by the IAS in southwest Florida. The IAS and the LPZ of the UFA have fewer competing users but have more saline groundwater quality, whereas the UPZ of the UFA has better quality groundwater but a greater number of competing users. These factors (competing users and ambient groundwater quality) are among several that must be carefully evaluated to determine utility for ASR development.

5.3 Discussion of Model Framework

5.3.1 SAS

The SAS is present throughout the area simulated by the five models. Horizontal hydraulic conductivity and thickness are reasonably well known. Vertical hydraulic conductivity is less well known but can be extrapolated in most cases from measured values of horizontal hydraulic conductivity. Through most of peninsular Florida, the SAS consists of unconsolidated deposits of sand, shell, and clay. In south Florida, there is a significant limestone component to the SAS. It is known locally as the Lower Tamiami Aquifer (LTA). In this area, the SAS is composed of an upper unconfined aquifer, which overlies the confined LTA. In southeast Florida, the Biscayne aquifer has a significant limestone component.

5.3.2 Confining and Semi-confining Units

Direct simulation of the confining and semi-confining units will be problematic because little data is available that characterizes their hydraulic properties. In most cases, only leakance is available when vertical hydraulic conductivity and thickness are needed. Hydraulic characteristics of the confining unit below the SAS are fairly well known. This unit retards the flow of groundwater between the SAS and the underlying IAS (where present). Where the IAS is not present, the confining unit is designated as the ICU. The ICU separates the SAS from the underlying UFA. In areas where the IAS or ICU is not present, the UFA is considered unconfined. In areas where the ICU is present, the hydraulic properties of model Layers 2 through 4 must be modified so that they collectively simulate a confining unit, the ICU. In areas where both the ICU and IAS are not present and the UFA is unconfined, Layers 1 through 4 would be rendered inactive. Reese (2004) identified three confining units (MC1, MC2, and LC) in the FAS. MC1 is equivalent to middle confining unit I or II of Miller and separates the UF from the MF. MC2 is equivalent to middle confining unit VI of Miller (1986) and separates the MF from the LFA. LC is found on top of the BZ and is equivalent to middle confining unit VIII (Miller, 1986). The vertical hydraulic conductivity and thickness values of MC1, MC2, and LC are poorly known and will be problematic to define in the CERP Model.

5.3.3 Intermediate Aquifer System

The IAS contains significant permeable zones in west-central Florida and southwest Florida. Three permeable zones, known locally as PZ1, PZ2, and PZ3, have been defined in west-central Florida south of State Road 60 in Hillsborough County. PZ2 and PZ3 are more widespread than PZ1 and are found in Sarasota, Desoto, and Charlotte Counties. In southwest Florida (Lee and Collier Counties) the IAS contains the Sandstone Aquifer and the Mid-Hawthorn Aquifer. Both aquifers are significant sources of potable water supply in these counties. Outside of southwest Florida and west-central Florida, the IAS is not present and consists instead of significant confining units known as the ICU. CH2M HILL recommends that the IAS be simulated as one active layer in west-central Florida and as two active layers in southwest Florida. Outside of these two areas, the IAS layers should be simulated as semi-confining units representing the ICU. The hydraulic characteristics of the IAS and ICU are fairly well known.

5.3.4 Upper Floridan Aquifer

The UFA can be simulated as one discrete permeable unit, which is the approach of the SD Model, Peninsular Model, ETB Model, and DWRM. The LEC Model and EC Model simulated the UFA as two or more active model layers. Two dominant permeable zones have been identified in the UFA within the wider model area. Hydraulic characteristics of the UPZ and LPZ of the UFA are fairly well defined and different in magnitude, with the LPZ being considerable more transmissive. There is ample evidence from APTs in Florida that the two permeable units act as one hydraulic unit with little confinement between them. As a result, the common approach has been to simulate the UFA as one model layer and utilize hydraulic properties as an average of the two units. However, hydraulic properties for both permeable zones are sufficiently well known to warrant delineation as two separate layers. The UPZ of the UFA is commonly found in the Suwannee Limestone and lower

Miocene formations, whereas the LPZ is commonly found at the bottom of the Ocala Limestone, or top of the Avon Park Formation. In central and eastern Florida, the Suwannee Limestone is not present and the UPZ is found at the top of the Ocala Limestone. Based upon the review of all eight models, CH2M HILL recommends that the UFA be simulated with two active layers representing the UPZ and LPZ. Areas where no APTs have been performed will require estimation of hydraulic parameters.

Based on CH2M HILL's ASR and injection well experience concerning horizontal anisotropy, the carbonate formations that typically comprise the storage zones are likely to have varying physical properties (anisotropy) in the horizontal direction around the well. These properties are difficult to quantify at the local level and can only be inferred regionally. The dominant structural fracture pattern in the Eocene sediments suggests two preferential orientations, one NW - SE, and the other SW - NE. It is possible that permeable zones within the Floridan aquifer have similar orientations, however, direct evidence from other wells is lacking. In the typical ASR or DIW facility, the number of monitoring wells is inadequate to evaluate anisotropic conditions and only anecdotal observations are possible. Because the influence of anisotropic conditions may vary from well to well, it is very difficult to predict the local affect on aquifer behavior. Experience suggests that in most cases, any detrimental affects can be overcome with careful selection of open hole intervals and well spacing. However, there will be a certain percentage of sites where local fracture and cavity systems will impact the specific capacity of a particular well and may impact the performance of water supply wells and ASR wells. This is true in Floridan aquifer wells throughout the state. On a regional scale, it is common practice to assume the Floridan aquifer behaves as an isotropic and homogeneous unit with large scale features, such as springs, rivers, recharge areas, coastal discharge, etc., influencing the potentiometric surface and subsequent groundwater flow patterns. This has proven to be a reasonable assumption for regional scale evaluations.

5.3.5 Middle Floridan Aquifer and Lower Floridan Aquifer

The MF is a new informal hydrogeologic unit (Reese, 2004) and as such is not discussed in any of the documentation for the eight models. In the model documentation, the FAS is subdivided into the UFA and LFA, which is consistent with previous USGS reports (Miller, 1986). According to Miller, the MCU separates the UFA from the LFA in west central and southwest Florida. In central and eastern Florida, the MSCU separates the UFA from the LFA. Two permeable zones in the LFA are identified in the model documentation. They consist of an upper permeable zone (typically located with the lower portion of the Avon Park Formation) and the Boulder Zone (BZ), which is located within the Oldsmar Formation. The upper permeable zone of the LFA is designated by Reese (2004) as LF1.

The MF is a permeable zone that appears to be located within the middle portion of the Avon Park Formation above the uppermost permeable zone (LF1) of the LFA. The MF appears to be sandwiched between two confining units that have been defined as MC1 and MC2 by Reese (2004). The lower confining unit (MC2) is also known as middle confining unit VI (Miller, 1986) and is restricted to south Florida. Relatively little information is known about the MF because there has been no need to drill into this unit due to poor water quality.

For the CERP Model, the LFA should therefore be simulated as containing two major permeable zones: LF1 and the BZ. The MF should be simulated as a distinct permeable zone separate from the LFA. Alternatively, the MF could be considered a separate permeable zone of the LFA. However, because there are significant confining units separating the MF from the UFA above and LFA below, it was decided to define it as a separate aquifer. The lowermost permeable zone of the LFA is the BZ and is typically found within the Oldsmar Formation. Relatively little hydraulic data is available for the MF and LFA due to availability of good quality water in shallower aquifers. Groundwater quality in the LFA (LF1) is relatively poor in west-central, southwest, and south Florida. In central and eastern Florida, groundwater quality is relatively good in LF1, which in these areas of Florida is utilized extensively as a source of drinking water.

5.4 Discussion of Model Grid or Mesh Spacings

The USACE intends to use a finite- element approach to the model simulations. It is difficult to determine the number of elements that will be required without knowing the exact geometry of the elements in the proposed finite-element model. Each finite-element model is different and different element configurations can be used (i.e., trapezoid verses triangular). All of the models reviewed utilized the finite-difference mathematical formulation. Most of the models used 2,500-foot to 5,000-foot uniform cell sizes depending on the size of the model study area and the detail the authors were targeting without exceeding the available computing power.

Assuming the model will cover an area from north of Orlando to the Florida Keys and from the east coast to the west coast, the dimensions of the model will be approximately 150 miles from east to west and 300 miles from north to south. Given our level of understanding of the distribution of aquifer properties in peninsular Florida it would be appropriate to assume that cell size or element size should approximate one mile or a significant portion of one mile in dimension. Of course, the greater the resolution required, the greater the processing power required. A compromise must be reached that accounts for the desired resolution of the mathematical model and the availability of processing power and speed. A rough estimate of the number of finite-difference cells required for the model assuming certain cell sizes and 14 model layers is provided below:

Cell Size	No. Columns	No. Rows	No. of Cells or Calculation Points
1 Mile	150	300	45,000
0.5 Mile	300	600	180,000
0.25 Mile	600	1,200	720,000

Square shaped cells are assumed, that is cell dimensions are the same along the X and Y axis. An aspect ratio of up to 5 can be used in most finite-element models so the geometry of the cells/elements can easily deviate from the square. The number of cells or calculation points would increase accordingly if the number of layers used to simulate the hydrogeologic regime is increased. As many of 28 layers (2 model layers per hydrogeologic layer) may be utilized to achieve the desired level of accuracy.

SECTION 6

Recommended CERP Model Framework

Fourteen layers are recommended for the CERP Model to simulate the hydrologic regime of peninsular Florida. This layering scheme (previously presented) includes seven semi-confining/confining units and seven permeable units. The permeable units consist of the SAS (Layer 1), IAS (Layer 3), UPZ of the UFA (Layer 5), LPZ of the UFA (Layer 7), MF (Layer 9), LF1 (Layer 11), and BZ (Layer 13).

Alternatively, the model framework can be reduced to 12 layers if the IAS is not simulated because it is only present in west-central Florida and southwest Florida. The SAS and BZ could also be simulated as arrays of constant heads to further simplify the CERP Model.

Southwest Florida Region Model Review TM

Southwest Florida Region Groundwater Model Review: Sepulveda (2002), Beach and Chan (2003), Barcelo and Basso (1993), HydroGeoLogic (2002), and Environmental Simulations, Inc. (2004)

PREPARED FOR: US Army Corp of Engineers

PREPARED BY: CH2M HILL

DATE: December 14, 2005

PROJECT NUMBER: 334350.TW.03

Contents

Introduction and Purpose

The goal of this project is to collect and summarize data from available model documentation and provide recommendations to the U.S. Army Corps of Engineers (USACE) Jacksonville District for the development of a Regional Groundwater Model of Florida. This Technical Memorandum (TM) summarizes the model reviews for northern and west-central Florida. A second TM has been prepared that summarizes three separate models from central and south Florida.

Five models were reviewed:

- Peninsular Model (Sepulveda, 2002)
- Southern District of SWFWMD Model (Beach and Chan, 2003)
- Eastern Tampa Bay Model (Barcelo and Basso, 1993)
- HydroGeoLogic Model (HydroGeoLogic, 2002)
- District Wide Regulatory Model (Environmental Simulations, Inc. [ESI], 2004)

Figure 1 shows the geographic relationship between the five model areas.

Comparison of Model Frameworks

The Peninsular Model developed by Sepulveda (2002) extends from Charlton and Camden Counties in south Georgia to near the Palm Beach County – Martin County line in south Florida. The Beach and Chan Model (2003), known as the Southern District (SD) Model, encompasses a smaller area, from Hernando County in the north to Lee County in the south and from the Gulf of Mexico in the west to the Kissimmee River in the east. The Eastern Tampa Bay (ETB) Model (Barcelo and Basso, 1993) is an earlier version of the SD Model and includes a smaller area, extending from Hillsborough County in the north to Charlotte County in the south, from the Gulf of Mexico in the west to Polk County in the east. The SD Model area includes all of the ETB Model area, while the Peninsular Model includes the areas of both the ETB Model and the SD Model. The District Wide Regulatory (DWR) Model (ESI, 2004) is a smaller subset of the Peninsular Model and coincides with the boundaries of the Southwest Florida Water Management District (SWFWMD) plus a buffer zone of approximately 10 miles on all sides. The southern boundary of the DWR Model was extended past the southern boundary of the Peninsular Model to coincide with the southern boundary of the SWFWMD. The HydroGeoLogic Model (2002) is a smaller subset of the SD Model and includes the southern half of Hillsborough County and all of Manatee and Sarasota Counties. Unlike the other models, the HydroGeoLogic Model simulates solute transport and density-driven groundwater movement. All five models are finite-difference models.

Three aquifer systems are present within the area simulated by the five groundwater models. The surficial aquifer system (SAS) is the uppermost water-bearing hydrogeologic unit. The SAS mostly consists of variable amounts of sand, clay, sandy clay, shell beds, silt, and clay. The SAS extends throughout most of the study area, except where the Upper Floridan aquifer (UFA) is unconfined. The intermediate aquifer system (IAS) underlies the SAS and extends throughout most of southwest Florida. State Road 60 is generally considered the northern boundary of the IAS in western Florida. The unit consists mainly of clastic sediments interbedded with carbonate rocks that generally coincide with the Hawthorn Group. Confining beds that overlie the UFA and underlie the SAS limit the vertical extent of the IAS in west-central Florida. In the absence of significant permeable zones, the IAS is defined as the intermediate confining unit (ICU). The ICU is present outside of west-central Florida, wherever the IAS pinches out. The UFA is considered to be unconfined in areas where the ICU or IAS is absent or very thin.

The Floridan Aquifer System (FAS) is a thick sequence of limestone and dolomitic limestone of Oligocene and Eocene ages with highly variable permeability. The FAS is divided into two aquifers of relatively high permeability, referred to as the UFA and the Lower Floridan aquifer (LFA). These aquifers are separated by a less permeable unit called the Middle

Confining Unit (MCU) in west-central Florida and in the northwest part of the study area, and the middle semi-confining unit (MSCU) in east-central Florida. The top of the UFA coincides with the top of the Tampa Member, Suwannee Limestone or the Ocala Limestone, depending upon location. The bottom of the UFA is the top of the shallowest, significant, regional confining unit.

In east-central Florida, the UFA and LFA are separated by the MSCU, a sequence of somewhat permeable, soft, chalky, limestone that locally contains some gypsum and chert and commonly is partially dolomitized. In west-central Florida and in the northwest part of the study area, the UFA and LFA are separated by the MCU, which is composed of gypsiferous dolomite and dolomitic limestone of considerably lower permeability than that of the MSCU in east-central Florida.

Two discrete permeable zones have been defined in the UFA. The upper permeable zone (UPZ) has been identified within sections of the Suwannee Limestone and the Tampa Member of the Arcadia Formation. The lower permeable zone (LPZ) of the UFA has been identified within the lower part of the Ocala Limestone and the upper part of the Avon Park Limestone. The Ocala Limestone occurs between the Suwannee Limestone and the Avon Park Limestone and is thought to function as a semi-confining unit between the UPZ and LPZ.

Two discrete permeable zones have been identified in the LFA in northeast Florida. They consist of a UPZ also known as LF1, and the lower Fernandina permeable zone (FPZ). In south Florida, two permeable zones have also been identified. The upper producing zone (LF1) is found within the lower portion of the Avon Park Formation below the MCU, while the lower producing zone is found in the Oldsmar Formation. The lower producing zone is known as the "Boulder Zone" due to drilling characteristics and is known for extremely high transmissivity. The Middle Floridan Aquifer identified by Reese (2004) is not discussed in any of the model documentation.

The five models compared for this TM are provided in Table 1. The Peninsular Model includes four layers: the SAS, IAS (ICU), UFA, and LFA. Layer 2 is either the IAS or ICU, depending upon location. The UPZ and LPZ of the UFA are simulated as one layer (Layer 3) given the evidence that there is significant hydraulic connection between the units. Layer 4 is the LFA, which is not simulated in the SD Model or the ETB Model. In west-central Florida where the SD Model and ETB Model are situated, groundwater in the LFA is highly saline. As a result, the LFA is not simulated in those area models.

The SD Model explicitly simulates separate permeable zones found in the IAS in west-central Florida. Permeable zones known locally as PZ2 and PZ3 are simulated as Layers 2 and 3, respectively. In contrast, the Peninsular Model utilizes one layer to simulate the IAS. Layers 4 and 5 of the SD Model simulate the UPZ and LPZ of the UFA. The Peninsular Model utilizes one layer to simulate the UFA. The LFA, which the Peninsular Model simulates, is not simulated by the SD Model.

The ETB Model has three layers, which simulate the SAS, IAS and the UFA. The LFA is not simulated nor are multiple zones of permeability in the IAS or UFA. All four models indirectly simulate semi-confining units and confining units with arrays of leakance values. The DWR Model is very similar to and is based on the Peninsular Model. Like the Peninsular Model, the DWR Model consists of four layers. Layer 1 is the SAS. Layer 2 is the

IAS, and Layer 3 is the UFA. Layer 4 is the LFA. Unlike the Peninsular Model, which utilizes constant heads to simulate the SAS, the SAS is actively simulated in the DWR Model. Layer 2 of the DWR Model simulates PZ3 of the IAS whereas Layer 2 of the Peninsular Model simulates the average of PZ2 and PZ3 of the IAS. The SD Model simulates PZ2 and PZ3 as separate layers. Another similarity between the Peninsular Model and the DWR Model is that the base of the model is considered to be the 5,000 milligrams per liter (mg/L) chloride concentration. Strata that contain groundwater with a chloride concentration in excess of 5,000 mg/L are not simulated. In west-central Florida, the LFA is highly mineralized and therefore is not simulated by either model.

The HydroGeoLogic Model is different from the other four models in that it is designed to simulate density-driven, solute transport processes. The HydroGeoLogic Model is based on the SD Model, but covers a smaller geographic area consisting of southern Hillsborough County, Manatee County, and Sarasota County. A notable difference between the two models is that the semi-confining units are explicitly simulated in the HydroGeoLogic Model as separate model layers. The other four models simulate advective groundwater movement and represent semi-confining units with arrays of leakance. The semi-confining units are not directly simulated with model layers. Ten layers are used in the HydroGeoLogic Model to simulate the permeable and less permeable units in the Suwannee Limestone, Ocala Limestone, and Avon Park Formation. The SAS and IAS are not simulated directly in the HydroGeoLogic Model. General-head boundary cells are used instead to simulate the movement of water vertically into the Suwannee Limestone, which is the top of the model. The bottom of the model is the MCU. Two model layers are used to simulate the Suwannee Limestone, while three layers are used to simulate the Ocala Limestone. Five layers are used to simulate the Avon Park Formation. The primary purpose of the HydroGeoLogic Model is to simulate the movement of the saltwater/freshwater interface and the vertical movement of saline water in order to make sound decisions regarding permit applications. Likewise, the primary purpose of the four advective transport models is to simulate potential impacts to the various aquifer systems without consideration of density differences in the groundwater.

Model Summaries

Sepulveda, 2002. Simulation of Groundwater Flow in the Intermediate and Floridan Aquifer Systems in Peninsular Florida, U.S. Geological Survey Water-Resources Investigations Report 02-4009.

Model Area

The active model area encompasses approximately 40,800 square miles in peninsular Florida, as shown in Figure 2, from Charlton and Camden Counties in Georgia to near the Palm Beach – Martin County line in south Florida. The west-to-east extent of the study area spans approximately 200 miles, from the Gulf of Mexico to the Atlantic Ocean.

Hydrogeologic Framework

The hydrogeologis units of the study area are shown in Figure 3. The SAS is the uppermost water-bearing hydrogeologic unit. The SAS mostly consists of variable amounts of sand,

clay, sandy clay, shell beds, silt, and clay. Limestone units within the SAS are primarily in southwest Florida. The SAS extends throughout most of the study area, except where the UFA is unconfined. The IAS underlies the SAS and extends throughout most of southwest Florida. The unit consists mainly of clastic sediments interbedded with carbonate rocks that generally coincide with the Hawthorn Group. Confining beds that overlie the UFA and underlie the SAS limit the vertical extent of the IAS in west-central Florida. The thickness of the IAS varies from approximately 25 feet in parts of Hillsborough and Polk Counties to approximately 400 feet in Charlotte County.

The hydrogeologic units, ICU and IAS, within the Hawthorn Group are differentiated based upon the permeability of the rock. In contrast to the IAS, the ICU is considerably less permeable. The UFA is considered to be unconfined in areas where the ICU or IAS is absent or very thin.

The FAS is a thick sequence of limestone and dolomitic limestone of Oligocene and Eocene ages with highly variable permeability. The FAS is divided into two aquifers of relatively high permeability, referred to as the UFA and the LFA. These aquifers are separated by a less permeable unit called the MCU in west-central Florida and in the northwest part of the study area, and the MSCU in east-central Florida. The top of the UFA coincides either with the top of the Suwannee Limestone or the top of the Ocala Limestone, depending upon location. Rather than a single-low permeability unit separating the UFA and LFA, several units of regional extent separate the UFA from the LFA. Any of the regionally extensive low-permeability units may contain thin layers of moderate to high permeability. These confining units are not continuous and do not necessarily consist of the same rock type everywhere.

In east-central Florida, the UFA and LFA are separated by the MSCU, a sequence of somewhat permeable, soft, chalky, limestone that locally contains some gypsum and chert and commonly is partially dolomitized. In west-central Florida and in the northwest part of the study area, the UFA and LFA are separated by the MCU, which is composed of gypsiferous dolomite and dolomitic limestone of considerably lower permeability than that of the MSCU in east-central Florida.

In northeast Florida, the LFA is subdivided into two zones, the upper zone of the LFA and the FPZ. In southeast-central Florida, a localized production zone called the Boulder zone occurs within the LFA. Generally low-permeability dolomite and evaporite beds form the sub-Floridan confining unit, or the base of the FAS. These beds of very low permeability serve as the hydraulic base of the FAS and in the study area, and range in elevation from approximately -1,200 feet mean sea level (msl) in the northwest to approximately -4,100 feet msl in south Florida.

Conceptual Model

The conceptual groundwater flow system is shown in cross sections on Figure 4. Both sections are oriented from east to west. The regional groundwater flow system was simulated as a quasi-three-dimensional groundwater flow model with four layers. Figure 5 shows the principal hydrogeologic units and equivalent layers in the regional model. The SAS, IAS (or ICU in areas where the IAS is absent), the UFA and the LFA were designated Layers 1 through 4, respectively. The SAS was simulated as a source-sink layer. Confining

layers were simulated by using vertical leakance arrays. Model-simulated groundwater flow occurs horizontally within the aquifers and vertically through the confining units.

The IAS (Layer 2) in southwest and south-central Florida was simulated as a single active aquifer bounded above and below by arrays of leakance values. Because this model is restricted to simulating the movement of freshwater within the aquifers, areas where the IAS, the UFA and the LFA (Layers 2, 3, and 4) contain water with chloride concentrations exceeding 5,000 mg/L are considered inactive. Recharge to or discharge from the IAS is assumed to occur through the upper or lower confining units of the IAS.

The MCU was represented by vertical leakance values that limit water exchange between the UFA (Layer 3) and the LFA (Layer 4) in west-central and southwest Florida, and in the northwest part of the study area to a greater degree than in areas where the MSCU is present. The MSCU in east-central, southeast, and northeast Florida was represented by an array of vertical leakance values that allowed water exchange between the UFA and LFA.

The River, Drain, and Recharge packages were used in this groundwater model. The River package was used to simulate the discharge of water to and from rivers in unconfined areas of the UFA. The discharge of groundwater to swamps in unconfined areas of the UFA and the flow from UFA springs located outside river cells were simulated by using the Drain package. Flow from springs was simulated as discharge to drain cells using the measured or estimated spring pool altitude as the drain elevation. The net recharge rates to unconfined areas of the UFA were assigned using the Recharge package.

Numerical Model

The Peninsular Model is based on the numerical, finite-difference code MODFLOW, which was developed by McDonald and Harbaugh (1984 and 1996). Steady-state conditions were simulated by the model. Average groundwater resource conditions from August 1993 through July 1994 served as the target for the steady-state model.

Model Description

The Peninsular Model was conceptualized as a quasi-three-dimensional flow model with horizontal flow in the aquifer systems and vertical leakance through the confining layers. The confining units are not explicitly simulated but are represented by arrays of leakance. Groundwater flow is predominantly horizontal in the aquifer systems and vertical in the confining units.

Model Grid and Discretization

The Peninsular Model is divided into four layers.

- Layer 1 – SAS
- Layer 2 – IAS (or ICU)
- Layer 3 – UFA
- Layer 4 – LFA

The model grid is oriented along the north-south axis. All model cells are 5,000 feet by 5,000 feet, with 210 columns and 300 rows.

Boundary Conditions

The SAS (Layer 1) was simulated as a layer of constant heads. A no-flow boundary condition was applied along all lateral boundaries of Layer 2 (IAS or ICU). Flow entering or leaving cells in Layer 2 is assumed to occur as either horizontal flow to neighboring cells or vertical flow to either the SAS (Layer 1) or the UFA (Layer 3). Lateral boundary conditions for the UFA (Layer 3) and the LFA (Layer 4) were either no-flow or specified head. Along the Gulf of Mexico in Citrus, Hernando, and Pasco Counties, most of the lateral flow in the UFA is assumed to be discharged by numerous springs. Based on this observation, no-flow conditions were applied to the boundary of Layer 3 in those areas. Specified heads were used elsewhere along the boundary of Layer 3. No-flow conditions were applied along all lateral boundaries in Layer 4 (LFA). The eastern and western boundaries of the LFA coincided with the location at which the chloride concentration in the LFA exceeded 5,000 mg/L. Specified heads in the UFA along the northeastern boundary of the model were set equal to the equivalent freshwater head.

Transmissivity

Transmissivity in the IAS ranged from 100 square feet per day (ft^2/d) along the northern, eastern and western boundaries of the IAS to 30,000 ft^2/d in Sarasota County (Figure 6). Transmissivity of the UFA ranged from 3,000 ft^2/d in areas where the UFA is thin to 12,000,000 ft^2/d in areas of cavernous limestone near springs (Figure 7). Transmissivity values for the LFA (Figure 8) ranged from 5,000 ft^2/d along parts of the lateral boundaries of the LFA to 760,000 ft^2/d in northeast Florida. High transmissivity values were simulated in parts of Orange County and south Florida.

Leakance

Leakance values for the upper confining unit of the IAS, ICU and MCU/MSCU between the UFA and LFA are shown on Figures 9, 10, and 11, respectively.

Beach and Chan, 2003. Southern District Groundwater Flow Model Version 1.0, Prepared by the Hydrologic Evaluation Section, Resource Conservation and Development Department, Southwest Florida Water Management District.

Model Area

The modeled area was delineated to minimize any boundary effects on the principal area of interest: the Southern Water Use Caution Area (SWUCA). The modeled area generally extends from central Hernando County in the north to central Lee County in the south. The model extends from about 5 to 20 miles into the Gulf of Mexico on the west side and to the Kissimmee River on the east side. The active model area is approximately 12,800 square miles. The SWUCA covers approximately 5,500 square miles of this area. Figure 12 shows the model area and extent of the SWUCA.

Hydrogeologic Framework

The local groundwater flow system is comprised of three vertically sequenced aquifer systems. In descending order, these systems are the unconfined SAS, the confined IAS, and the confined UFA. The SAS is generally shallow and extends from land surface to the upper

confining unit of the IAS. Thickness varies from 5 to 50 feet over most of the southern SWFWMD, but depths as high as 300 feet are reached in the vicinity of the Lake Wales Ridge. Reported hydraulic conductivities range from 5 to 15 ft/day in the northern part of the basin and 10 to 60 ft/d in the southern counties.

The IAS consists of confining units and multiple permeable zones bounded by the SAS above and the UFA below. The IAS functions not only as an aquifer system, but as the ICU between the SAS and UFA. The IAS consists of three principal permeable zones designated as PZ1, PZ2, and PZ3. PZ1 is often well connected hydraulically to the SAS and is of local significance only. PZ2 ranges in thickness from 20 to 190 feet and is more productive than PZ1. PZ2 is generally well separated hydraulically from both the upper and lower permeable zones. PZ3 ranges in thickness from 0 to 300 feet. Transmissivity for PZ1 ranges from 50 to 8,000 ft^2/d; PZ2 ranges from 200 to 13,300 ft^2/d; and PZ3 ranges from 30 to 15,400 ft^2/d. Depending on location, the IAS can be recharged by leakance from the overlying SAS or by upward leakance from the underlying FAS, or both. The geology and hydrogeology of the SD Model are shown on Figure 13.

The UFA consists of a thick sequence of carbonate rocks which range from 2,500 feet to 3,200 feet thick over the model area. The UFA is confined above by the lower confining unit of the IAS and below by the MCU. The UFA is divided into two permeable units: the UPZ and the LPZ. UPZ and LPZ are separated by a semi-confining unit. The UPZ includes most of the Suwannee Limestone and sometimes the overlying Tampa Formation. Transmissivities of the UPZ range from 1,400 ft^2/d to 290,000 ft^2/d. The Ocala Limestone coincides with the semi-confining unit (SCU) between the UPZ and LPZ. The SCU ranges in thickness from approximately 200 feet in the northern area of the model to more than 500 feet in the south.

The LPZ occurs principally in the Avon Park Formation and is sometimes referred to as the "high T zone." Fracturing and secondary porosity are the principal mechanism of this permeability. Transmissivity varies from 5,000 ft^2/d to 1,600,000 ft^2/d.

Conceptual Model

The conceptual model was devised to include the hydrologic units discussed above. Figure 14 is an east-west, hydrogeologic cross-section of the conceptual model. Figure 15 is a north-south hydrogeologic cross section of the conceptual model. Five major permeable zones are simulated from three separate aquifer systems. Intervening semi-confining units are simulated indirectly in the model via leakance arrays. Regional groundwater flow direction is west towards the coast. Equivalent freshwater heads were utilized to simulate the saltwater interface in the LPZ. The aquifer systems generally thicken and dip from north to south. Equivalent porous media conditions are assumed.

Numerical Model

The SD Model is based on the numerical, finite-difference code MODFLOW, which was developed by McDonald and Harbaugh (1984 and 1996). Both steady-state and transient conditions were simulated. Average groundwater resource conditions for the year 1993 served as the target for the steady-state model. For the transient simulations, the model was calibrated to hydrologic conditions from January 1993 through December 1993.

Model Description

The SD Model was conceptualized as a quasi-three dimensional flow model because of the strong horizontal flow in the aquifer systems and the tight confinement between the SAS and the UFA and within the IAS. Groundwater flow is predominantly horizontal in the aquifer systems and vertical in the confining units.

Model Grid and Discretization

The SD Model is divided into five layers:

- Layer 1 – SAS
- Layer 2 – PZ2 of the IAS
- Layer 3 – PZ3 of the IAS
- Layer 4 – UPZ of the UFA
- Layer 5 – LPZ of the UFA

The model grid is oriented along the north-south axis and aligned with the Peninsular Model (Sepulveda, 2002). All model cells are 5,000 feet by 5,000 feet.

Boundary Conditions

The model is bounded above by specified heads which represent the SAS. The bottom of the model is the MCU, which is considered to be impermeable. The lateral boundaries are a combination of specified heads and specified flux (no flow). The lateral boundaries of Layers 2 and 3 are specified as no-flow except along the southern boundary, which is defined as constant heads.

The lateral boundaries of the UFA, Layers 4 and 5, are generally no-flow along the northern and southern boundaries. The east side of the model is subdivided into 5 separate constant head reaches. The offshore boundary is designated as a no-flow boundary in Layer 4 and as equivalent freshwater heads in Layer 5. General head boundaries are not utilized in this model.

Transmissivity

Calibrated transmissivities for Layers 2 through 5 are shown on Figures 16, 17, 18, and 19. The transmissivity for Layer 2 (PZ2) varies from 1 ft^2/d to 66,000 ft^2/d. PZ2 and PZ3 do not extend to the northern part of the model, which is why a transmissivity of 1 ft^2/d is specified. Transmissivity of Layer 3 (PZ3) varies from 1 ft^2/d to 18,000 ft^2/d. Transmissivities are generally higher in Layer 4 (UPZ), ranging from 2,000 ft^2/d to 350,000 ft^2/d. The highest transmissivities in the entire model are found in Layer 5 (LPZ) and ranges from 19,000 ft^2/d to 900,000 ft^2/d.

Leakance

Leakance between Layer 1 (SAS) and Layer 2 (PZ2) and between Layers 2 and 3 (PZ3) range from 0.000001 day^{-1} to 0.003 day^{-1}. Leakance between Layer 3 (PZ3) and Layer 4 (LPZ) ranges from 0.0000018 to 1.0 day^{-1}. Leakance of 1.0 day^{-1} assumes full communication between the layers. Between Layer 4 (UPZ) and Layer 5 (LPZ), only one leakance value is assigned: 0.01 day^{-1}. Figures 20, 21, 22 and 23 show calibrated leakance values for each layer of the SD Model.

Barcelo and Basso, 1993. Computer Model of Groundwater Flow in the Eastern Tampa Bay Water Use Caution Area: Southwest Florida Water Management District.

Model Area

The ETB Model includes all of Manatee, Hardee, Sarasota and Desoto Counties and parts of Hillsborough, Pinellas, Polk, Charlotte, Glades, and Highlands Counties. The ETB Model is an earlier version of the SD Model (Beach and Chan, 2003), which was previously discussed. The SD Model extends beyond the boundaries of the ETB Model to include Pasco and Hernando Counties to the north and Lee County to the south.

Hydrogeologic Framework

Groundwater in the study area occurs in three principal aquifers; the SAS, IAS, and UFA. The aquifers are separated by clay confining units that restrict the vertical movement of water. The geological framework and hydrostratigraphy of the study area are the same as that for the SD Model, as shown on Figure 13 (presented previously).

The SAS is found throughout the study area and consists of marine and non-marine quartz sand, clayey sand, shell, shelly marl and phosphorite, with some marl and limestone. Average thickness is approximately 25 feet, but ranges from less than 10 feet near the coast to several hundred feet in the eastern portion of the study area. Hydraulic properties of the SAS vary widely. Transmissivity varies from 20 ft^2/d in the northern part of the study area to 5,300 ft^2/d in Charlotte and Highlands Counties. Specific yield ranges from 0.05 to 0.30.

The IAS is found throughout the study area and comprises all water bearing units and confining beds between the overlying SAS and underlying UFA. The IAS consists of three principal parts: the upper intermediate confining bed which separates the surficial aquifer from the permeable units of the IAS; one to three permeable units; and the lower intermediate confining bed which separates the IAS from the underlying UFA. Thickness of the IAS ranges from 100 feet in Polk County to greater than 700 feet in Charlotte County. Transmissivity ranges from less than 300 ft^2/d to 15,400 ft^2/d. In the northern portion of the study area, transmissivity is generally less than 4,400 ft^2/d except along the Peace River in Polk County. In the southern portion of the study area, the upper limit for transmissivity is approximately 15,000 ft^2/d.

The upper ICU limits the flow of groundwater between the SAS and the IAS. The lower ICU restricts flow between the IAS and the UFA. The upper ICU is composed of sandy clay, clay, and marl that are part of the Peace River Formation of the Hawthorn Group. The thickness of the upper ICU ranges from 25 feet in northern Hillsborough County and Polk County to about 150 feet in central Desoto County. In the extreme northern part of the study area the confining bed becomes thin and discontinuous due to differential erosion and karst activity. The lower ICU is generally composed of sandy clay and clayey sand that is located near the base of the Tampa Member of the Arcadia Formation. The thickness of the unit ranges from less than 25 feet in Polk County to approximately 250 feet in the southeastern portion of the study area.

The UFA is composed of permeable sections of the Tampa Member, Suwannee Limestone, Ocala Limestone, and Avon Park Formation. The base of the UFA is the top of the MCU,

which is considered to be the first occurrence of vertically persistent, intergranular evaporites. This study does not consider the LFA which exists below the MCU and contains highly mineralized water. Thickness of the UFA ranges from approximately 1,000 feet in the northern portion of the study area to 1,400 feet toward the south.

Within the UFA are two permeable zones. These zones are typically associated with the Tampa Member and Suwannee Limestone, permeable portions of the Ocala Limestone (upper producing zone) and the highly permeable zones (lower producing zone) within the Avon Park Formation. The UPZ and LPZ are separated by the semiconfining portions of the Ocala Limestone.

The significance of two permeable zones is important in areas where the water quality of the LPZ is poor. In the inland part of the study area, highly productive wells are completed into the LPZ. Toward the southwest portion of the study area groundwater in the LPZ becomes increasingly mineralized. As a result, wells are typically constructed into the lower portions of the IAS and the UPZ of the UFA.

Although the Ocala Limestone is regarded as a semiconfining unit, there is evidence to suggest that there is sufficient hydraulic connection across the Ocala Limestone such that the UFA functions as a single hydraulic unit. Transmissivity of the LPZ range from 860,000 ft^2/d in eastern Desoto County to 36,000 ft^2/d in east-central Hillsborough County.

Conceptual Model

The conceptual model is similar to that of the SD Model (Figures 14 and 15, previously presented) and was devised to include the hydrologic units discussed above. Recharge to the UFA primarily results from rainfall that infiltrates the land surface and percolates downward through the SAS and IAS. Leakage occurs across the semiconfining beds that separate the IAS and SAS, and the IAS and the UFA. Although the UFA has two major producing zones, the aquifer is conceptualized as a single hydrologic unit. Regional groundwater flow in the UFA occurs predominantly in the LPZ. The IAS and UFA are simulated as single layer isotropic mediums with groundwater moving in horizontal planes. Horizontal flow in the confining beds is negligible compared to horizontal flow in the adjacent aquifers. Storage of water in the confining beds is negligible. Movement of the saltwater interface is assumed to have little effect on calculated heads. Heads in the SAS are assumed to be insensitive to changes in stress in the underlying aquifers.

Numerical Model

The ETB model is based on the numerical, finite-difference code MODFLOW, which was developed by McDonald and Harbaugh (1984 and 1996). Both steady-state and transient conditions were simulated by the model. Average groundwater resource conditions for the year 1989 served as the target for the steady-state model. For the transient simulations, the model was calibrated to hydrologic conditions from October 1988 through September 1989.

Model Description

The ETB Model was conceptualized as a quasi-three dimensional flow model because of the strong horizontal flow in the aquifer systems and the tight confinement between the SAS

and the UFA and within the IAS. Groundwater flow is predominantly horizontal in the aquifer systems and vertical in the confining units.

Model Grid and Discretization

The SD Model is divided into three layers:

- Layer 1 – SAS
- Layer 2 – IAS
- Layer 3 – UFA

The model grid is oriented along the north-south axis with uniform grid spacing of 2 miles by 2 miles, and consists of 56 rows and 60 columns.

Boundary Conditions

Water levels in Layer 1 (SAS) were held constant during model calibration. Specified heads were utilized through Layer 1. A combination no-flow cells and constant head cells were utilized along the boundary of Layer 2 (IAS). No-flow cells were utilized along the northern, eastern and southern boundaries of the model in Layer 2. Constant head cells were used along the western boundary of the model in Layer 2. A combination of head-dependant flux cells, constant head cells and no-flow cells were utilized along the boundary of Layer 3 (UFA).

Transmissivity

Transmissivity in Layer 2 (IAS) ranges from less than 1 ft^2/d along the northern boundary of the model to 11,000 ft^2/d in Charlotte County. Transmissivity of Layer 3 (UFA) ranges from 33,500 ft^2/d to 400,000 ft^2/d.

Leakance

Five zones were used to define leakance between Layers 1 and 2. Leakance varies between 0.00001 day^{-1} and 0.00067 day^{-1}. Six zones were used to define leakance between Layers 2 and 3.

HydroGeoLogic, Inc., June 2002. Three-Dimensional Density-Dependant Flow and Transport Modeling of Saltwater Intrusion in the Southern Water Use Caution Area

Model Area

The HydroGeoLogic Model is based upon the SD Model (Beach and Chan, 2003) discussed previously and an uncalibrated, saltwater intrusion model that was developed by Waterstone Environmental Hydrology and Engineering, Inc. (Waterstone). The domain of the HydroGeoLogic Model includes the southern half of Hillsborough County and all of Manatee and Sarasota Counties. The HydroGeoLogic Model is a smaller subset of the SD Model in terms of geographic area. The simulated area coincides with the domain of the Waterstone Model. Hydraulic properties and boundary conditions were assumed from the SD Model, while the model domain, grid spacing, and layer thicknesses were assumed from the Waterstone Model.

Hydrogeologic Framework

The hydrogeologic framework for this model is exactly the same as that of the SD Model. The local groundwater flow system is comprised of three vertically sequenced aquifer systems and their intervening semi-confining units. In descending order, these aquifer systems are the unconfined SAS, the confined IAS, and the confined UFA. As with the SD Model, for this model the LFA is not considered because it contains highly mineralized groundwater and is not utilized for water supply.

Conceptual Model

The hydrogeologic framework was conceptualized as 10 layers in the HydroGeoLogic Model. In order to simulate density-dependant flow and transport, intervening semi-confining layers must be explicitly modeled rather than using arrays of leakance. Hydraulic conductivity and thickness must therefore be specified for each aquifer and semi-confining unit. The Suwannee Limestone, Ocala Limestone, and Avon Park Formation are subdivided into two, three, and five finite-difference layers, respectively. These layers explicitly simulate permeable units and semi-confining units that have been identified in the three formations. The geometry of the hydrostratigraphic units assigned in the current model (i.e., top and bottom elevations) was adopted from the Waterstone Model. During their modeling investigation, Waterstone estimated the top and bottom elevations for all of the hydrostratigraphic units based on lithologic data provided by the SWFWMD. The uppermost formation in the HydroGeoLogic Model is the Suwannee Limestone. Only the UFA was simulated in the HydroGeoLogic Model. Rather than explicitly incorporating the SAS and IAS/ICU into the density-dependant model, vertical flow through these aquifers is simulated by specifying a general-head boundary condition at the top of the UPZ within the Suwannee Limestone. Hydraulic heads for the SAS and leakance values in the SD Model were used to calculate the general-head boundary conditions.

Numerical Model

The computer code MODHMS was selected for construction of the flow and solute transport model. MODHMS is a MODFLOW-based code developed by HydroGeoLogic for evaluating complex hydrologic and hydrogeologic settings. The density-dependant transport capabilities of MODHMS have been incorporated from DSTRAM, which is a well established and applied saltwater intrusion model developed by Huyakorn and Panday (1991). The MODFLOW-based structure of MODHMS makes the code fully compatible in terms of numerical approximations, grid structure and input/output data structures with the other MODFLOW based models developed for the SWFWMD. All of the MODFLOW features are available for use within MODHMS, including boundary conditions such as drains, streams, general-head conditions, and those involving water table conditions, infiltration, aquitard leakages, and pumping and injection wells. For contaminant transport simulation, MODHMS accounts for advection, anisotropic hydrodynamic dispersion with separate aerial and vertical components for longitudinal and transverse dispersivities, linear equilibrium sorption and first-order degradation reactions.

MODHMS is capable of simulating density-dependant, single-phase fluid flow and solute transport in saturated porous media. The code is applicable for complex situations where fluid flow is influenced significantly by variations in solute concentration.

Model Description

The HydroGeoLogic Model is fully three-dimensional in that semi-confining layers are explicitly simulated together with the permeable zones that comprise the aquifer systems. Arrays of thickness and hydraulic conductivity are specified for each permeable layer and semi-confining layer. Arrays of leakance are not utilized to implicitly simulate the semi-confining layers. The semi-confining layers must be fully three-dimensional in order to accurately simulate the saltwater interface, which is a physical feature that crosses aquifer systems in the vertical and horizontal directions.

Model Grid and Discretization

Ten layers are utilized to vertically discretize the UFA. The layers discretize the Suwannee Limestone, Ocala Limestone and Avon Park Formation. The top two layers are used to simulate the Suwannee Limestone. The next three layers are used to simulate the Ocala Limestone, and the bottom five layers are used for the Avon Park Formation. Multiple layers were used for each formation in order to explicitly simulate permeable zones and semi-confining layers. Formation boundaries were not necessarily used to delineate layer boundaries but rather contrasts in permeability were used to delineate separate layers.

The density-dependant model grid consists of 103 columns and 123 rows with spacings that range from 2,500 to 5,000 feet. The grid is deformed in the vertical direction to conform to permeability/formation geometries and topography.

Boundary Conditions

General-head boundary conditions were utilized in the top layer to simulate flow from the SAS and IAS, which were not directly simulated. Pre-development heads from the SD Model were used to provide constant heads boundaries along the northern, southern and eastern faces of the HydroGeoLogic Model. Constant heads along these boundaries were assigned to the Suwannee Limestone and the model layers that comprise the Avon Park Formation. The western boundary conditions were also defined as constant heads. The bottom boundary of the model was simulated as no-flow conditions. The bottom boundary coincides with the MCU.

Hydraulic Parameters

Hydraulic conductivity and thickness for each model layer must be specified. Initial values for hydraulic conductivity of the model layers were derived from calibrated transmissivity and leakance values that were assigned to the SD Model. It was assumed that horizontal hydraulic conductivity is isotropic in all model layers. Transmissivity from the SD Model was divided by unit thickness values from the Waterstone Model to yield arrays of hydraulic conductivity for each model layer. A horizontal to vertical anisotropy of 100:1 was assumed for each aquifer unit. Leakance and transmissivity are not specified in the fully three-dimensional modeling approach taken by the HydroGeoLogic Model.

Environmental Simulations, Inc., April 2004. Development of the District Wide Regulation Model for Southwest Florida Water Management District.

Model Area

Environmental Simulations, Inc. (ESI) was retained by the SWFWMD to assist in formulating their approach to regional groundwater modeling. The goal of the project was two-fold. First, develop a District Wide Regulation Model (DWRM), which is a modified version of the USGS model of the IAS and FAS in Peninsular Florida (Sepulveda, 2002) covering the entire SWFWMD plus a buffer area surrounding the SWFWMD. The USGS model developed by Sepulveda is known as the Peninsular Model and was described previously. The second goal was to develop a modified telescopic mesh refinement (TMR) technique that would streamline the SWFWMD's review of Water Use Permits.

The DWRM approach was to use the Peninsular Model as a starting point and activate the SAS layer, which the USGS treated as an array of constant heads. The Peninsular model was also reduced in size to cover an area slightly larger than the SWFWMD. The overall regional modeling approach was subdivided into several tasks.

- Reduce the Peninsular Model to cover only the SWFWMD
- Activate the SAS layer
- Create SWFWMD wide stream coverage for use in the calibration and TMR
- Calibrate the SAS layer
- Create new TMR routine

The area outside the SWFWMD was eliminated from the Peninsular Model. The boundary of the new model was the SWFWMD boundary plus a buffer area of approximately 10 miles so that permits at the edge of the SWFWMD boundary could be evaluated. Because the original Peninsular Model did not extend fully to the southern boundary of the SWFWMD, 22 rows were added to the DWR Model. The southern boundaries of the DWR Model were made to coincide with the SD Model.

Hydrogeologic Framework

The hydrogeologic framework is the same as the Peninsular Model. The SAS is the uppermost water-bearing hydrogeologic unit. The SAS mostly consists of variable amounts of sand, clay, sandy clay, shell beds, silt, and clay. Limestone units within the SAS are primarily in southwest Florida. The SAS extends throughout most of the study area, except where the UFA is unconfined. The IAS underlies the SAS and extends throughout most of southwest Florida. The unit consists mainly of clastic sediments interbedded with carbonate rocks that generally coincide with the Hawthorn Group. Confining beds that overlie the UFA and underlie the SAS limit the vertical extent of the IAS in west-central Florida. The thickness of the IAS varies from approximately 25 feet in parts of Hillsborough and Polk Counties to approximately 400 feet in Charlotte County.

The hydrogeologic units (ICU and IAS) within the Hawthorn Group are differentiated based upon the permeability of the rock. In contrast to the IAS, the ICU is considerably less permeable. The UFA is considered to be unconfined in areas where the ICU or IAS is absent or very thin.

The FAS is a thick sequence of limestone and dolomitic limestone of Oligocene and Eocene ages with highly variable permeability. The FAS is divided into two aquifers of relatively high permeability, referred to as the UFA and the LFA. These aquifers are separated by a less permeable unit called the MCU in west-central Florida and in the northwest part of the study area, and MSCU in east-central Florida. The top of the UFA coincides either with the top of the Suwannee Limestone or the top of the Ocala Limestone, depending upon location. Rather than a single low-permeability unit separating the UFA and LFA, several units of regional extent separate the UFA from the LFA. Any of the regionally extensive low-permeability units may contain thin layers of moderate to high permeability. These confining units are not continuous and do not necessarily consist of the same rock type everywhere.

In west-central Florida, the UFA and LFA are separated by the MCU, which is composed of gypsiferous dolomite and dolomitic limestone of considerably lower permeability than that of the MSCU in east-central Florida.

Conceptual Model

The conceptual groundwater flow system is the same as the Peninsular Model except that the SAS (Layer 1) is actively simulated in the DWRM. In the Peninsular Model, the SAS was simulated as an array of constant heads. The SAS, IAS (or ICU in areas where the IAS is absent), the UFA, and the LFA were designated Layers 1 through 4, respectively. Confining layers were simulated by using vertical leakance arrays. Model-simulated groundwater flow occurs horizontally within the aquifers and vertically through the confining units.

The IAS (Layer 2) in was simulated as a single active aquifer bounded above and below by arrays of leakance values. Because this model is restricted to simulating the movement of freshwater within the aquifers; areas where the IAS, the UFA and the LFA (Layers 2 through 4) contain water with chloride concentrations exceeding 5,000 mg/L are considered inactive. Recharge to or discharge from the IAS is assumed to occur through the upper or lower confining units of the IAS.

The MCU was represented by vertical leakance values that limit water exchange between the UFA (Layer 3) and the LFA (Layer 4) in west-central and southwest Florida.

The River, Drain, and Recharge packages were used in this groundwater model. The River package was used to simulate the discharge of water to and from rivers in unconfined areas of the UFA. The discharge of groundwater to swamps in unconfined areas of the UFA and the flow from UFA springs located outside river cells was simulated by using the Drain package. Flow from springs was simulated as discharge to drain cells using the measured or estimated spring pool altitude as the drain elevation. The net recharge rates to unconfined areas of the UFA were assigned using the Recharge package.

Numerical Model

The DWR Model is based on the numerical, finite-difference code MODFLOW, which was developed by McDonald and Harbaugh (1984 and 1996). MODFLOW96 was the version of MODFLOW used for the DWR Model. Steady-state conditions were simulated by the model. Average groundwater resource conditions from August 1993 through July 1994 served as the target for the steady-state model.

Model Description

Like the Peninsular Model, the DWR Model was conceptualized as a quasi-three-dimensional flow model with horizontal flow in the aquifer systems and vertical leakance through the confining layers. The confining units are not explicitly simulated but are represented by arrays of leakance. Groundwater flow is predominantly horizontal in the aquifer systems and vertical in the confining units.

Model Grid and Discretization

The DWR Model is divided into four layers:

- Layer 1 – SAS
- Layer 2 – Intermediate Aquifer System (IAS)
- Layer 3 – Upper Floridan Aquifer
- Layer 4 – Lower Florida Aquifer

The model grid is oriented along the north-south axis. All model cells are 5,000 feet by 5,000 feet, with 210 columns and 322 rows.

Boundary Conditions

Constant head cells in most of the SAS (Layer 1) were changed to active cells except around the outer edges of the model and within major lakes and streams. Layers 1 and 2 were changed from no-flow cells to active cells in the northern portion of the SWFWMD where the FAS is unconfined. General-head boundaries were placed along boundaries that were continuous within the Peninsular Model. Model properties and boundary conditions in the southern part of the SWFWMD were imported from the SD Model. Heads assigned to the new general head boundaries were taken from the Peninsular Model. Conductance of the GHB cells was computed using hydraulic conductivity and cell thickness of the Peninsular Model.

Hydraulic Parameters

Hydraulic conductivity in the SAS (Layer 1) ranges from about 10 to 80 ft/day with most areas varying between 10 and 30 ft/day. The transmissivity of the IAS (Layer 2) ranges from about 100 ft^2/d to 25,000 ft^2/d with most areas between 1,000 and 10,000 ft^2/d. The transmissivity of the UFA ranges from about 1,000 ft^2/d to 10,000,000 ft^2/d in the calibrated DWR Model. In the southern part of the SWFWMD, the maximum transmissivity was set to 2,000,000 ft^2/d based upon results of aquifer performance tests in the area. UFA transmissivities in the northern portion of the SWFWMD were allowed to be as high as 10,000,000 ft^2/d, which was about the maximum transmissivity in the Peninsular Model. Most the UFA (Layer 3) had a transmissivity on the order of 100,000 ft^2/d. The average transmissivity of the LFA (Layer 4) was about 190,000 ft^2/d. In general, the arrays of transmissivity (Layers 2, 3, 4) and hydraulic conductivity (Layer 1) conform to the range of field values reported in the literature and the SWFWMD's database.

Leakance values for the interface between the SAS and IAS range from about 1.0×10^{-6} day^{-1} to 0.1 day^{-1}. Most of the higher leakance values are for the northern part of the SWFWMD where the SAS is in contact with the UFA. Leakance values between the IAS and UFA range from 1.0×10^{-6} day^{-1} to 0.01 day^{-1} with most areas being around 0.001 day^{-1}.

Southeast Florida Region Groundwater Model Review: Fairbank et al. (1999), McGurk and Presley (2002), and Bower et al. (1990)

PREPARED FOR: USACE Jacksonville District

PREPARED BY: CH2M HILL

DATE: November 21, 2005

PROJECT NUMBER: 334350.TW.03

Contents

Introduction and Purpose

The goal of this project is to collect and summarize data from available model documentation and provide recommendations to the U.S. Army Corps of Engineers (USACE) Jacksonville District for the development of a Regional Groundwater Model of Florida. This Technical Memorandum (TM) summarizes the model reviews for middle and southern Florida.

Three models were reviewed. These models covered the middle and southern part of the Florida peninsula. **Figure 1** shows the extent of the individual models. These models are referenced in this TM as follows:

- Lower East Coast Floridan Aquifer Model (Fairbank et al., 1999)
- East-Central Floridan Aquifer Model (McGurk and Presley, 2002)
- Lee County Model (Bower et al., 1990)

Comparison of Hydrogeology and Model Frameworks

Three principal aquifer systems are present in the area of interest. These aquifer systems include the Surficial Aquifer System (SAS), the Intermediate Aquifer System (IAS), and the Floridan Aquifer System (FAS). These aquifers are represented in each of the models.

The SAS covers most of the area of interest. It consists of unconsolidated sand, shelly sand, and shell with locally important limestone beds. Groundwater is generally under unconfined conditions and is recharged from the surface or, where heads are higher in deeper formations, from below. Transmissivity values vary widely from 1,000 to more than 10,000 square feet per day (ft^2/d). The most productive parts of the undifferentiated SAS occur in Collier and Hendry Counties. In the southeastern part of the state, the SAS is known as the Biscayne Aquifer and is the major source of fresh water for the region. Aquifer tests in the Biscayne Aquifer in Brevard County have resulted in calculated transmissivities of more than 1,000,000 ft^2/d (Randazzo, 1997).

Aquifers that lie below the SAS and above the FAS are referred to as the IAS. The IAS consists of beds of sand, sandy limestone, limestone, and dolomite, and is bounded by clay confining units above and below. Water in the IAS exists under confined conditions. Transmissivity values vary but are generally reported to be less than 10,000 ft^2/d. The system is an important source of water for Sarasota, Charlotte, and Lee Counties, where the FAS beneath the IAS contains brackish water (Randazzo, 1997).

The FAS exists throughout the state of Florida, and has been defined based on its permeability, which is at least an order of magnitude greater than the associated confining units above and below the aquifer. In most of the study area, the FAS can be divided into the Upper Floridan Aquifer (UFA) and Lower Floridan Aquifer (LFA). The UFA is generally the most productive and best known part of the aquifer. The LFA is less well known because it is deeper and generally filled with saltwater. The "Boulder Zone" exists in the LFA in the southeast part of the state. Transmissivity values for the UFA range from less than 50,000 ft^2/d to more than 100,000 ft^2/d in the northern part of the study area (Randazzo, 1997). The transmissivty of the Boulder Zone in the LFA has been estimated to be as high as 24.6×10^6 ft^2/d (Meyer, 1989).

The three models reviewed cover different geographic areas and model the three aquifer systems differently based on the goals of the model, available data, and aquifer characteristics in the area. **Table 1** provides a brief comparison of the model frameworks.

TABLE 1
Comparison of Model Frameworks

Model Summaries

Lower East Coast Floridan Aquifer Model (Fairbank et al., 1999)

Conceptual Model

A three-dimensional, steady-state model was created for the Lower East Coast Planning Area. Appendix A provides figures from the model documentation. The model includes three primary flow zones; two are within the UFA and a third is in the LFA. Flow Zone 1 includes permeable zones at or near the top of the Avon Park Formation and the Ocala Limestone (Layer 3). Flow Zone 2 includes permeable zones within the upper part of the Avon Park Formation (Layer 5). Flow Zone 3 includes the shallowest producing intervals at or near the top of the Oldsmar Formation (Layer 7). Low permeability units between the primary flow zones are included explicitly in this model. Additionally, the SAS and the Boulder Zone are included as constant head boundaries at the top and bottom of the model, respectively. Figure 2 in Appendix A provides the Flow Zone Conceptualization.

Numerical Model

Model Grid Description

Based on the available documentation, the model covers 16,434 square miles and has a total of nine layers with a uniform grid spacing of 1 mile. The model grid domain is shown in Figure 1 in Appendix A.

Range of Hydraulic Conductivity and Transmissivity

Table 2 presents horizontal and vertical hydraulic conductivity calues reported in the model documentation. Variable layer thickness resulted in variable values of transmissivity. Sensitivity analysis of the model to values of hydraulic conductivity in the model layers is included in the model documentation.

TABLE 2
Model Layers and Hydraulic Conductivity Values
Southeast Florida Region Model Review

Layer	Formation	Layer Type	Horizontal K (ft/day)	Vertical K (ft/day)
Layer 1	Surficial Aquifer System	Constant Head	N/A	N/A
Layer 2	Semi Confining Units	Leakance Layer	0.5	1.0 e-5
Layer 3	Upper Floridan (Avon Park, Ocala)	Active Layer	175	8.0
Layer 4	Semi Confining Units	Leakance Layer	0.09	7.0 e-3
Layer 5	Upper Floridan (Avon Park)	Active Layer	75	9.0
Layer 6	Semi Confining Units	Leakance Layer	9	2.2 e-3
Layer 7	Lower Floridan (Oldsmar)	Active Layer	99	2.2 e-4
Layer 8	Semi Confining Units	Leakance Layer	0.9	1.7 e-3
Layer 9	Base of Floridan (Boulder Zone)	Constant Head	N/A	N/A

Layer thickness varied based on contact elevations collected from test borings and wells drilled in the study area. Table 1 included in Appendix A provides the data used for layer elevations. Hydrostratigraphic picks for model layers are based on data compiled from reports prepared by consultants and SFWMD. The model documentation provides an extensive list of well/test drilling sites and layer elevations.

Recharge

Recharge is not explicitly modeled. Instead, Layer 1 is modeled as a constant head boundary condition which supplies recharge or allows discharge through the semiconfining Layer 2.

Boundary Conditions

The top and bottom layers (Layer 1 and Layer 9) are modeled as constant head boundaries which supply recharge or allows discharge of groundwater through the associated semiconfining units. General head boundaries are utilized laterally around the model domain. Figures 4 and 10 in Appendix A show the locations of model boundaries. The constant head value for Layer 1 was calculated to be 2.5 feet from existing land surface. Lake Okeechobee was modeled at 15.4 feet which represents the average stage for the period of record. Starting head and boundary conditions for lower layers were created using pressure data from the SFWMD monitoring well network and FDEP monitoring wells. A total of 26 District wells and 47 utility wells were used to gather information. Figures 4 through 10 in Appendix A show initial head distributions.

Applied Stresses

Only two prescribed flow conditions (pumping wells) are included in the model. Average values of pumping for the Boynton Beach ASR facility and the Jupiter reverse osmosis (RO) facility were used during calibration of the model. Figure 3 in Appendix A shows the locations of the pumping facilities included in the model.

Calibration

The steady-state calibration period for the model is from 1995 to 1997. Two facilities operated continuously during this period and were included in the model: the Boynton Beach ASR facility and the Jupiter RO facility. Initial values for aquifer parameters were based on representative values collected from wells completed in the intervals included in the model. Table 2 in Appendix A provides the basis for the parameters. Table 10 in Appendix A compares the calculated and model calibrated values.

Water quality in the FAS in the area of the model varies, causing density differences which affect groundwater flow. The model utilizes "fresh-water equivalent head values" to account for this water quality variation.

East-Central Floridan Aquifer Model (McGurk and Presley, 2002)

Conceptual Model

A three-dimensional steady-state model was created, expanding on previous regional models covering all or parts of Orange, Seminole, Brevard, Lake, Osceola, Marion, Polk, Sumter, and Volusia Counties. Appendix B provides figures from the model documentation. Figures 1 and 2 in Appendix B show the location of the modeled area. The model was created to simulate pre-development conditions, modern day post-development conditions, and future flow conditions which incorporate increased water supply demands.

The SAS, the Intermediate Confining Unit (ICU), and the FAS are simulated. The SAS consists of sand, silt, clayey sand, and shell beds, and receives recharge from rainfall, irrigation water, septic tank effluent, rapid infiltration basins and other sources. The ICU separates the SAS from the FAS. The thickness of the confining unit and its hydrogeologic properties are highly variable. The FAS includes the Cedar Key Formation, Oldsmar Formation, Avon Park Formation, and the Ocala Limestone. The FAS is separated into the UFA, the middle semiconfining unit, and the LFA. Figure 7 in Appendix B provides the geologic and hydrostratigraphic units within the project area. Figure 25 in Appendix B shows a cross section with the units and direction of saline and fresh groundwater flow.

Numerical Model

Model Grid Description

The model covers 7,568 square miles. The grid is uniform with 2,500-foot by 2,500-foot square cells. Layer elevations were calculated based on data from data collected from previous studies and an extensive list of wells and test borings is included in the appendix of the model documentation. Figures 4 and 5 in Appendix B show the locations of wells completed in the SAS and FAS utilized for this study. Figures 9 through 14 in Appendix B show layer elevations within the model. At cell locations where the saline water interface

elevation was calculated to be above an aquifer layer bottom elevation, the bottom elevation of the flow domain was recomputed to equal the saline water interface elevation. Cells where the saline water interface was calculated to be within 20 feet of the top of an aquifer layer were considered to be saline and therefore inactive.

Range of Hydraulic Conductivity and Transmissivity

The model includes variable values of hydraulic conductivity and associated transmissivity. Figure 8 in Appendix B provides the locations of aquifer performance tests completed in the study area. Table 3 provides the ranges reported. Additionally, Figures 65 through 76 in Appendix B show the spatial distribution of the aquifer parameters.

TABLE 3
Model Layers and Hydraulic Conductivity Values
Southeast Florida Region Model Review

Layer	Formation	Layer Type	Horizontal K (ft/day)	Vertical K (ft/day)
Layer 1	Surficial Aquifer System	Unconfined Active	20	0.001 - 0.1
Layer 2	Upper Floridan (Avon Park, Ocala)	Confined Active	50-5000	0.25-50
Layer 3	Upper Floridan (Avon Park)	Confined Active	50-5000	0.01 – 1.5
Layer 4	Lower Floridan	Confined Active	15-500	

Recharge

The model utilizes the recharge package to apply recharge to the SAS based on detailed information including precipitation, water applied to rapid infiltration basins, septic tank effluent, and irrigation.

Boundary Conditions

General head boundaries are utilized laterally around the model. The head values are based on estimated predevelopment heads in Layers 2 and 3. Layer 4, the LFA, generally varied from +2 feet to -2 feet from the upper layer elevations depending on known discharge/recharge zones. An exception is noted in the southwest where it was 10 to 20 feet lower based on local data. Figure 28 in Appendix B shows modeled lateral boundaries.

General head boundaries were also used to simulate the water level and flux changes along the seaward boundary between saltwater and freshwater within the interior of the grid. This boundary condition was selected to allow for changes due to the moving transition zone. Lakes, rivers, and other surface water attributes were modeled as constant heads cells and rivers as appropriate.

Applied Stresses

Drainage wells provide significant man made source of recharge to the FAS. These injection wells are numerous in the model. Injection rates were based on detailed evaluation of injection well locations and types from available reports. Pumping wells are shown in Figures 30 through 32 of Appendix B for each of the model layers.

Calibration

The model was calibrated to average 1995 steady-state conditions. Calibration included comparison of observed and modeled groundwater levels as well as evaluation of stream flow and spring flow data.

Data utilized to create this detailed model came from many sources. Rainfall, surface water data, observation and test well data, groundwater withdrawal data, wastewater treatment plant flows, and reuse data were obtained from agencies and reports on previous models and studies. An extensive appendix (more than 400 pages) provided with the model documentation contains much of this information.

Lee County Model (Bower et al., 1990)

Conceptual Model

The Lee County Model was created to be used for predictive purposes when evaluating requests for large groundwater withdrawals and to serve as a basis for groundwater management planning in Lee County. The three aquifer systems within the study area are the SAS (including the water table and lower Tamiami aquifers), the IAS (including the sandstone and Mid-Hawthorn and associated confining units), and the FAS (including the lower Hawthorn, Suwannee, and deeper aquifers). In the study area, the FAS contains water with salinity levels above recommended standards for potable use.

Figure 1 in Appendix C shows the location of the study area. Figure 2 in Appendix C provides the generalized hydrogeologic cross section. Figure 3 in Appendix C provides a cross section showing aquifers and corresponding model layers.

Numerical Model

Model Grid Resolution

The model extends across Lee County and covers more than 2,000 square miles. The model consists of 42 rows and 48 columns. Cells in the interior of the model are 1 mile square. Cells on the north and west sides of the model were expanded to reduce boundary effects seen during early calibration attempts. Figures 5 and 6 in Appendix C show the model domain and grid.

Range of Hydraulic Conductivity and Transmissivity

Values for transmissivity were variable for all layers except Layer 6. Figures A-38 through A-54 provide areal distribution of hydraulic parameters included in the model. Table 4 contains the approximate ranges taken from these figures. Vertical conductance (Vcon) is substituted for vertical conductivity to be consistent with the model documentation. Vertical hydraulic conductivity can be calculated from the Vcon values by multiplying them by the confining layer thickness. However, these data are not available in the documentation.

TABLE 4
Model Layers, Hydraulic Conductivity, Transmissivity and Vertical Conductance Values
South Florida Model Review

Layer	Formation	Layer Type	Horizontal K/T (ft/day)/(ft^2/day)	Transmissivity (ft^2/day)	Vcon (1/day)
Layer 1	Surficial Aquifer System (Water Table)	Active-Unconfined		<500 to 1,500	< 6.0 e-5 to >1.6 e-4
Layer 2	Surficial Aquifer System (Lower Tamiami Aquifer)	Active-Confined		<10,000 to >40,000	<3.6e-5 to >9.0e-5
Layer 3	Intermediate Aquifer System (Sandstone Aquifer)	Active-Confined	.001-100	<2,000 to >10,000	<3.0e-11 to >7.5e-11
Layer 4	Intermediate Aquifer System (Mid-Hawthorn Aquifer)	Active-Confined	10-30	<500 to >3,500	<1.0e-5 to >4.0e-5
Layer 5	Floridan Aquifer System (Lower Hawthorn Aquifer)	Active-Confined	56	<8,000 to >16,000	<7.0e-5 to >1.4e-4
Layer 6	Floridan Aquifer System (Suwannee and Deeper Aquifers)	Active-Confined		10,368	7.0e-5
Layer 7	Floridan Aquifer System (Suwannee and Deeper Aquifers)	Constant Head		N/A	N/A

Range of Storage and Specific Yield

Layer 1 specific yield was set uniformly at 0.2. Storage coefficients in Layers 2 through 5 were set to $1e^{-6}$ multiplied by the layer thickness. Layer 5 storativity was set at a uniform value of $1e^{-4}$.

Recharge

Recharge was calculated for model cells based on net precipitation, surface drainage, and evapotranspiration. Values for each cell were calculated on a monthly basis from April 1985 to September 1986.

Boundary Conditions

Constant head boundaries were used laterally around this model as a vertical boundary layer in Layer 7. The River package was used to simulate rivers and some canals in the study area. Additionally, major canals in the East Coast Water Control District were simulated using the drain package. General head boundaries were not used in this model. Figure 7 in Appendix C shows the locations of specified head boundaries. Figure 8 in Appendix C shows the locations of river and drain cells.

Applied Stresses

The model contains groundwater withdrawals representing public water supplies, irrigation demands, and domestic self-supply wells. Figure 8 in Appendix C shows the locations of public well fields. Figure 9 in Appendix C shows the locations of cells where irrigation

withdrawals are applied to the model. Figure 12 in Appendix C shows locations where domestic self supply is included in the model.

Calibration

Both steady-state and transient calibrations were performed. The steady state run was used as a starting point for the transient run. The transient model run was from April 1985 to September 1986. The 12-month period from October 1985 to September 1986 was used for calibration.

Model Comparison to Hydrogeologic Framework

The aquifer parameters taken from the models were compared to the values in the hydrogeologic framework document. The greatest source of uncertainty in this evaluation is the comparison of values for the Middle Floridan Aquifer, which is not explicitly described in the documentation of these models. Where there are two flow zones modeled in the UFA, the lower zone is assumed to correspond to the Middle Floridan Aquifer. Tables 5, 6, and 7 below compare the values.

TABLE 5
Lower East Coast Floridan Model – Comparison to Hydrogeologic Framework
Southeast Florida Region Model Review

Aquifer Hydrogeologic Parameter	Average Framework Value (ft^2/d)	Approx Model Range (ft^2/d)
UF Transmissivity	24,911	2,800-82,600
MF Transmissivity	109,517	1,900-29,500
LF Transmissivity	63,164	3,100-32,400
UF Storativity	1.15E-03	NA
MF Storativity	5.05E-03	NA
Middle Confining Unit 1	2.52E-01	7.00E-03
Middle Confining Unit 2	7.52E-01	2.20E-03

TABLE 6
East Central Floridan Model – Comparison to Hydrogeologic Framework
Southeast Florida Region Model Review

Aquifer Hydrogeologic Parameter	Average Framework Value (ft^2/d)	Approx Model Range (ft^2/d)
UF Transmissivity	36,226	20,000-1,000,000
MF Transmissivity	229,821	20,000-1,000,000
LF Transmissivity	130,379	2,500-685000
UF Storativity	4.62E-04	NA
MF Storativity	6.24E-04	NA
Middle Confining Unit 1	7.30E-01	
Middle Confining Unit 2	1.00E-01	.05-1

TABLE 7
Lee County Model – Comparison to Hydrogeologic Framework
Southeast Florida Region Model Review

Aquifer Hydrogeologic Parameter	Average Framework Value (ft^2/d)	Approx Model Range (ft^2/d)
UF Transmissivity	15,051	8,000-16,000
MF Transmissivity	306,721	1.04E+04
LF Transmissivity	50,731	NA
UF Storativity	2.11E-04	1.00E-04
MF Storativity	6.40E-05	1.00E-04
Middle Confining Unit 1	2.32E-01	2.57E-03
Middle Confining Unit 2	1.47E-01	NA

APPENDIX C

Dispersion Database TM

Sub-Task No. 3 - Groundwater Dispersion Literature Search and Database for ASR Regional Study Groundwater Model Development

PREPARED FOR: U.S. Army Corp of Engineers-Jacksonville District and the South Florida Water Management District

PREPARED BY: CH2M HILL/Tampa, Florida

DATE: December 14, 2005

PROJECT NUMBER: 334350.TW.03

This technical memorandum (TM) has been prepared for the U.S. Army Corp of Engineers (USACE), Jacksonville District and the South Florida Water Management District (SFWMD) in support of the Comprehensive Everglades Restoration Project (CERP). The scope of work for this TM is based on Sub-Task 3 of the Aquifer Storage and Recovery (ASR) Test Well Work Plan Development and Model Data Collection (revised June 10, 2005) and provides documentation for the preparation of a groundwater dispersion database, provided herein. The goal of this research effort was to provide dispersion data on primarily sandstone and carbonate aquifers with a focus on technical sources from Florida and other similar geologic environments from the United States and other areas of the world. Based on the USACE's scope of work, technical papers, reports and other sources available to and obtained by CH2M HILL were reviewed and dispersion values were tabulated. In addition to the dispersion data, which was typically presented as longitudinal dispersivity, other pertinent information, where available, was also tabulated in the data base for comparative purposes. This supplemental aquifer data includes: transmissivity, storativity, transverse dispersivity, and molecular dispersivity, and aquifer name, matrix, thickness, and type.

The dispersion database is provided in Exhibit 1. Abstracts for each literature sources used in the development of the database are provided in Exhibit 2 and electronic copies (Adobe format) of published technical papers and reports are provided on compact disk (which includes the entire Sub-Task 3 deliverable) as Exhibit 3.

CH2M HILL conducted the initial literature reviews targeting sources for dispersion data for sandstones and carbonate aquifers. Dispersion values for other sedimentary, igneous and metamorphic aquifer matrixes have also been included and may be useful for evaluation of fractured flow through dolomite, where applicable.CH2M HILL was able to obtain dispersion data from primarily domestic technical publications, which were limited in number. To supplement dispersion data from foreign sources, CH2M HILL contracted Nerac, Inc., an outside research service. The combined research effort generated 40 literature sources from which the dispersion data was obtained and tabulated.

Very few of the documents had physical data on dispersivity based on tracer or other in-situ testing. Many of the dispersivity values presented in the cited literature were estimated, established from other sources, or the results of groundwater model calibration. It is also noted that the differences in the ranges of dispersivity values depend on how the coefficient was being used. The values based on large-scale model calibration were relatively high, while those based on matching results from single-well tracer tests were quite low. This illustrates that dispersivity is scale dependent and also dependent on its ultimate use in modeling or calculations. Essentially, dispersivity is a modeling calibration factor rather than an aquifer parameter. It depends not only on the nature of the aquifer materials, but also on the scale of the flow field and the scale at which it is being mathematically described.

(1) Abstract: Longitudinal Dispersivity Data and Implications for Scaling Behavior. Dirk Schulze-Makuch. 2005.

Longitudinal dispersivity data were compiled from 109 different authors for different types of geological media. The data were subdivided into different subsets. Dispersivity values for consolidated media were subdivided as basalts, granites, sandstones, and carbonate rocks, while unconsolidated sediments were subdivided into three reliability classes. The datasets provided here may provide groundwater practitioners a preliminary guide to estimate dispersivity values at various scales and to guide and verify theories on scaling behavior. Based on the dataset presented here, the relationship that empirically best described the dispersivity data in regard to scale of measurement was in the form of a power law. The scaling exponent for consolidated and unconsolidated geological media varied between 0.40 and 0.92, and 0.44 and 0.94, respectively. Higher reliability subsets of data for the unconsolidated sediments and more frequently tested rock formations indicate that the scaling exponent is at the lower end of the observed range, close to 0.5. No significant difference in scaling exponent was found among different media, and no clear evidence exists for the presence of an upperbound or asymptotic behavior on the relationship for any of the analyzed media.

(2) Abstract: Analysis of Ground-Water Flow and Injection Fluid Transport in the Floridan Aquifer near Pensacola, FL. Ward, David S., et al. 1992.

Liquid waste has been injected into a permeable part of the lower limestone of the Floridan aquifer since 1963, raising hydraulic head in the injection zone throughout a region of northwestern Florida. The injection zone consists of a moderately permeable limestone, hydraulically isolated from overlying aquifers by a thick layer of clay. The formation fluid is saline, but becomes fresher up dip, northward where the limestone crops out. Numerical simulations were performed at regional and local scales to assess the regional pressure increase, to analyze the movement of the 10,000 mg/l total dissolved solids (TDS) isopleth (formation fluid) in the lower limestone of the Floridan aquifer, and to analyze the migration of the injection fluid, both historically and predictively, in the injection formation. This work is based largely on previous work by Merritt (1984), but uses the SWIFT code. Modifications to Merritt's work include increasing the hydraulic conductivity near the injection wells and using more recent injection rates; extensions include particle tracking and solute transport modeling. The simulations indicate that regional pressure increases should be much less than previously predicted. Using the new results, by the year 2033, the average movement of the 10,000 mg/l TDS isopleth due to injection is expected to be approximately 2200 ft (671 in). Additionally, by the year 2033, the undiluted injection fluid (95% of injection concentration) should migrate to an approximate diameter of 2.1 mi (3.4 km) from the injection wells.

(3) Abstract: Analysis of Tests of Subsurface Injection, Storage, and Recovery in the Lower Floridan Aquifer, Okeechobee County, FL. USGS. 2005.

The analysis of capture zones of pumping wells is useful for designing pumping systems and wellhead protection programs. Using discharge potentials, equations are derived that can be applied to confined, unconfined, or combined confined and unconfined aquifers. The transient equations

are transcendental and cannot be solved explicitly. However, infinite-time (steady-state) equations are presented which can be solved. They define an area in which, theoretically, all the water in the aquifer will eventually reach the pumping well, although the equations do not consider the effects of hydrodynamic dispersion. Equations for calculating the stagnation point, upgradient divide, and dividing streamline within the aquifer and an example problem are presented.

(4) Analytical Model for Estimation of Steady-State Capture Zones of Pumping Wells in Confined and Unconfined Aquifers. Grubb, Start. 1993.

The analysis of capture zones of pumping wells is useful for designing pumping systems and wellhead protection programs. Using discharge potentials, equations are derived that can be applied to confined, unconfined, or combined confined and unconfined aquifers. The transient equations are transcendental and cannot be solved explicitly. However, infinite-time (steady-state) equations are presented which can be solved. They define an area in which, theoretically, all the water in the aquifer will eventually reach the pumping well, although the equations do not consider the effects of hydrodynamic dispersion. Equations for calculating the stagnation point, upgradient divide, and dividing streamline within the aquifer and an example problem are presented.

(5) Apparent Relative Retardation of Tritium and Bromide in dolomite. Leap, Darrell I. 1993.

In order to determine the suitability of bromide as a surrogate for tritium for ground-water tracing in fractured and fissured dolomite, apparent relative retardation coefficients of bromide with respect to tritium were computed by the cumulative relative mass-time method from breakthrough curves of both substances, when used simultaneously as tracers in a two-well recirculating tracer test. Throughout the 33.78-day test, relative retardation differences of only a few hundredths were detected for most of the testing time.

Tritium was less retarded in flow through highly transmissive openings than in more diffuse flow. Bromide was generally retarded relative to tritium except at the pumping well where the concentrations of both were diluted an order of magnitude below those in the monitoring wells, and tritium was retarded slightly more than bromide.

Apparent relative retardation was found to change with transmissivity, concentration, flow-path length and time, but not enough to rule out bromide as a suitable surrogate for, or even better than, tritium in dolomite if the limitations of each tracer are known.

(6) Aquifer Analysis and Modeling in a Fractured, Hetrogeneous Medium. Lee, R.R. et al. 1992.

A ground-water flow and contaminant transport modeling study was performed at a proposed low-level radioactive waste disposal site on the Department of Energy's Oak Ridge Reservation to assess the accuracy of a computer simulation of the flow field in the shallow water-table aquifer. The migration of a ground-water tracer, under controlled field conditions, was used as a

comparative benchmark of solute transport simulations assuming different aquifer characteristics. A conventional approach to aquifer analysis and modeling, which assumed the domain to be homogeneous with low anisotropy, resulted in an inaccurate simulation of tracer migration. Alternative conceptual models were formulated which considered the effects of geologic heterogeneities on tracer migration which could be verified by additional data acquisition and analysis. Application of the alternative concepts in numerical modeling resulted in more accurate simulations of tracer migration. These results suggested that local geology created discrete flow pathways oriented oblique to the maximum gradient which were unresolved in conventional aquifer analysis. Results of the study showed that standard approaches to aquifer analysis and computer modeling are crudely representative of the flow field and provide nonconservative estimates of contaminant transport at the scale of a waste disposal unit. By adopting an iterative approach to site characterization, conceptual model formulation, and numerical modeling, the level of resolution provided by a ground-water tracer was accurately simulated.

(7) Design Guidelines for Conventional Pump-and-Treat Systems. Cohen, Robert M. 1997.

The RCRA/Superfund Ground-Water Forum is a group of scientists representing EPA's Regional Superfund Offices, committed to the identification and resolution of ground-water issues affecting the remediation of Superfund sites. Design of conventional ground-water extraction and injection (i.e., pump-and-treat) systems has been identified by the Forum as an issue of concern to decision makers. This issue paper focuses on design of conventional ground-water extraction and injection systems used in subsurface remediation.

(8) Dispersivity Estimates from a Tracer Experiment in a Sandy Aquifer. Mallants, Dirk. 1999.

The success or failure of transport models in predicting the migration of a contaminant plume in ground water depends to a large extent on the quality of flow and transport parameters used. In this study, we investigate the spatial variability in the tracer velocity and dispersivity in a shallow sandy aquifer in northern Belgium. Based on hydraulic conductivity measurements on cores sampled along a vertical profile, the aquifer was found to be mildly heterogeneous, i.e., with the variance of the log-transformed conductivity K, 62i.,K, equal to 0.22. By means of a natural gradient tracer experiment, transport of a chloride tracer was investigated in a three-dimensional network of multilevel point samplers (MLS). Least squares fitting of a two-dimensional transport model to the individual breakthrough curves resulted in an average longitudinal dispersivity that was 10 times larger than the transverse dispersivity. The results further showed the existence of a dispersion-scale effect whereby the depth-averaged longitudinal dispersivity increases with increasing travel distance. The average longitudinal dispersivity corresponding to a travel distance of 10 m was equal to 0.2 m. We finally show that theoretical expressions for the macroscopic dispersivity tensor, which require input on hydraulic conductivity heterogeneity, could be used here to approximate the observed dispersive behavior. These conceptually simple models are useful to estimate macroscopic dispersivities when no tracer data are available.

(9) GroundWater Flow in a Fractured Carbonate Aquifer Inferred from Combined Hydrogeological and Geochemical Measurements. Zanini, L. 1999.

A conceptual model for ground water flow is presented for a fractured Silurian dolomite in the Niagara Escarpment area of southern Ontario. Such a model is necessary to facilitate remedial efforts of a PCB-contaminated site located in Smithville, Ontario. Both physical and chemical hydrogeological observations obtained from field investigations were used to deduce the structure of the ground water flow system in the fracture network. The field study was conducted using observations obtained from six bore holes drilled in the vicinity of the town of Smithville. The boreholes were diamond cored through the entire thickness of the dolomite formation (approximately 45 m), hydraulically tested using a 2 m packer spacing and then completed using multipacker casing strings. Measurements of hydraulic head were obtained on a weekly basis over a period of two years, and ground water from each borehole interval was collected for geochemical analyses for inorganic and isotopic composition. Transmissivity measurements indicate that the dolomite is divided into two ground water flow systems separated by an extensive unit of low transmissivity that is pervasive throughout the region. The upper flow system is characterized by water enriched in Mg^{2+} and $S0_4^{2-}$. Below the low transmissivity zone, ground water increases in salinity and is enriched in Cat^{2+} and $S0_4^{2-}$. Based on the geochemistry, the rate of ground water migration in the lower flow system is surmised to be much less than that in the upper system. Measurements of hydraulic head in conjunction with the results of the analyses of the environmental isotopes ($\delta^{18}O$ and $\delta^{2}H$) suggest that ground water flow is mainly horizontal and likely governed by enlarged bedding plane fractures. The isotope geochemistry and topographical features further suggest that ground water recharge is occurring approximately 2 km to the north of Smithville.

(10) Hydrogeologic Investigation and Simulation of Ground-Water Flow in the Upper Floridan Aquifer of North-Central Florida and Southwestern Georgia and delineation of contributing areas for selected City of Tallahassee, Florida, Water Supply Wells (WRI 95-4296). Davis, Hal. 1996.

A 4-year investigation of the Upper Floridan aquifer and ground-water flow system in Leon County, Florida, and surrounding counties of north-central Florida and southwestern Georgia began in 1990. The purpose of the investigation was to describe the ground-water flow system to delineate the contributing areas to selected City of Tallahassee, Florida, water-supply wells. The investigation was prompted by the detection low levels of tetrachloroethylene in ground-water samples collected from several of the city's water supply wells.

Hydrologic data and previous studies indicate that; ground-water flow within the Upper Floridan aquifer can be considered steady-state; the Upper Floridan aquifer is a single water-bearing unit; recharge is from precipitation; and that discharge occurs as spring flow, leakage rivers, leakage to the Gulf of Mexico, and pumpage. Measured transmissivities of the aquifer ranged from 1,300 ft^2/d (feet squared per day) to 1,300,000 ft^2/d.

Steady-state ground-water flow in the Upper Floridan aquifer was simulated using a three-dimensional ground-water flow model. Transmissivities ranging from less than 5,000 ft^2/d to greater than 11,000,000 ft^2/d were required to calibrate to observed conditions. Recharge rates used

in the model ranged from 18.0 inches per year in areas where the aquifer was unconfined to less than 2 inches per year in broad areas where the aquifer was confined.

Contributing areas to five Tallahassee water-supply wells were simulated by particle-tracking techniques. Particles were seeded in model cells containing pumping wells then tracked backwards in time toward recharge areas. The contributing area for each well was simulated twice, once assuming a porosity of 25 percent and once assuming a porosity of 5 percent. A porosity of 25 percent is considered a reasonable average value for the Upper Floridan aquifer; the 5 percent porosity simulated the movement of ground-water through only solution-enhanced bedding plains and fractures. The contributing areas were generally elliptical in shape, reflecting the influence of the sloping potentiometric surface. The contributing areas delineated for a 5 percent porosity were always much larger than those determined using a 25 percent porosity. The lowest average ground-water velocity computed within a contributing area, using a 25 percent porosity, was 1.0 ft/d (foot per day) and the highest velocity was 1.6 ft/d. The lowest average ground-water velocity, determined using a 5 percent porosity, was 2.4 ft/d and the highest was 7.4 ft/d.

The contributing areas for each of the five wells was also determined analytically and compared to the model-derived areas. The upgradient width of the simulated contributing areas were larger than the upgradient width of the analytically determined contributing areas for four of the five wells. The model could more accurately delineate contributing areas because of the ability to simulate wells as partially penetrating and by incorporating complex, three-dimensional aquifer characteristics, which the analytical method could not.

(11) Hydrogeology and Analysis of Aquifer Characteristics in West-Central Pinellas County, Florida (OFR-99-18s). Broska, James C. 1999.

The U.S. Geological Survey, in cooperation with Pinellas County, Florida, conducted an investigation to describe the hydrogeology and analyze the aquifer characteristics in west-central Pinellas County. A production test well and four monitor wells were constructed in Pinellas County at Walsingham Park during 1996-97. Water-quality sampling, static and dynamic borehole geophysical surveys, and hydraulic tests were conducted at the wells to delineate the hydrogeology at Walsingham Park. A 9-day aquifer test was conducted to determine the hydraulic characteristics of the aquifer system and observe the changes in water quality due to pumping.

A numerical model was constructed to simulate the aquifer test and calculate values for hydraulic conductivity and storage coefficient for permeable zones and confining units at Walsingham Park. Final calibrated values for hydraulic conductivity for the different permeable zones and confining units at the test site were 18 feet per day for Upper Zone A, 750 feet per day for Lower Zone A, 1 foot per day for Zone B, $1x10^{-4}$ feet per day for the intermediate confining unit, and 10 feet per day for the semiconfining unit separating Upper Zone A and Lower Zone A. Final calibrated values for storage coefficient were $3.1x10^{-4}$ for Upper Zone A, $8.6x10^{-5}$ for Lower Zone A, $2.6x10^{-5}$ for Zone B, $3.1x10^{-4}$ for the intermediate confining unit, and $4.3x10^{-5}$ for the semiconfining unit separating Upper Zone A and Lower Zone A. Estimates of transmissivity for Upper Zone A and Lower Zone A were about 2,500 and 37,500 feet squared per day, respectively.

(12) Hydrogeology of Effluent Disposal Zones, Floridan Aquifer, South Florida. Broska, James C. 1991.

The increasing population of south Florida is creating a need for greater waste-water disposal capacity. The people of Florida are dependent on ground water for drinking, irrigation, and other uses. The emphasis on preservation of surface-water quality means that many surface waters are not allowed to receive effluent from municipal or industrial sources. Since the 1940s, the highly transmissive zones of the nonpotable portion of the Floridan aquifer have served as disposal zones for oil field brine and later for industrial and municipal effluent.

The Floridan aquifer of south Florida is a carbonate Cenozoic age aquifer. Transmissivities between 0.5 and 21 million gpd/ft exist in cavernous and fractured sequences in the aquifer. Confining zones that overlie the disposal intervals have transmissivities and hydraulic conductivities one to three orders of magnitude less than the injection intervals. These confining zones prevent low density municipal effluent from rising upward through the overlying saline waters.

This paper provides an integration of previously published work with recent site-specific data collected from deep injection wells drilled in the last two decades.

(13) Important Observations and Parameters for a Salt Water Intrusion Model. Shoemaker, W. Barclay. 2003

Sensitivity analysis with a density-dependent ground water flow simulator can provide insight and understanding of salt water intrusion calibration problems far beyond what is possible through intuitive analysis alone. Five simple experimental simulations presented here demonstrate this point. Results show that dispersivity is a very important parameter for reproducing a steady-state distribution of hydraulic head, salinity, and flow in the transition zone between fresh water and salt water in a coastal aquifer system. When estimating dispersivity, the following conclusions can be drawn about the data types and locations considered. (1) The “toe” of the transition zone is the most effective location for hydraulic head and salinity observations. (2) Areas near the coastline where submarine ground water discharge occurs are the most effective locations for flow observations. (3) Salinity observations are more effective than hydraulic head observations. (4) The importance of flow observations aligned perpendicular to the shoreline varies dramatically depending on distance seaward from the shoreline. Extreme parameter correlation can prohibit unique estimation of permeability parameters such as hydraulic conductivity and flow parameters such as recharge in a density-dependent ground water flow model when using hydraulic head and salinity observations. Adding flow observations perpendicular to the shoreline in areas where ground water is exchanged with the ocean body can reduce the correlation, potentially resulting in unique estimates of these parameter values. Results are expected to be directly applicable to many complex situations, and have implications for model development whether or not formal optimization methods are used in model calibration.

(14) Calculation of Low-Range Flow Velocities in Fractured Carbonate Media from Borehole Hydrochemical Logging Data Comparison with Thermometric results. Bidaux, Pascal. 1992.

Flow rates and concentrations from fractures intersected by a borehole can be estimated by matching simulated concentration profiles to the observed variations in water chemistry along the borehole. Experiments in karstic rocks prove that hydraulic short circuits between fractures yield a very complex flow pattern, and that flow velocities in the borehole may be higher than the velocity at which the piezometric level varies. Combined temperature and concentration studies characterize flow in both high permeability channels and slightly fissured blocks, as chemical profiles detect low velocity flows that cannot be identified on temperature profiles. Such studies are therefore advisable to characterize natural flow in fractured carbonate rocks, but also in other fractured media.

(15) Calculation of Ground Water Ages – A Comparative Analysis. Castro, Maria C. 2004

Ground water age is a fundamental, yet complex, concept in ground water hydrology. Discrepancies between results obtained through different modeling approaches for ground water age calculation have been reported, in particular, between ground water ages modeled by advection and direct simulation of around water ages (e.g., age-mass approach), which includes effects of advection and dispersion. Here, through a series of two-dimensional (2D) simulations, the impact of water mixing through advection and dispersion on modeled ages is systematically stronger in areas where water velocities are smaller and far more pronounced on ^{14}C ages. This effect is also observed in one-dimensional models. 2D simulations show that longitudinal dispersion generally acts as a "source" of ^{14}C, while vertical dispersion acts as a "sink," leading to apparent younger or older modeled ^{14}C ages as compared to advective and directly simulated ground water ages. The presence of permeable and impermeable faults provides an equally important source for discrepancies, leading to major differences in modeled ages among the three methods considered. Overall, our results show that a ^{14}C modeling approach using a solute transport model for calculating ground water age appears to be more reliable in ground water systems without faults and where water velocities are relatively high than in systems that are relatively more heterogeneous and those where faults are present. Among the three modeling approaches considered here, direct simulation of ground water age seems to yield the most consistent results in complex, heterogeneous ground wetter flow systems, giving a vertical age structure consistent with ages expected from consideration of the flow system.

(16) Can Contaminant Transport Models Predict Breakthrough? Peng, Wei-Shyuan et al. 2000.

A solute breakthrough curve measured during a two-well tracer test was successfully predicted in 1986 using specialized contaminant transport models. Water was injected into a confined, unconsolidated sand aquifer and pumped out 125 feet (38.3 m) away at the same steady rate. The injected water was spiked with bromide for over three days; the outflow concentration was monitored for a month. Based on previous tests, the horizontal hydraulic conductivity of the thick

aquifer varied by a factor of seven among 12 layers. Assuming stratified flow with small dispersivities, two research groups accurately predicted breakthrough with three-dimensional (12-layer) models using curvilinear elements following the arc-shaped flowlines in this test.

Can contaminant transport models commonly used in industry, that use rectangular blocks, also reproduce this breakthrough curve? The two-well test was simulated with four MODELOW-based models, LT3D (FD and HMOC options), MODFLOWT, MOC3D, and MODFLOW-SUR-FACT.

Using the same 12 layers and small dispersivity used in the successful 1986 simulations, these models fit almost as accurately as the models using curvilinear blocks. Subtle variations in the curves illustrate differences among the codes. Sensitivities of the results to number and size of grid blocks, number of layers, boundary conditions, and values of dispersivity and porosity are briefly presented. The fit between calculated and measured breakthrough curves degenerated as the number of layers and/or grid blocks decreased, reflecting a loss of model predictive power as the level of characterization lessened. Therefore, the breakthrough curve for most field sites can be predicted only qualitatively due to limited characterization of the hydrogeology and contaminant source strength.

(17) Dampening of Transverse Dispersion in the Halocline in Karst Limestone in the Northeastern Yucatan Peninsula. Stoessell, Ronald K. 1994.

A range of hydrodynamic dispersion coefficients was estimated for fracture-fluid and combined fracture and pore-fluid flow within the halocline of the limestone aquifer forming the surface of the northern Yucatan Peninsula. The coefficients are fit parameters in a model reproducing observed halocline profiles in a sinkhole and in a borehole near the northeastern coast. Fitted coefficients range from 10^{-7} to $10^{-4}cm^2/sec$, of which molecular diffusion, without transverse (vertical) dispersion, can account for 10^{-7} to $10^{-5}cm^2/sec$. The mechanical stability of the vertical density gradient in the halocline dampens transverse dispersion in pore fluids and in fracture fluids that are transitional between laminar and turbulent flow. The dampening is proportional to the ratio of the energy needed for the fluid to rise and displace a less dense fluid to the vertical component of the kinetic energy of the fluid. The ratio of these two energies is at a maximum during the initial stage of development of a halocline and decreases as the halocline widens.

(18) Data Analysis Methods for Determining Two-dimensional Dispersive Parameters. Jiao, Jiu J. 1993.

Two methods for calculating two-dimensional hydrodynamic dispersion parameters by analyzing experimental data, the dispersive-plume-area (DPA) method and the linear-graphic (LG) method, are proposed in this paper. The DPA method determines the dispersive parameters by analyzing the dispersive plume area after injection of a salt-water slug into an aquifer. The transverse and longitudinal dispersivity and even the porosity of an aquifer may be derived. The LG method transforms the concentration-time curve into a straight line. Using the slope of the line, dispersivity and velocity can be obtained. Both methods are examined using theoretical considerations and practical examples.

(19) Descriptions of Anisotropy and Heterogeneity and their Effect on Ground-Water Flow and Areas of Contribution to Public Supply Wells in a Karst Carbonate Aquifer system. Knochenmus, Lari A. 1996.

Delineation of areas of contribution to wells tapping a karst carbonate aquifer system can be extremely difficult using conventional approaches designed for isotropic and homogeneous aquifers, because ground-water flow tends to be through solution-enhanced conduits. Nonradial flow along preferential zones can result in inaccurate estimates of flow paths and travel times. Because of the large variability in factors affecting contributing areas and an imperfect understanding of how these factors can vary, the estimation of contributing areas is an approximation at best.

To better understand the effects of aquifer anisotropy and heterogeneity on areas of contribution, an exploratory modeling approach was used. MODFLOW, a numerical flow model, and MODPATH, a particle tracking program, were used to generate time-related areas of contribution for six hypothetical carbonate aquifer system types. The six types were conceptualized to approximate different types of aquifer anisotropy and heterogeneity. These include: (1) an isotropic and homogeneous single-layer system; (2) an anisotropic in a horizontal plane single-layer system; (3) a discrete vertically fractured single-layer system; (4) a multilayered system; (5) a doubly porous single-layer system; and (6) a vertically and horizontally interconnected heterogeneous system. The simulated aquifer anisotropy was 5:1 (K_{xx}/K_{yy}) determined from TENSORM results. The simulated discrete vertical fracture network represents locations inferred from mapped photolineaments. The simulated enhanced flow zones were determined from borehole video and geophysical logs. Areas of contribution were simulated for two prototype regions. The two prototypes were selected to be representative of the hydrologic diversity within the study area and were designated the Central Swamp and Lake Terrace regions.

Localized conditions in pumping, production well distribution, and aquifer transmissivity affect the size, shape, and orientation of areas of contribution to public supply wells. The simulated areas of contribution are 60 percent larger in the Central Swamp region where pumpage is more than double and transmissivity is about half that of the Lake Terrace region. Although these factors are important, this study focused on the effects from hydrogeologic factors common to karst carbonate aquifer systems.

This study indicates that the distribution and type of aquifer anisotropy and heterogeneity will affect the size, shape, and orientation of areas of contribution in a karst carbonate aquifer system. The size of the 50-year time-related areas of contribution ranged from 8.2 to 39.1 square miles in the Central Swamp region and from 4.0 to 18.3 square miles in the Lake Terrace region. Simulations showed that the size of areas of contribution is primarily affected by simulated withdrawal rates, effective porosity of the carbonate rock, and transmissivity. The shape and orientation of the simulated areas of contribution primarily result from aquifer anisotropy, well distribution, flow along solution-enhanced zones, and short-circuiting of flow through fracture networks.

Comparisons also were made between protection zones delineated using analytical models areas of contribution delineated using numerical models. The size of the 5-year time-related protection zone in the Central Swamp region using analytical model was almost twice as large as numerically simulated area of contribution, and more than eight times larger than the numeric simulated area of contribution in the Lake Terrace region. The differences in size are primarily t result of how the flow field is approximated. The analytical method assumes only lateral fl to wells but numerical

methods allow particle move laterally and vertically. Additionally, multiple-well-interference effects resulting from the close proximity of several pumping wells cal: individual capture zones to converge or diver depending on the difference in pumping rates orientation among the wells. Such an interpretation is not available from analytical methods. simulated distributions of aquifer anisotropy heterogeneity, in this study, were highly conceptualized, but were based on plausible occurrence anisotropy and heterogeneity inherent in carbonate aquifer systems.

(20) Influence of Pore Pressure on Apparent Dispersity of a Fissured Dolomitic Aquifer. Leap, Darrell I. 1991.

The U.S. Geological Survey's Amargosa Tracer Calibration Site in southern Nevada has been used for three different recirculating tracer tests using as tracers: (1) tritium, (2) sulfur-35, and (3) tritium and bromide together. Although the physical setup, well spacings, and thus apparent scale were the same in all tests, the recirculating rates and pore pressures were different. Apparent dispersivities found in the three tests differed considerably, revealing an inverse relationship between computed dispersivity and recirculation rate. These differences are believed to be caused primarily by changes in fissure-aperture widths and thus, hydraulic conductivities, with resulting changes in flow rates and directions caused by changes in pore pressure between different tests in the presence of high ambient pore pressure. The results of this study indicate that forced-gradient tracer tests for determination of dispersivity should not be performed when ambient pore pressure and/or testing pore pressure is a significant percentage of overburden pressure. In addition, apparent dispersivity calculated by forced-gradient tracer tests can differ considerably from that of unstressed natural situations, and consequent solute-transport estimates are likely to be in error.

(21) Inventory and Review of Aquifer Storage and Recovery in Southern Florida. Reese, Ronald S. 2002.

Aquifer storage and recovery in southern Florida has been proposed on an unprecedented scale as part of the Comprehensive Everglades Restoration Plan. Aquifer storage and recovery wells were constructed or are under construction at 27 sites in southern Florida, mostly by local municipalities or counties located in coastal areas. The Upper Floridan aquifer, the principal storage zone of interest to the restoration plan, is the aquifer being used at 22 of the sites. The aquifer is brackish to saline in southern Florida, which can greatly affect the recovery of the freshwater recharged and stored.

Well data were inventoried and compiled for all wells at most of the 27 sites. Construction and testing data were compiled into four main categories: (1) well identification, location, and construction data; (2) hydraulic test data; (3) ambient formation water-quality data; and (4) cycle testing data. Each cycle during testing or operation includes periods of recharge of freshwater, storage, and recovery that each last days or months. Cycle testing data include calculations of recovery efficiency, which is the percentage of the total amount of potable water recharged for each cycle that is recovered.

Calculated cycle test data include potable water recovery efficiencies for 16 of the 27 sites. However, the number of cycles at most sites was limited; except for two sites, the highest number of cycles was five. Only nine sites had a recovery efficiency above 10 percent for the first cycle, and

10 sites achieved a recovery efficiency above 30 percent during at least one cycle. The highest recovery efficiency achieved per cycle was 84 percent for cycle 16 at the Boynton Beach site. Factors that could affect recovery of freshwater varied widely between sites. The thickness of the open storage zone at all sites ranged from 45 to 452 feet. For sites with the storage zone in the Upper Floridan aquifer, transmissivity based on tests of the storage zones ranged from 800 to 108,000 feet squared per day, leakance values indicated that confinement is not good in some areas, and the chloride concentration of ambient water ranged from 500 to 11,000 milligrams per liter. Based on review of four case studies and data from other sites, several hydrogeologic and design factors appear to be important to the performance of aquifer storage and recovery in the Floridan aquifer system. Performance is maximized when the storage zone is thin and located at the top of the Upper Floridan aquifer, and transmissivity and salinity of the storage zone are moderate (less than 30,000 feet squared per day and 3,000 milligrams per liter of chloride concentration, respectively). The structural setting at a site could also be important because of the potential for updip migration of a recharged freshwater bubble due to density contrast or loss of overlying confinement due to deformation.

(22) Simulation of Subsurface Storage and Recovery of Effluent Using Multiple Wells, St. Petersburg, Florida. Yobbi, Dann K. 1997.

The potential for subsurface storage and recovery, otherwise called aquifer storage and recovery, of effluent in the uppermost producing zone of the Upper Floridan aquifer in St. Petersburg, Florida, was studied by the U.S. Geological Survey, in cooperation with the city of St. Petersburg and the Southwest Florida Water Management District. The success of subsurface storage and recovery depends on the recovery efficiency, or the quantity of water, relative to the quantity injected, that can be recovered before the water that is withdrawn fails to meet salinity limits. The viability of this practice will depend upon the ability of the injected zone to receive, store, and discharge the injected fluid.

A three-dimensional numerical model of ground-water flow and solute transport, incorporating available data on aquifer properties and water quality, was developed to evaluate the effects of changing various operational factors on recovery efficiency. The reference case for testing was a base model considered representative of the aquifer system underlying the Southwest St. Petersburg Water Treatment Facility. The base simulation used as a standard for comparison consisted of a single cycle of 90 days of simultaneous injection of effluent in three wells at a rate of 4.0 million gallons per day and then equal rate withdrawal of 4.0 million gallons per day until the pumped water in each well reached a dissolved solids concentration of 1,500 milligrams per liter. A recovery efficiency of 14.8 percent was estimated for the base simulation. Ten successive injection and recovery cycles increased recovery efficiency to about 56 percent. Based on model simulations for hypothetical conditions, recovery efficiency (1) increased with successive injection and recovery cycles; (2) increased when the volume of injectant increased; (3) decreased when storage time increased; (4) did not change significantly when the injection rate or recovery rate increased, or when the ratio of recovery rate to injection rate increased, and (5) was not significantly affected by any particular geometric arrangement of wells or by the number of wells when the volume of water injected remained constant. Recovery efficiency from multiple wells was nearly the same as from a single well. Recovery efficiency ranged from about 7 to 56 percent, in several tests.

Sensitivity of recovery efficiency to variations in selected parameters such as dissolved-solids concentration of the injection zone, permeability, vertical anisotropy, longitudinal and transverse dispersivities, and effective porosity was tested. Changes in the dissolved-solids concentration of the injection zone produced the greatest change in recovery efficiency. Uniform changes in dispersivity values produced the second greatest change in recovery efficiency. Generally, recovery efficiency increased when the above parameter values were decreased and recovery efficiency decreased when these parameter values were increased.

Density difference between native and injected waters was the most important factor affecting recovery efficiency in this study. For the base simulation, sensitivity tests indicated that recovery efficiency increased from about 15 to 78 percent when the dissolved-solids concentration of the native water decreased from about 7,800 to 500 milligrams per liter.

Dispersivity is another important factor affecting recovery efficiency. For the base simulation, sensitivity tests indicated that recovery efficiencies from about 9 to 24 percent can be obtained for difference dispersivity values. A field determination of dispersivity was not made as part of this study, and values used may not be representative of the actual dispersive characteristics of the aquifer system at the study site. However, dispersivity values tested are within the range of values used in previous studies.

(23) Simulation of Subsurface Storage and Recovery of Treated Effluent Injected in a Saline Aquifer, St. Petersburg, Florida. Yobbi, Dann K. 1996.

The potential for subsurface storage and recovery of treated effluent into the uppermost producing zone (zone A) of the Upper Floridan aquifer in St. Petersburg, Florida, is being studied by the U.S. Geological Survey, in cooperation with the city of St. Petersburg and the Southwest Florida Water Management District. A measure of the success of this practice is the recovery efficiency, or the quantity of water relative to the quantity injected, that can be recovered before the water that is withdrawn fails to meet water-quality standards. The feasibility of this practice will depend upon the ability of the injected zone to receive, store, and discharge the injected fluid.

A cylindrical model of ground-water flow and solute transport, incorporating available data on aquifer properties and water quality, was developed to determine the relation of recovery efficiency to various aquifer and fluid properties that could prevail in the study area. The reference case for testing was a base model considered representative of the saline aquifer underlying St. Petersburg. Parameter variations in the tests represent possible variations in aquifer conditions in the area. The model also was used to study the effect of various cyclic injection and withdrawal schemes on the recovery efficiency of the well and aquifer system.

A base simulation assuming 15 days of injection of effluent at a rate of 1.0 million gallons per day and 15 days of withdrawal at a rate of 1.0 million gallons per day was used as reference to compare changes in various hydraulic and chemical parameters on recovery efficiency. A recovery efficiency of 20 percent was estimated for the base simulation. For practical ranges of hydraulic and fluid properties that could prevail in the study area, the model analysis indicates that (1) the greater the density contrast between injected and resident formation water, the lower the recovery efficiency, (2) recovery efficiency decreases significantly as dispersion increases, (3) high formation permeability favors low recovery efficiencies, and (4) porosity and anisotropy have little

effect on recovery efficiencies. In several hypothetical tests, the recovery efficiency fluctuated between about 4 and 76 percent.

The sensitivity of recovery efficiency to variations in the rate and duration of injection (0.25, 0.50, 1.0, and 2.0 million gallons per day) and withdrawal cycles (60, 180, and 365 days) was determined. For a given operational scheme, recovery efficiency increased as the injection and withdrawal rate is increased. Model results indicate that recovery efficiencies of between about 23 and 37 percent can be obtained for different subsurface storage and recovery schemes. Five successive injection, storage, and recovery cycles can increase the recovery efficiency to about 46 to 62 percent. There is a larger rate of increase at smaller rates than at larger rates. Over the range of variables studied, recovery efficiency improved with successive cycles, increasing rapidly during initial cycles then more slowly at later cycles.

The operation of a single well used for subsurface storage and recovery appears to be technically feasible under moderately favorable conditions; however, the recovery efficiency is highly dependent upon local physical and operational parameters. A combination of hydraulic, chemical, and operational parameters that minimize dispersion and buoyancy flow, maximizes recovery efficiency. Recovery efficiency was optimal where resident formation water density and permeabilities were relatively similar and low.

(24) Tests of Subsurface Storage or Freshwater at Hialeah, Dade County, Florida, and Numerical Simulation of the Salinity of Recovered Water. Merritt, Michael L. 1997.

Injection and observation wells were drilled in late 1974 for the purpose of conducting tests of storage and recovery of potable water in the brackish Upper Floridan aquifer. Three tests, involving storage and recovery cycles of varying volumes and storage period lengths, were performed between July 1975 and January 1980. Recovery was by natural artesian flow, and recovery efficiencies were 32.9, 47.8, and 38.5 percent. Wellbore plugging occurred during the injection stages, but injectivity was restored by periodic 2- to 3-hour backflushes at the natural artesian flow rate.

An interval of shelly limestone between 1,015 and 1,050 feet below land surface contained the flow zone. Data from an analysis of 18 spinner flowmeter logs indicated that the principal part of the flow zone extended from 1,024 to 1,036 feet below land surface and that minor amounts of flow occurred to a depth of about 1,047 feet. A neutron porosity log indicated the bulk porosity of both the flow zone and confining layers to be 35 percent. Chloride and dissolved-solids concentrations of water in the flow zone were 1,200 and 2,700 milligrams per liter, respectively.

A three-dimensional, finite-difference flow and solute-transport code was used to simulate pressure data measured during an aquifer test and observed salinity increases in recovered water during storage and recovery cycles. The aquifer test conducted in February 1975 was simulated by using a hydraulic conductivity estimate of 800 feet per day and a rock compressibility estimate of 0.0000400 (pound per square inch). The equivalent transmissivity and storage coefficients were 9,600 cubic feet per day per square foot times foot of aquifer thickness and 7.8×10^{-5}, respectively. Simulation of observed salinity increases during the three recoveries required dispersivities of 65 feet, a molecular diffusivity of 0.0002 foot squared per day, and a regional pore velocity of 260 feet per year. Central differencing in space and time was used for the solute-transport computations as well as an experimental method of computing vertical dispersion that used a scaling factor of 0.013.

Additional simulations of the aquifer-test data and recovery salinities were obtained based on assumptions that (1) the flow zone was 21 feet thick, (2) flow-zone effective porosity was 20 percent, and (3) flow-zone hydraulic conductivity was bipolar anisotropic by a ratio of 10:1. The four sets of simulation values were used in model runs in which 10 years of annual injection, storage, and recovery cycles were simulated. Computed recovery efficiencies increased from 40 percent in the first year to 68 percent in later cycles. The high regional pore velocity required for model calibration substantially limited the recovery efficiency achieved in later cycles.

(25) The Impact of Matrix Diffusion on the Cleanup of Fractured Igneous, Metamorphic and Sedimentary Rock Aquifers. Mutch, Robert D. 1993.

Aquifer restoration has been recognized for many years to be an extremely difficult undertaking. For a variety of reasons, restoration of fractured rock aquifers appears to be especially difficult. One reason is the phenomenon of matrix diffusion. Matrix diffusion refers to the process by which contaminants diffuse into and out of the relatively immobile matrix pore water from the mobile fracture water.

In most (but not all) fractured rock, groundwater moves primarily through the interconnected network of fractures and the pore water within the matrix of the rock is relatively immobile. As contaminated groundwater moves through the fractures, the contamination is also subject to diffusion into the often stagnant matrix pore water of the rock. The diffusion of contaminants into the rock matrix is beneficial in one respect in that it retards the advance of a contaminant plume through a fractured rock aquifer. However, the diffusion-controlled release of contaminants from the rock matrix can substantially prolong aquifer cleanup efforts over what would be possible in a simple porous medium aquifer of equivalent hydraulic conductivity.

In order to evaluate the impact of matrix diffusion upon the cleanup of fractured rock aquifers, a simple mathematical model has been developed which predicts contaminant levels along a representative fracture in the rock as a function of position, time, and past history of contaminant levels in the groundwater. The model takes into account the characteristics of the fractured rock through which the groundwater is moving, specifically fracture porosity, matrix porosity, fracture spacing, matrix diffusivity, groundwater velocity in the fractures, longitudinal dispersion constant, and length of the groundwater flow path.

The model is employed to evaluate the effect of matrix diffusion on the cleanup of typical sedimentary rock aquifers and typical metamorphic or igneous aquifers. Through sensitivity analyses, the modeling reveals the parameters most strongly governing the process. The modeling also looks at the effect of pump and treat systems and specifically the “rebound effect” that can result from premature cessation of pump and treat systems.

(26) Use of Chemical and Isotopic Tracers to Characterize the Interactions Between Groundwater and Surface Water in Mantled Karst. Katz, Brian G. 1997.

In the mantled karst terrane of northern Florida, the water quality of the Upper Floridan aquifer is influenced by the degree of connectivity between the aquifer and the surface. Chemical and isotopic analyses [$^{l8}O/^{16}O$ ($\delta^{18}O$), $^{2}H/^{1}H$ (δD), $^{13}C/^{12}C$ ($\delta^{13}C$), tritium (^{3}H), and strontium-87/strontium-86 ($^{87}Sr/\ ^{86}Sr$)] along with geochemical mass-balance modeling were used to identify the dominant hydrochemical processes that control the composition of ground water as it evolves downgradient in two systems. In one system, surface water enters the Upper Floridan aquifer through a sinkhole located in the Northern Highlands physiographic unit. In the other system, surface water enters the aquifer through a sinkhole lake (Lake Bradford) in the Woodville Karst Plain. Differences in the composition of water isotopes ($\delta^{18}O$ and δD) in rainfall, ground water, and surface water were used to develop mixing models of surface water (leakage of water to the Upper Floridan aquifer from a sinkhole lake and a sinkhole) and ground water. Using mass-balance calculations, based on differences in $\delta^{18}O$ and δD, the proportion of lake water that mixed with meteoric water ranged from 7 to 86% in water from wells located in close proximity to Lake Bradford. In deeper parts of the Upper Floridan aquifer, water enriched in ^{18}O and D from five of 12 sampled municipal wells indicated that recharge from a sinkhole (1 to 24%) and surface water with an evaporated isotopic signature (2 to 32%) was mixing with ground water.

The solute isotopes, $\delta^{13}C$ and $^{87}Sr/^{86}Sr$, were used to test the sensitivity of binary and ternary mixing models, and to estimate the amount of mass transfer of carbon and other dissolved species in geochemical reactions. In ground water downgradient from Lake Bradford, the dominant processes controlling carbon cycling in ground water were dissolution of carbonate minerals, aerobic degradation of organic matter, and hydrolysis of silicate minerals. In the deeper parts of the Upper Floridan aquifer, the major processes controlling the concentrations of major dissolved species included dissolution of calcite and dolomite, and degradation of organic matter under oxic conditions. The Upper Floridan aquifer is highly susceptible to contamination from activities at the land surface in the Tallahassee area. The presence of post-1950s concentrations of ^{3}H in ground water from depths greater than 100 m below land surface indicates that water throughout much of the Upper Floridan aquifer has been recharged during the last 40 years. Even though mixing is likely between ground water and surface water in many parts of the study area, the Upper Floridan aquifer produces good quality water, which due to dilution effects shows little if any impact from trace elements or nutrients that are present in surface waters.

(27) Potential for Saltwater Intrusion into the Lower Tamiami Aquifer near Bonita Springs, Southwestern Florida. Shoemaker, W. Barclay. 2003.

A study was conducted to examine the potential for saltwater intrusion into the lower Tamiami aquifer beneath Bonita Springs in south western Florida. Field data were collected, and constant- and variable-density ground-water flow simulations were performed that: (1) spatially quantified modern and seasonal stresses, (2) identified potential mechanisms of saltwater intrusion, and (3) estimated the potential extent of saltwater intrusion for the area of concern.

MODFLOW and the inverse modeling routine UCODE were used to spatially quantify modern and seasonal stresses by calibrating a constant-density ground-water flow model to field data collected

in 1996. The model was calibrated by assuming hydraulic conductivity parameters were accurate and by estimating unmonitored ground-water pumpage and potential evapotranspiration with UCODE. Uncertainty in these estimated parameters was quantified with 95-percent confidence intervals. These confidence intervals indicate more uncertainty (or less reliability) in the estimates of unmonitored ground-water pumpage than estimates of pan-evaporation multipliers, because of the nature and distribution of observations used during calibration. Comparison of simulated water levels, streamflows, and net recharge with field data suggests the model is a good representation of field conditions.

Potential mechanisms of saltwater intrusion into the lower Tamiami aquifer include: (1) lateral inland movement of the freshwater-saltwater interface from the southwestern coast of Florida; (2) upward leakage from deeper saline waterbearing zones through natural upwelling and upconing, both of which could occur as diffuse upward flow through semiconfining layers, conduit flow through karst features, or pipe flow through leaky artesian wells; (3) downward leakage of saltwater from surface-water channels; and (4) movement of unflushed pockets of relict seawater. Of the many potential mechanisms of saltwater intrusion, field data and variable-density ground-water flow simulations suggest that upconing is of utmost concern, and lateral encroachment is of second-most concern. This interpretation is uncertain, however, because the predominance of saltwater intrusion through leaky artesian wells with connection to deeper, more saline, and higher pressure aquifers was difficult to establish.

Effective management of ground-water resources in southwestern Florida requires an understanding of the potential extent of saltwater intrusion in the lower Tamiami aquifer near Bonita Springs. Variable-density, ground-water flow simulations suggest that when saltwater is at dynamic equilibrium with 1996 seasonal stresses, the extent of saltwater intrusion is about 100 square kilometers areally and 70,000 hectare-meters volumetrically. The volumetric extent of saltwater intrusion was most sensitive to changes in recharge, ground-water pumpage, sea level, salinity of the Gulf of Mexico, and the potentiometric surface of the sandstone aquifer, respectively.

(28) Preliminary Assessment of Injection, Storage, and Recovery of Freshwater in the Lower Hawthorn Aquifer, Cape Coral, Florida. Quinones-Aponte, Vincente. 1995.

A preliminary assessment of subsurface injection, storage and recovery of fresh canal water was made in the naturally brackish lower Hawthorn aquifer in Cape Coral, southwestern Florida. A digital modeling approach was used for this preliminary assessment, incorporating available data on hydrologic conditions, aquifer properties, and water quality to simulate density-dependent groundwater flow and advective-dispersive transport of a conservative ground-water solute (chloride ion).

A baseline simulation was used as reference to compare the effects of changing various operational factors on the recovery efficiency. A recovery efficiency of 64 percent was estimated for the baseline simulation. Based on the model, the recovery efficiency increases if the injection rate and recovery rates are increased and if the ratio of recovery rate to injection rate is increased. Recovery efficiency decreases if the amount of water injected is increased; slightly decreases if the storage time is increased; is not changed significantly if the water is injected to a specific flow zone; increases with successive cycles of injection, storage, and recovery; and decreases if the chloride concentrations in either the injection water or native aquifer water are increased. In everal hypothetical tests, the recovery efficiency fluctuated between 22 and about 100 percent.

Two successive cycles could bring the recovery efficiency from 60 to about 80 percent. Interlayer solute mass movement across the upper and lower boundaries seems to be the most important factor affecting the recovery efficiency. A sensitivity analysis was performed applying a technique in which the change in the various factors and the corresponding model responses are normalized so that meaningful comparisons among the responses could be made. The general results from the sensitivity analysis indicated that the permeabilities of the upper and lower flow zones were the most important factors that produced the greatest changes in the relative sensitivity of the recovery efficiency. Almost equally significant changes occurred in the relative sensitivity of the recovery efficiency when all porosity values of the upper and lower flow zones and the leaky confining units and the vertical anisotropy ratio were changed.

The advective factors are the most important in the Cape Coral area according to the sensitivity analysis. However, the dispersivity values used in the model were extrapolated from studies conducted at the nearby Lee County Water Treatment Plant, and these values might not be representative of the actual dispersive characteristics of the lower Hawthorn aquifer in the Cape Coral area.

29) Process-Based Interpretation of Tracer Tests in Carbonate Aquifers. Birk, Steffin. 2004.

A tracer test in a carbonate aquifer is analyzed using the method of moments and two analytical advection dispersion models (ADMs) as well as a numerical model. The numerical model is a coupled continuum-pipe flow and transport model that accounts for two different flow components in karstified carbonate aquifers, i.e., rapid and often turbulent conduit flow and Darcian flow in the fissured porous rock. All techniques employed provide reasonable fits to the tracer breakthrough curve (TBC) measured at a spring. The resulting parameter estimates are compared to investigate how each conceptual model of flow and transport processes that forms the basis of the analyses affects the interpretation of the tracer test. Numerical modeling results suggest that the method of moments and the analytical ADMs tend to overestimate the conduit volume because part of the water discharged at the spring is wrongly attributed to the conduit system if flow in the fissured porous rock is ignored. In addition, numerical modeling suggests that mixing of the two flow components accounts for part of the dispersion apparent in the measured TBC, while the remaining part can be attributed to Taylor dispersion. These processes, however, cannot reasonably explain the tail of the TBC. Instead, retention in immobile-fluid regions as included in a nonequilibrium ADM provides a possible explanation.

30) Recovering Fresh Water Stored in Saline Limestone Aquifers. Merritt, Michael L. 1985.

Numerical modeling techniques are used to examine the hydrogeologic, design, and management factors governing the recovery efficiency of subsurface fresh-water storage. The modeling approach permitted many combinations of conditions to be studied. A sensitivity analysis was used that consisted of varying certain parameters while keeping constant as many other parameters or processes as possible. The results show that a loss of recovery efficiency resulted from: (1) processes causing mixing of injected fresh water with native saline water (hydrodynamic

dispersion); (2) processes or conditions causing the irreversible displacement of the injected fresh water with respect to the well (buoyancy stratification and background hydraulic gradients); or (3) processes or procedures causing injection and withdrawal flow patterns to be dissimilar (dissimilar injection and withdrawal schedules in multiple-well systems). Other results indicated that recovery efficiency improved considerably during the first several successive cycles, provided that each recovery phase ended when the chloride concentration of withdrawn water exceeded established criteria for potability (usually 250 milligrams per liter). Other findings were that fresh water injected into highly permeable or highly saline aquifers would buoy rapidly with a deleterious effect on recovery efficiency.

(31) Water and Radioactive Tracer Flow in a Heterogeneous Field-Scale System. Dunnivant, Frank M. 1998.

A coupled field-scale aquifer pumping and water infiltration test was conducted at the Idaho National Engineering and Environmental Laboratory in order to evaluate subsurface water and contaminant transport processes in a heterogeneous flow system. The test included an aquifer pumping test to determine the storage properties of the aquifer and the state of confinement of the aquifer (~190 m below land surface), and a vadose zone infiltration test to determine vertical moisture and radioactive tracer migration rates. Pump test results indicated that the Snake River Plain Aquifer was locally unconfined with a transmissivity ranging from 5.57×10^5 to 9.29×10^4 m^2/day. Moisture monitoring with neutron probes indicated that infiltrating water was initially transported vertically through the upper basalt layer of the vadose zone, primarily through fractures and rubble zones, at an average rate of 5 m/day (based on vertical distance traveled and first arrival of water at the monitoring points). Analysis of breakthrough curves for a conservative tracer allowed estimation of the arrival of the peak concentration and yielded an average velocity of 1 m/day. The migration velocities from the neutron probe and tracer tests are in good agreement given the scale of the test and difference in analysis techniques. None of the data sets showed a correlation between migration velocity (arrival time) and distance from the point source, but they strongly indicate preferential flow through discrete fractures. Upon reaching the first continuous sedimentary interbed layer in the basalt formation, water flow was diverted laterally along the interbed surface where it spread outward in primarily three areas corresponding to topographic lows on the interbed surface, and slowly infiltrated into the interbed. The nonpredictable movement of water and tracer through specific fractures underlying the site suggests that a priori prediction of transmissive fractures in this media is not possible. Results do suggest that the continuous sedimentary interbed layers, in general, impede vertical water flow and contaminant migration.

(32) Predictive Modeling Results for the City of St. Petersburg's Deep Injection Well system (and associated technical memorandums). CH2M HILL. 1996.

The City of St. Petersburg is pursuing injection well operating permits for 10 deep injection wells at its four Water Reclamation Facilities (WRFs). Solute transport modeling is being used as a tool to develop a better understanding of historical and projected water quality changes at the City's four injection sites. The City has negotiated consent orders with the Florida Department of Environmental Protection (FDEP) to continue operation of the deep injection wells while outstanding permitting issues are addressed. As part of the consent order process, the City is

developing technical data in support of the injection well operating permits. Technical Memorandum No. STM-3 is the third in a series of technical memoranda related to solute transport modeling conducted in support of the re-permitting process. Technical Memorandum No. STM-1, Development of the Solute Transport Conceptual Model, was submitted to the FDEP Technical Advisory Committee (TAC) in February 1995. Background information and the conceptual approach to the modeling was described in STM-1. Technical Memorandum No. STM-2, Solute Transport Model Calibration for the City of St. Petersburg's Deep Injection Well Systems, was presented to the FDEP TAC in October 1995. In STM-2, the numerical representation of the conceptual model was presented, and simulated and observed water quality and water level trends were compared at each of the four WRFs.

In this Technical Memorandum (STM-3), Predictive Modeling Results for the City of St. Petersburg's Deep Injection Well Systems, the calibrated model simulations presented in STM-2 are extended into the future to evaluate possible changes in water quality in selected hydrogeologic zones. The results of this effort are intended to provide insight to the City and the FDEP TAC to aid in development of an appropriate permitting strategy for each WRF.

(33) A Critical Review of Data on Field-Scale Dispersion in Aquifers. Gelhar, Lynn W. 1992.

A critical review of dispersivity observations from 59 different field sites was developed by compiling extensive tabulations of information on aquifer type, hydraulic properties, flow configuration, type of monitoring network, tracer, method of data interpretation, overall scale of observation and longitudinal, horizontal transverse and vertical transverse dispersivities from original sources. This information was then used to classify the dispersivity data into three reliability classes. Overall, the data indicate a trend of systematic increase of the longitudinal dispersivity with observation scale but the trend is much less clear when the reliability of the data is considered. The longitudinal dispersivities ranged from 10^{-2} to 10^{4}m for scales ranging from 10^{-1} to 10^{5}m, but the largest scale for high reliability data was only 250 m. When the data are classified according to porous versus fractured media there does not appear to be any significant difference between these aquifer types. At a given scale, the longitudinal dispersivity values are found to range over 2-3 orders of magnitude and the higher reliability data tend to fall in the lower portion of this range. It is not appropriate to represent the longitudinal dispersivity data by a single universal line. The variations in dispersivity reflect the influence of differing degrees of aquifer heterogeneity at different sites. The data on transverse dispersivities are more limited but clearly indicate that vertical transverse dispersivities are typically an order of magnitude smaller than horizontal transverse dispersivities. Reanalyses of data from several of the field sites show that improved interpretations most often lead to smaller dispersivities. Overall, it is concluded that longitudinal dispersivities in the lower part of the indicated range are more likely to be realistic for field applications.

(34) ASR-UK: Elucidating the Hydrogeological Issues Associated with Aquifer Storage and Recovery in the UK. Gales, I.N. 2002.

The results of a study, funded by BGS, UKWIR and EA, and undertaken between 1995 and 1998, indicated that there is a large potential for development of Aquifer Storage Recovery (ASR) schemes in the UK at a wide range of scales (Jones et al., 1998). The study stimulated considerable interest and, at that time, three water companies had initiated field trials. Several other schemes were at the desk study stage.

Experience from the United States shows that ASR is frequently a cost-effective solution to a wide variety of water supply, as well as water quality problems. The potential of the technology in Britain needed to be more fully evaluated, in order to optimize the use of our water resources, both fresh and wastewater. However, several uncertainties were highlighted by this study that could constrain the acceptance and utilization of ASR as a component in strategies for sustainable management of water resources.

The project reported here, ASR-UK, addresses some of the issues identified through generic research and the development of guidelines and models to assist in decision-making throughout the investigative, development and implementation stages of schemes. The issues addressed are:

- Research into the controls on dispersion and diffusion of injected water and their impacts on recovery efficiency. Models were developed to predict the extent and movement of "bubbles" of stored water in aquifers as well as changes in water quality with time. Work initially focused on the Chalk aquifer but other aquifers were also investigated.
- The impacts of geochemical interactions between native and injected water as well as water-rock interactions. The adverse as well as the beneficial effects need to be predicted in order to address them in the most cost-effective manner. The project therefore aimed to assess the significance of these reactions on the permeability of aquifers, the quality of recovered water and the efficiency of schemes.
- During the life of the project, the importance of the environmental impacts of ASR schemes, in relation to the operational cycle used, became increasingly apparent. Quantification of these impacts is required throughout all phases of a study, from the initial assessment of the potential of a site, through the staged testing to implementation and commissioning of a scheme.

The project was designed to address these issues through review of current knowledge and the application and development of models, some of which can be used as tools in current and future investigations. It was initially planned that the development of these models would be closely aligned with on-going investigations and field trials, which would provide data to validate the models as well as providing feedback to the investigation. This proved to be the case with the investigations in the Chalk aquifer but little data were available from other aquifers.

(35) Results from a forced Gradient Tracer Test in a Fractured Aquifer with Simultaneous Input of Different Tracers. Bender, A. 2001.

Interpretation of pumping test and tracer test data allowed for the evaluation of capture areas of discharge wells as well as important hydraulic parameters of a multi-layered aquifer system such as longitudinal dispersivity, hydraulic conductivity, effective porosity and leakage flow. Evaluation of the tracer breakthrough curves was realized using a analytical solution of the mass transport equation for radial symmetric flow patterns induced by the forced gradient tracer test. The results of the tracer test yielded important input parameters for subsequent calculations of pollution spreading with a numerical groundwater model to optimize the location and necessary pumping rats of future discharge wells as part of hydraulic remediation measures.

(36) Analysis of a Vertical Dipole Tracer Test in Highly Fractured Rock. Sanford, William E. 2002.

The results of a vertical dipole tracer experiment performed in highly fractured rocks of the Clare Valley, South Australia, are presented. The injection and withdrawal piezometers were both screened over 3 m and were separated by 6 m (midpoint to midpoint). Due to the long screen length, several fracture sets were intersected, some of which do not connect the two piezometers. Dissolved helium and bromide were injected into the dipole flow field for 75 minutes, followed by an additional 510 minutes of flushing. The breakthrough of helium was retarded relative to bromide, as was expected due to the greater aqueous diffusion coefficient of helium. Also, only ~25% of the total mass injected of both tracers was recovered. Modeling of the tracer transport was accomplished using an analytical one-dimensional flow and transport model for flow through a fracture with diffusion into the matrix. The assumptions made include: streamlines connecting the injection and withdrawal point can be modeled as a dipole of equal strength, flow along each streamline is one dimensional, and there is a constant Peclet number for each streamline. In contrast to many other field tracer studies performed in fractured rock, the actual travel length between piezometers was not known. Modeling was accomplished by fitting the characteristics of the tracer breakthrough curves (BTCs), such as arrival times of the peak concentration and the center of mass. The important steps were to determine the fracture aperture (240 um) based on the parameters that influence the rate of matrix diffusion (this controls the arrival time of the peak concentration), estimating the travel distance (11 m) by fitting the time of arrival of the centers of mass of the tracers; and estimating fracture dispersivity (0.5 m) by fitting the times that the inflection points occurred on the front and back limbs of the BTCs. This method works even though there was dilution in the withdrawal well, the amount of which can be estimated by determining the value that the modeled concentrations need to be reduced to fit the data (~50%). The use of two tracers with different diffusion coefficients was not necessary, but it provides important checks in the modeling process because the apparent retardation between the two tracers is evidence of matrix diffusion and the BTCs of both tracers need to be accurately modeled by the best fit parameters.

(37) Field Test for Effective Porosity and Dispersivity in Fractured Dolomite, the WIPP, Southeastern New Mexico. Gonzalez, D.D. 1981.

The Waste Isolation Pilot Plant (WIPP), a demonstration facility 26 mi (41.6 km) east of Carlsbad, New Mexico, used to store transuranic waste in Permiam-bedded salts, has been under field investigation since 1975. Hydrologically, the area is characterized by a typical semiarid environment underlaid by four confined aquifer systems whose transmissivities range from 10 to 10^{-5} ft ^{2}/d (1 to 10^{-6} m^2/d).

Previous local hydrogeologic investigations show a fractured dolomite, whose thickness and depth of burial range from 22 to 24 ft (6.7 to 7.3 m) and 498 to 897 ft (152 to 274 m), respectively, as the most likely groundwater vehicle to transport waste to be biosphere in the event such a repository is breached. To describe adequately and to predict solute transport, certain hydraulic characteristics of the transporting medium need to be estimated along a hypothetical flow path. Effective porosity and dispersivity are two parameters which are most difficult to predict, particularly in fractured rock exhibiting low trransmissivities. This paper describes the results of the first of a series of two-well recirculation tracing tests to be performed. The recirculation tests were performed using an extraction-injection well couplet similar to that described by Grove and Beetem (1971). Tests duration was 270 days and resulted in a well-defined breakthrough curve.

(38) Deuterated Tracers for Assessing Natural Attenuation in Contaminated Groundwater. Davis, G.B. 2000.

Three groundwater tracer tests using deuterium-labelled-benzene, toluene, xylene and naphthalene (BTXN), trichloroethene (TCE) and munitions compounds (e.g. trinitrotoluene-TNT) were carried out in Australia to determine sorption, biodegradation and other transport parameters for contaminant plumes. The BTXN and TCE tests were natural gradient tests in an anaerobic sand aquifer, and the third munitions tracer test was a forced gradient test in a fractured basalt aquifer. Sorption coefficients, biodegradation rates and dispersion coefficients were estimated from multi-depth and location monitoring and modelling. The use of deuterium-labelled tracers is shown to be viable and attractive, although difficulties with in-field operations and environmental policy may limit application of such a technique.

(39) Analysis of Solute Transport in a Heterogeneous Aquifer: The Krauthausen Field Experiment. Vereecken, H. 2002.

A field-scale natural gradient tracer experiment with bromide, uranin and lithium was conducted in a heterogeneous aquifer at Krauthausen, Germany. The temporal and spatial evolution of the solute plumes was monitored over 398 days for bromide and 449 days for uranin and lithium. The spatial variability of basic aquifer parameters, hydraulic conductivity, and sorption parameters of the aquifer material was investigated in detail. Local Darcian velocities were measured using NH_4BR^{82} as a radioactive tracer in 33 observation wells. Vertical and horizontal correlation lengths of hydraulic properties were determined using variogram analysis. The magnitude of the local Darcian velocities was found to be lognormally distributed. In addition, the groundwater flow direction

showed a clear trend in the vertical direction. The horizontal correlation length of the magnitude of Darcian velocity agreed with the correlation length of *K* estimated from grain size data. Batch experiments on aquifer sediments showed that sorption of uranin and lithium could be described by a Freundlich isotherm. The Freundlich *n* parameter of uranin sorption showed little variation with depth. The time evolution of the bromide plume was quantified in terms of spatial moments. The longitudinal effective dispersivity estimated from spatial moment analysis was within the range of calculated effective dispersivities, taking into account the uncertainty of estimates of the ln *K* statistics.

A Critical Review of Data on Field-Scale Dispersion in Aquifers

LYNN W. GELHAR

Department of Civil Engineering, Massachusetts Institute of Technology, Cambridge

CLAIRE WELTY

Department of Civil and Architectural Engineering, Drexel University, Philadelphia, Pennsylvania

KENNETH R. REHFELDT

Illinois State Water Survey, Champaign

A critical review of dispersivity observations from 59 different field sites was developed by compiling extensive tabulations of information on aquifer type, hydraulic properties, flow configuration, type of monitoring network, tracer, method of data interpretation, overall scale of observation and longitudinal, horizontal transverse and vertical transverse dispersivities from original sources. This information was then used to classify the dispersivity data into three reliability classes. Overall, the data indicate a trend of systematic increase of the longitudinal dispersivity with observation scale but the trend is much less clear when the reliability of the data is considered. The longitudinal dispersivities ranged from 10^{-2} to 10^{4} m for scales ranging from 10^{-1} to 10^{5} m, but the largest scale for high reliability data was only 250 m. When the data are classified according to porous versus fractured media there does not appear to be any significant difference between these aquifer types. At a given scale, the longitudinal dispersivity values are found to range over 2–3 orders of magnitude and the higher reliability data tend to fall in the lower portion of this range. It is not appropriate to represent the longitudinal dispersivity data by a single universal line. The variations in dispersivity reflect the influence of differing degrees of aquifer heterogeneity at different sites. The data on transverse dispersivities are more limited but clearly indicate that vertical transverse dispersivities are typically an order of magnitude smaller than horizontal transverse dispersivities. Reanalyses of data from several of the field sites show that improved interpretations most often lead to smaller dispersivities. Overall, it is concluded that longitudinal dispersivities in the lower part of the indicated range are more likely to be realistic for field applications.

INTRODUCTION

The phenomenon of dispersive mixing of solutes in aquifers has been the subject of considerable research interest over the past 10 years. Characterizing the dispersivity at a particular field site is essential to any effort in predicting the subsurface movement and spreading of a contaminant plume at that location. Both theoretical and experimental investigations have found that field-scale dispersivities are several orders of magnitude greater than lab-scale values for the same material; it is generally agreed that this difference is a reflection of the influence of natural heterogeneities which produce irregular flow patterns at the field scale. Consequently, laboratory measurements of dispersivity cannot be used to predict field values of dispersivity. Instead field-scale tracer tests are sometimes conducted to estimate dispersivity at a particular site.

Early efforts to document the scale dependence of dispersivity [*Lallemand-Barres and Peaudecerf*, 1978; *Anderson*, 1979; *Pickens and Grisak*, 1981; *Beims*, 1983; *Neretnieks*, 1985] were based on field values of dispersivity reported in the literature and the test scales associated with those values. These studies were useful in that they indeed documented field evidence of the scale effect, but they were lacking in that they did not assess the reliability of the data presented. Because we felt that the data would be more meaningful if their variable quality was recognized, we assembled the dispersivity data along with related information from the original sources and evaluated the reliability or quality of these data [*Gelhar et al.*, 1985]. The graphical results of that work have been widely used by both practitioners and theoreticians, often without appropriate consideration of the reliability of the data. For example, recent theoretical developments based on fractal concepts [*Philip*, 1986; *Wheatcraft and Tyler*, 1988; *Neuman*, 1990] have relied on information similar to that in the work by *Gelhar et al.* [1985] but those studies disregarded the issue of the reliability of the data. We feel that it is important to update the dispersivity information including results from recent comprehensive field experiments and at the same time focus on the interpretations of the reliability of the data. With these goals in mind, this work develops the following: (1) an outline of the theoretical description of dispersive mixing in porous media; (2) a tabular summary of existing data on values of field-scale dispersivity and related site information reported in the literature; (3) an evaluation of the reliability or quality of these values based on clearly delineated criteria; and (4) discussion and interpretation of the applied and theoretical implications of the data.

THEORETICAL CONCEPTS OF FIELD-SCALE DISPERSIVE MIXING

The mass balance equation governing the transport of an ideal chemically nonreactive conservative solute by a homo-

geneous fluid (constant density and viscosity) that flows through a rigid saturated porous medium is commonly expressed as [e.g., *Bear*, 1972; *de Marsily*, 1986]

$$\frac{\partial c}{\partial t} + v_i \frac{\partial c}{\partial x_i} = \frac{\partial}{\partial x_i}\left(D_{ij} \frac{\partial c}{\partial x_j}\right) \qquad i, j = 1, 2, 3 \qquad (1)$$

where c is the solute concentration, v_i is the seepage velocity component in the x_i direction, and D_{ij} are the components of the dispersion coefficient tensor. The right-hand side of (1) represents the net dispersive transport which is presumed to be Fickian, i.e., the dispersive mass flux is proportional to the concentration gradient. Some investigators [e.g., *Robertson and Barraclough*, 1973; *Bredehoeft and Pinder*, 1973] alternatively define the dispersion coefficient tensor including the porosity n as $D^*_{ij} = nD_{ij}$. When it was clear that D^*_{ij} was used in a study, we converted to the more common form used in (1). The mean flow direction is taken to be x_1, with $v_1 = v$, $v_2 = v_3 = 0$. Assuming that x_1, x_2, and x_3 are principal directions, the dispersivity is simply the ratio of the appropriate component of the dispersive coefficient tensor divided by the magnitude of the seepage velocity, v. To distinguish the field-scale dispersivities from laboratory values, the field-scale values are designated by the uppercase letter A [see *Gelhar and Axness*, 1983] and, to allow for anisotropy of transverse dispersion, a third dispersivity coefficient is used as follows:

$$D_{11} = A_L v \qquad D_{22} = A_T v \qquad D_{33} = A_V v \qquad (2)$$

where A_L is the longitudinal macrodispersivity (field scale), and A_T is the horizontal transverse macrodispersivity, and A_V is the vertical transverse macrodispersivity.

The classical equation (1) with macrodispersivities (2) is standardly used for applied modeling of field-scale solute transport. The macrodispersivities are considered to be a property of some region of the aquifer. Although the macrodispersivity may be a function of space, in most applications it is assumed constant over a region of the aquifer that encompasses the entire plume both horizontally and vertically. Real solute plumes are observed to be three-dimensional [*LeBlanc*, 1982; *Perlmutter and Lieber*, 1970; *MacFarlane et al.*, 1983] and often of limited vertical extent. Although the classical equation is three-dimensional, the two-dimensional form is most commonly applied. Reasons for the use of the two-dimensional form of the equation include lack of three-dimensional data and in the case of numerical models, restrictions on the size of data arrays in the model. Seldom is the two-dimensional form justified on the basis of site conditions or plume observations.

A number of theoretical studies have proposed methods of describing field-scale dispersive mixing. All of the theories view field-scale dispersion as being produced by some kind of small-scale heterogeneity or variability of the aquifer. At present there is considerable debate concerning how to parameterize the variability and model field-scale solute transport. Assuming a perfectly layered aquifer, one group [*Molz et al.*, 1983, 1986] suggests measuring the variability in detail and modeling the transport in each layer with local-scale dispersivities, thus eliminating the need for a field-scale dispersivity. Again assuming a layered aquifer, a second group suggests the use of a scale-dependent or time-dependent field-scale dispersivity [e.g., *Pickens and Grisak*, 1981; *Dieulin*, 1980]. A third group [e.g., *Gelhar and Axness*, 1983; *Dagan*, 1982; *Neuman et al.*, 1987] has examined more general three-dimensional heterogeneity with stochastic methods and concluded the classical equation with constant field-scale dispersivities is applicable to describe transport over large distances. These stochastic approaches incorporate the effects of practically unknowable small-scale variations in flow by means of macrodispersivities which are used in a deterministic transport model describing the large-scale variations in flow by means of the convection terms. Nonetheless, under what circumstances a field-scale dispersivity can be used to describe field-scale solute transport is still an open question. Until the issue is resolved, the field-scale dispersivity concept can be regarded as a working hypothesis which has a sound theoretical basis and finds wide application.

FIELD DATA ON DISPERSIVITY

Summary of Observations

A literature review was conducted to collect reported values of dispersivity from published analyses of field-scale tracer tests and contaminant transport modeling efforts. The literature sources and pertinent data characterizing each reviewed study are summarized in Table 1 which includes information on 59 different field sites. The information compiled from each study includes site location, description of aquifer material, average aquifer saturated thickness, hydraulic conductivity or transmissivity, effective porosity, mean pore velocity, flow configuration, dimensionality of monitoring network, tracer type and input conditions, length scale of the test or problem, reported values of longitudinal and horizontal and vertical transverse dispersivities, and classification of the reliability of the reported data. Blank entries indicate that the information was not provided in the cited documents. This table summarizes information for purposes of comparison only. More detail regarding a particular study may be found in the original sources.

Aquifer characteristics. As indicated by the second through sixth columns from the left, the study sites represent a wide variety of aquifer conditions and settings. Summarized in these columns is information on aquifer material, saturated thickness, hydraulic conductivity or transmissivity, and velocity. The aquifer thickness for each site is the arithmetic average of the range at that site. Hydraulic conductivity and transmissivity values show the range reported at the site. Reported values for effective porosity vary from 0.5% (for fractured media) to 60% (for porous media). When a value was reported as "porosity," we interpreted this as the effective porosity (interconnected pore space), the value used in analysis of the advection-dispersion equation. Where porosity was reported as "total porosity," we have indicated this in the table. The velocity column indicates the mean pore or seepage velocity at a site. In some cases the values were calculated from information provided on average specific discharge, q, and effective porosity, n, as $v = q/n$. Velocities ranged from 0.0003 to 200 m/d.

Methods of determining dispersivity. The seventh through tenth columns from the left summarize the method used to determine the dispersivity for each site. The seventh, eighth, and ninth columns from the left describe experimental conditions: flow configuration, monitoring, tracer and

input; the tenth column from the left summarizes methods of data interpretation. Dispersivity values were calculated or inferred from one of two types of subsurface solute transport events: large-scale, uncontrolled contamination (naturally occurring or human-induced) events, or controlled tracer tests.

Uncontrolled events are characterized by a source input history that is unknown, transport of contaminants by the ambient flow of groundwater, and solute plumes that often extend over regional scales (hundreds of meters). We describe naturally occurring events as "environmental" tracers, implying chemical constituents associated with uncontrolled natural changes occurring in groundwater before the start of a study. Examples of naturally occurring events include tritium in groundwater from recharge containing atmospheric bomb tritium, seawater intrusion, and mineral dissolution. These events are indicated in the "tracer and input" column by the notation "environmental" along with the type of chemical species reported. Examples of human-induced contamination events include leaks and spills to groundwater from landfills, storage tanks, surface impoundments, and infiltration basins. These types of events are indicated by the notation "contamination" in the tracer and input column. Values of dispersivity for uncontrolled events are commonly determined by fitting a one-, two-, or three-dimensional solute transport model to historical data; i.e., values of dispersivity are altered until model output matches historical solute concentration measurements.

The main features distinguishing controlled tracer tests from uncontrolled ones is that in the former, both the quantity and duration of solute input are known. This is indicated by "step" (continuous input of mass) or "pulse" ("instantaneous" or slug input) in the "tracer and input" column. Controlled tracer tests may be conducted under ambient groundwater flow conditions (also referred to as natural gradient tests), or under conditions where the flow configuration is induced by pumping or recharge. The type of test is reported in the "flow configuration" column. Induced flow configurations include radial, two-well, and forced uniform flow. In radial flow tracer tests, a pulse or step input of tracer is injected at a recharge well and the time distribution of tracer is recorded at an observation well (diverging radial flow test), or the tracer is injected at an observation well and the time distribution is recorded at a distant pumping well (converging radial flow test). In a two-well test, both a recharge well and pumping well are operating; tracer is injected at the recharge well and tracer breakthrough is observed at the pumping well. Recirculation of the water (containing tracer) from the pumping well to the recharge well is often employed. "Forced uniform flow" refers to the flow regime at the Bonnaud site in France, where a uniform flow field was generated between two lines of equally spaced wells, one line recharging and one line pumping, with both screened to the full depth of the aquifer. A discussion of the advantages and disadvantages of different types of tracer tests is presented by *Welty and Gelhar* [1989].

A number of methods have been used to evaluate the data from controlled tracer tests, as indicated by column headed "method of data interpretation." These include fitting of one-, or two- or three-dimensional solute transport analytical solutions, and the method of spatial moments. It should be noted that since the velocity is nonuniform for both radial and two-well tracer tests, analysis of the data must account for this effect to determine dispersivity properly for such cases. Nonuniform velocity effects have also been observed in ambient flow tracer tests.

The types of tracers used to determine dispersivity at each site are summarized in the "tracer and input" column along with the input conditions. A variety of chemical and microbiological tracers have been employed for controlled tracer tests. Discussions of the suitability of different chemical and microbial species for tracer tests are presented by *Davis et al.* [1980, 1985] and *Betson et al.* [1985]. A primary consideration in designing a controlled tracer test is whether the species is conservative or nonconservative. A conservative tracer is one that moves with the same velocity as the groundwater and does not undergo radioactive decay, adsorption, degradation, chemical reaction (or in the case of microorganisms, death). If any of these effects are present, they must be accounted for in evaluation of the dispersivity. Another factor important in the choice of a tracer is that it is not present in naturally occurring groundwater, or that it is injected at concentrations much higher than natural background levels.

The "monitoring" column indicates whether two- or three-dimensional monitoring was employed at a site. By two-dimensional monitoring we mean depth-averaged (vertically mixed). Three-dimensional monitoring implies point samples with depth. This information is noted because vertical mixing in an observation well influences the concentration of tracer in a water sample. Several studies [*Meyer et al.*, 1981; *Pickens and Grisak*, 1981] have shown that when a tracer is not injected over the full aquifer depth, vertically mixed samples underestimate the tracer concentration and as a result the longitudinal dispersivity is overestimated. This occurs because the tracer occupies only a portion of the vertical thickness. When a sample from the entire thickness is taken, the true tracer concentration is diluted in the well with tracer-free water. If an attempt is made to interpret the diluted ("measured") concentration, the dispersivity will be overestimated. At many sites there was no indication whether point or fully mixed sampling was performed. From examination of the cases where three-dimensional measurements of solute concentrations were made, it is clear that vertical mixing of the tracer as it travels through the aquifer is often very small [*Sudicky et al.*, 1983; *LeBlanc*, 1982; *Freyberg*, 1986; *Garabedian et al.*, 1988, 1991].

Field dispersivities and scale. The "scale of test" column represents the distance traveled from the source for ambient conditions, or the distance between injection and observation wells for the case of an induced flow configuration. The values of dispersivity reported at the indicated scale are given in the second column from the right. Data from the 59 sites yielded 106 values of longitudinal dispersivity, since often multiple investigations or multiple experiments by one investigator were performed at one site. A plot of the longitudinal dispersivity values as a function of scale is presented in Figure 1. The arithmetic average was plotted in cases where a range was reported either for the scale or dispersivity in Table 1. In some cases, values of dispersivity for individual layers were reported as well as an average "aquifer" value. In these cases the latter value was plotted for the given scale. The symbols on Figure 1 indicate whether the dispersivity value is for fractured media (open symbols, 18 values) or porous media (solid symbols, 88

TABLE 1. Summary of

Reference and Site Name	Aquifer Material	Average Aquifer Thickness, m	Hydraulic Conductivity (m/s) or Transmissivity (m^2/s)	Effective Porosity, %	Velocity, m/d	Flow Configuration
Adams and Gelhar [1991],§ Columbus, Mississippi	very heterogeneous sand and gravel	8	10^{-5} to 10^{-3} m/s	35	0.03–0.5	ambient
Ahlstrom et al. [1977], Hanford, Washington	glaciofluviatile sands and gravels	64	5.7×10^{-4} to 3.0 $\times 10^{-2}$ m/s			ambient
Bentley and Walter [1983], WIPP	fractured dolomite	5.5		18	0.3	two-well recirculating

*TDS denotes total dissolved solids; EC, electrical conductivity; PFB, pentafluorobenzoate; MTFMB, metatrifluoromethylbenzoate; MFB, metafluorobenzoate; Para-FB, parafluorobenzoate; RhWT, rhodamine-WT dye; and SCN, thiocyanate.

†A_L denotes longitudinal dispersivity; A_T, horizontal transverse dispersivity; and A_V, vertical transverse dispersivity. Reported values for A_L, A_T, and A_V are separated by slashes. Absence of slashes means that values were reported for A_L only. A comma or a dash separating entries means that multiple values or a range of values, respectively, were reported for a particular dispersivity component.

‡For description of classification criteria, see text.

‖Porosity-corrected dispersivity value.

values). The type of event evaluated is indicated by a circle (tracer test, 83 values), triangle (contamination event, 15 values), or square (environmental tracer, eight values). The total numbers of values of dispersivity for each type of medium and test are shown in Table 2. Any reported values of horizontal transverse dispersivity or vertical transverse dispersivity are also listed in the dispersivity column of Table 1. For the cases examined, 24 values of horizontal transverse dispersivity and nine values of vertical transverse dispersivity were reported. In nearly all cases, the horizontal values were found to be 1–2 orders of magnitude less than the longitudinal values, and the vertical values smaller by another order of magnitude.

Evaluation of Dispersivity Data

From Figure 1, it appears that longitudinal dispersivity increases with scale. Field observations of dispersivity ranged from 0.01 m to approximately 5500 m at scales of 0.75 m to 100 km. The longitudinal dispersivity for the two types of aquifer material (porous versus fractured media) tends to scatter over a similar range, although at a smaller scale fractured media seem to show higher values. At each scale there is at least a two-order-of-magnitude range in dispersivity. Because we noted a number of problems with data and their interpretation as we gathered them for Table 1, we would regard any conclusions about Figure 1 with skepticism until further qualifying statements can be made about the data points. Typical problems that we found with the studies reported in Table 1 include the following: data analysis not matched to flow configuration; mass input history unknown; nonconservative effects of tracer not accounted for; dimensionality of the monitoring not matched to the dimensionality of the analysis; and assumption of distinct geologic layers in analysis when their actual presence was not documented. Based on these problems, we decided to rate the data as high (I), medium (II), or low (III) reliability according to the criteria set forth below. Table 3 lists the criteria used to designate either high- or low-reliability data. No specific criteria were defined for the intermediate classification; it encompasses the dispersivity

values that do not fall into the high or low groups. These classifications do not place strict numerical confidence limits on reported dispersivities, but rather are intended to provide an order-of-magnitude estimate of the confidence we place on a given value. In general, we consider high-reliability dispersivity values to be accurate within a factor of 2. Low-reliability values are considered to be no more accurate than within 1 or 2 orders of magnitude. Intermediate reliability falls somewhere between the extremes. We wish to make a distinction between the judgment of the reliability of the reported dispersivity and the worth of a study. Often, the purpose of a study was for something other than the determination of dispersivity. Our classification of dispersivity is not intended as a judgment on the quality of a study as a whole, but rather to provide us with some criteria with which to screen the large number of data values obtained. By then examining the more reliable data, conclusions which evolve from the data will be more soundly based and alternative interpretations may become apparent.

High-reliability dispersivity data. For a reported dispersivity value to be classified as high reliability, each of the following criteria must have been met.

1. The tracer test was either ambient flow with known input, diverging radial flow, or a two-well pulse test (without recirculation). These three test configurations produce breakthrough curves which are sensitive to the dispersion coefficient and appear to work well in field applications [*Welty and Gelhar*, 1989]. The radial converging flow test is generally considered less satisfactory than the diverging test because breakthrough curves at the pumping well for the converging test frequently exhibit tailing, which complicates the interpretation of these tests. Some researchers attribute this behavior to two or more discrete geologic layers and try to reproduce the observed breakthrough curve by superposition of breakthrough curves in each layer, where the properties of each layer may differ [e.g., *Ivanovitch and Smith*, 1978; *Sauty*, 1977]. The problem with this interpretation is that there are typically numerous heterogeneities on a small scale that cannot be attributed solely to identifiable layers. One possible explanation of the tailing in radial convergent tests is sometimes termed "borehole flushing," where the tail of the breakthrough curve is attributed to the slow flushing of the input slug of tracer out of the injection borehole by the ambient groundwater flow. *Goblet* [1982] measured the slow flushing of tracer out of the

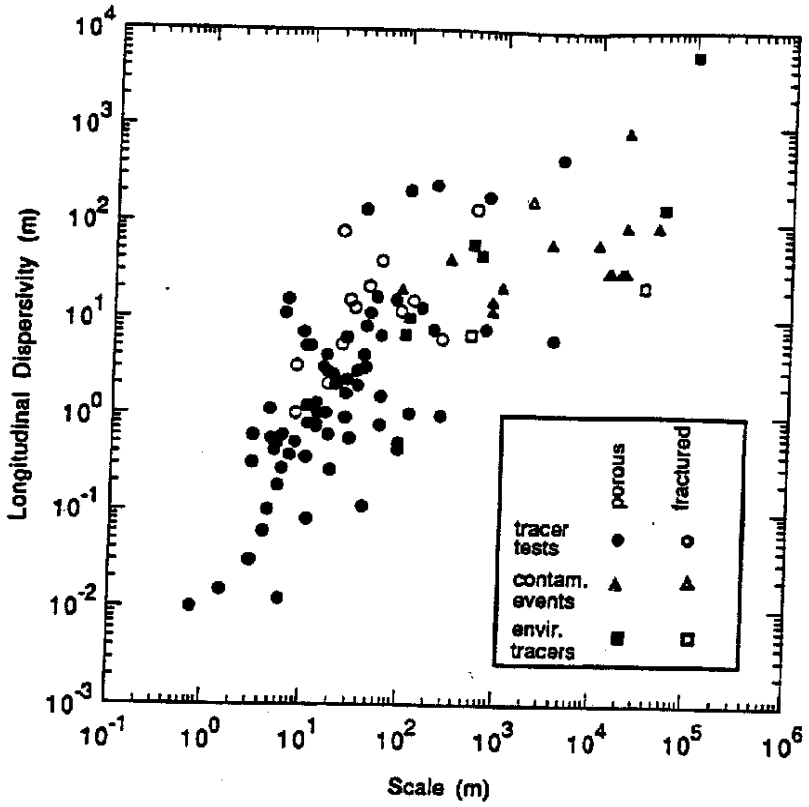

Fig. 1. Longitudinal dispersivity versus scale of observation identified by type of observation and type of aquifer. The data are from 59 field sites characterized by widely differing geologic materials.

borehole and modeled the effect as an exponentially decreasing input. His solution reproduced the tailing observed at the pumping well. In cases where borehole flushing was observed and accounted for, dispersivities obtained from a radial convergent flow test were not excluded from the high-reliability category.

2. The tracer input must be well defined. Both the input concentration and the temporal distribution of the input concentrations must be known (measured). If not, the input is another unknown in the solution of the advection-dispersion equation, and we are less confident in the resulting value of dispersivity.

3. The tracer must be conservative. A reactive or nonconservative tracer complicates the governing equations and resulted in additional parameters that must be estimated. Consequently, we are less confident in the resulting dispersivity. Tracers such as Cl^-, I^-, Br^-, and tritium were considered to be conservative.

4. The dimensionality of the tracer concentration measurements was appropriate. A tracer introduced into an aquifer will spread in three spatial dimensions. High-reliability dispersivities were judged to be those where three-dimensional monitoring was used in all cases except where the aquifer tracer had been injected and measured over the full depth of the aquifer; in this case two-dimensional monitoring was acceptable. In all other cases, where the dimension of the measurement was either not reported or where two-dimensional measurements were used where three-dimensional measurements should have been used, the dispersivity values were judged to be of lower reliability.

5. The analysis of the concentration data was appropriate. Since the interpretation of the tracer data is necessarily linked to the type of tracer test to which the interpretation method is applied, these two features of the field studies were evaluated together. The three general categories of data interpretation can be grouped as follows: (1) breakthrough curve analysis, usually applied to uniform ambient flow tests and radial flow tests [e.g., *Sauty*, 1980]; (2) method of spatial moments, applied to uniform ambient flow tests [*Freyberg*, 1986]; and (3) numerical methods, applied to contamination events [e.g., *Pinder*, 1973; *Konikow and Bredehoeft*, 1974].

A common difficulty with the interpretation of concentration data using breakthrough curve matching to determine dispersivity is the assumption that the dispersivity is constant. The field data assembled in this review suggest that this assumption is not valid, at least for small-scale tests (tens of meters). At larger scales (hundreds of meters) an asymptotic constant value of dispersivity is predicted by some theories. However, at most sites the displacement distance after which the dispersivity is constant is not

TABLE 2. Numbers of Dispersivities for Different Types of Tests and Media

	Tracer Type			
Media Type	Artificial	Contamination	Environmental	Total

Fractured	15	1	2	18
Total	83	15	8	106

TABLE 3. Criteria Used to Classify the Reliability of the Reported Dispersivity Values

Classification	Criteria
High reliability	Tracer test was either ambient flow, radial diverging flow, or two-well instantaneous pulse test (without recirculation). Tracer input was well defined. Tracer was conservative. Spatial dimensionality of the tracer concentration measurements was appropriate. Analysis of the tracer concentration data was appropriate.
Low reliability	Two-well recirculating test with step input was used. Single-well injection-withdrawal test with tracer monitoring at the single well was used. Tracer input was not clearly defined. Tracer breakthrough curve was assumed to be the superposition of breakthrough curves in separate layers. Measurement of tracer concentration in space was inadequate. Equation used to obtain dispersivity was not appropriate for the data collected.

known. Data for which no a priori assumptions were made regarding the dispersivity were considered to be highly reliable.

A second major problem with many of the analyses reviewed was that a one- or two-dimensional solution to the advection-dispersion equation was used when the spreading of the plume under consideration was three-dimensional in nature. High-reliability dispersivities were those for which the dimensionality of the solute plume, the solute measurements, and the data analyses were consistent.

Low-reliability dispersivity data. A reported dispersivity was classified as being of low reliability if one of the following criteria was met.

1. The two-well recirculating test with a step input was used. The problem with this configuration is that, except for very early time where concentrations are low, the breakthrough curve is not strongly influenced by dispersion, but rather is determined by the different travel times along the flow paths established by injection and pumping wells [*Welty and Gelhar*, 1989]. As a result, the two-well test with a step input is generally insensitive to dispersion. For this reason all tests of this type were considered to produce data of low reliability.

2. The single-well injection-withdrawal test was used with tracer monitoring at the pumping well. A difficulty encountered in the small-scale, single-well, injection-withdrawal test (where water is pumped into and out of one well) is that if observations are made at the production well, the dispersion process observed is different from one of unidirectional flow. The problem stems from the fact that macrodispersion near the injection well is due to velocity differences associated with layered heterogeneity of the hydraulic conductivity. In the single-well test with observations made at the production well, the effect observed is that of reversing the velocity of the water. If the tracer travels at different velocities in layers as it radiates outward, it will also travel with the same velocity pattern as it is drawn back to the production well. As a result, the mixing process is partially reversible and the dispersivity would be underestimated relative to the value for unidirectional flow. *Heller* [1972] has carried out experiments which demonstrate the reversibility effect on a laboratory scale.

3. The tracer input was not clearly defined. When a contamination event or environmental tracer is modeled, the tracer input (both quantity and temporal distribution) is not well defined and becomes another unknown in solving the advection-dispersion equation.

4. The tracer breakthrough curve was assumed to be the superposition of breakthrough curves in separate layers when there was little or no evidence of such layers at the field site. These studies generally assume that the porous medium is perfectly stratified, which, especially at the field scale, may not be a valid assumption. At a small scale (a few meters) where the existence of continuous layers may be a reasonable assumption, the dispersivity of each layer does not represent the field-scale parameter. The field-scale dispersivity is a result of the spreading due to the different velocities in each layer.

5. The measurement of tracer concentration in space was inadequate. Under ambient flow conditions the tracer is usually distributed in three-dimensional space, but if the measurements are two-dimensional then the actual tracer cloud cannot be analyzed lacking the appropriate data. If the tracer is introduced over the entire saturated thickness, then two-dimensional measurements would be adequate.

6. The equation used to obtain dispersivity was not appropriate for the data collected. Various assumptions regarding flow and solute characteristics are made in obtaining a solution to the advection-dispersion equation. To apply a particular solution to the data from a field experiment, the assumptions in that solution must be consistent with the experimental conditions. One common example is the case of applying a one-dimensional (uniform velocity) flow solution to a radial flow test in which the converging (or diverging) flow field around the pumping or injection well is clearly nonuniform.

Results of classification. From the classification process, 14 dispersivity values were judged to be of high reliability. The sites where these values were determined include Borden, Ontario, Canada; Otis Air Force Base, Cape Cod, Massachusetts; Hanford, Washington; Mobile, Alabama; University of California, Berkeley; Yavne region, Israel; Bonnaud, France (six tests); and Palo Alto bay lands. There were 61 values judged to be of low reliability for one or more of the reasons discussed above; 31 sites provided data judged to be of intermediate value. Figure 2 depicts the longitudinal dispersivity data replotted with symbols reflecting the reliability classification; the largest symbols indicate data judged to be of highest reliability.

The general compilation of all dispersivity data in Figure 1 indicates that dispersivity might increase indefinitely with scale, but after critically evaluating the data in terms of reliability as shown in Figure 2, it is evident that this trend cannot be extrapolated with confidence to all scales. The largest high-reliability dispersivity value is 4 m (Mobile, Alabama) and the largest scale of high-reliability values is 250 m (Cape Cod, Massachusetts). It is not clear from these data whether dispersivity increases indefinitely with scale or whether the relationship becomes constant for very large scales, as would be predicted by some theories. This points

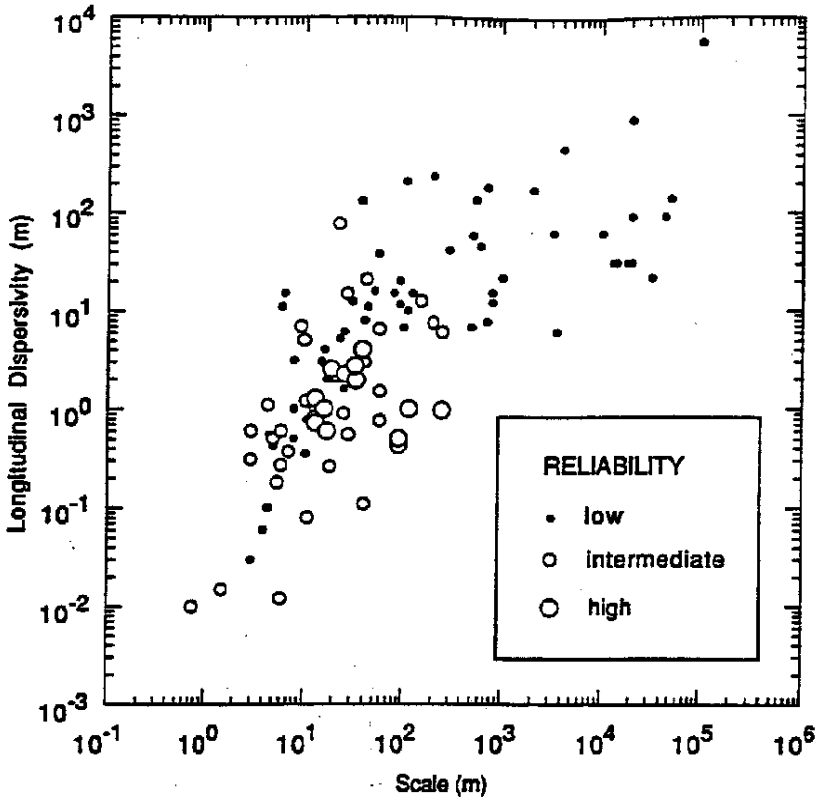

Fig. 2. Longitudinal dispersivity versus scale with data classified by reliability.

to a need for reliable data at scales larger than 250 m. Whether conducting controlled tracer tests at these very large scales is feasible is open to question.

When the reliability of the data is considered, the apparent difference between fractured and porous media at small scales (Figure 1) is regarded to be less significant because none of the fractured media data are of high reliability.

Reanalyses of Selected Dispersivity Data

In cases where the concentration data collected were of high reliability but the method of analysis could be improved, we reevaluated the data to determine a dispersivity value which we judged to be of higher reliability. The details of these analyses are reported by *Welty and Gelhar* [1989]. The results are summarized here.

Corbas, France. The data from this converging radial flow tracer test are reported by *Sauty* [1977]. These data are of particular interest because tests were conducted at three different scales in the same aquifer material; tracer was injected at 25, 50, and 150 m from a pumping well. *Sauty* [1977] evaluated these data using uniform flow solutions to the one-dimensional advection-dispersion equation. At the two smaller-scale tests, he assumed a two-layer scheme, although this assumption was not supported by geologic evidence. For this reason the data at the smaller scales were rated to be of lower reliability than the data at 150 m. We reevaluated these data using a solution that accounts for nonuniform, convergent radial flow effects and that makes no assumptions about geologic layers [*Welty and Gelhar*, 1989]. The values of dispersivity reported by Sauty at 25 m are 11 m and 1.25 m for the two hypothesized layers; we calculated a value of 2.4 m without the assumption of layers. At 50 m, Sauty calculated dispersivity values of 25 m and 6.25 m for the two layers; we calculate an overall value of 4.6 m. At a scale of 150 m, Sauty calculated a dispersivity value of 12.5 m without the assumption of layers; our calculation of 10.5 m is in close agreement. Our calculations indicate that dispersivity increases with scale, accounting for nonuniform flow effects and without the arbitrary assumption of geologic layers.

Savannah River Plant, Georgia. *Webster et al.* [1970] evaluated data from a two-well recirculating test using the methodology of *Grove and Beetem* [1971]. This analysis assumes uniform flow along stream tubes and sums individual breakthrough curves along the stream tubes to obtain a composite breakthrough curve. A dispersivity value of 134 m at a scale of 538 m was obtained using this method. We reevaluated the data using the methodology of *Gelhar* [1982] which accounts for nonuniform flow effects. We obtained a dispersivity value of 47 m from our analysis. We have more confidence in this value because the analysis more accurately represents the actual flow configuration.

Tucson, Arizona. The data reported by *Wilson* [1971] for a two-well test were also evaluated by *Robson* [1974] using a Grove and Beetem–type analysis. Wilson reported a value of longitudinal dispersivity of 15.2 m at a scale of 79.2 m. Using a nonuniform flow solution based on that of *Gelhar* [1982], we calculated a value of longitudinal dispersivity of 1.2 m, an order of magnitude smaller than that of Robson. Again, we have more confidence in this value because the analysis more accurately reflects the actual flow situation.

Columbus, Mississippi. The natural gradient tracer test at the Columbus site (E. E. Adams and L. W. Gelhar, Field

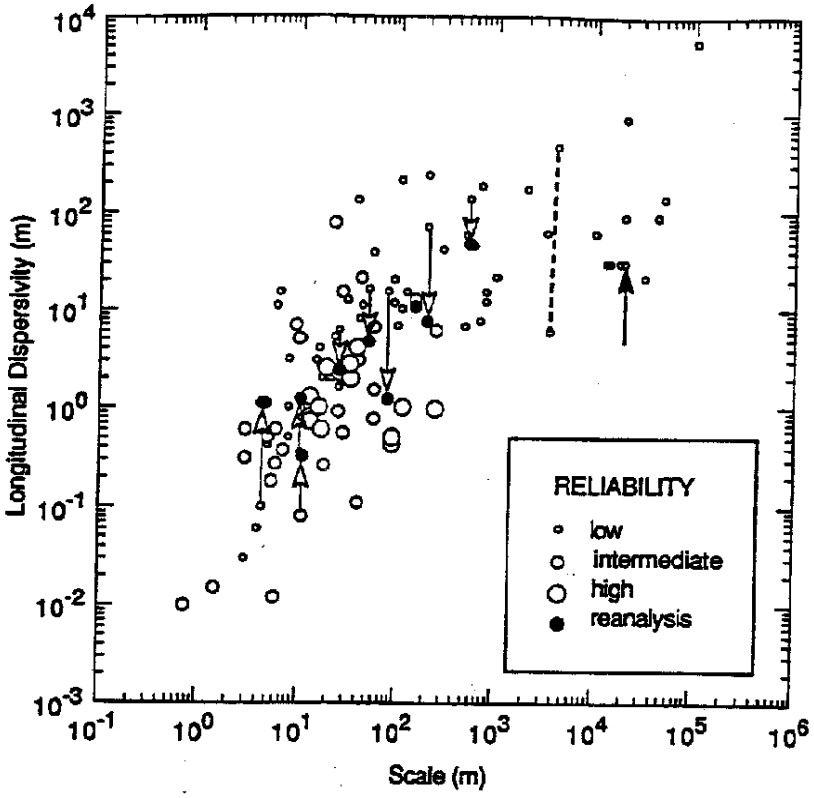

Fig. 3. Longitudinal dispersivity versus scale of observation with adjustments resulting from reanalyses. Arrows indicate reported values at tails and corresponding values from reanalyses at heads. Dashed line connects two dispersivity values determined at the Hanford site.

study of dispersion in a heterogeneous aquifer: Spatial moments analysis, submitted to *Water Resources Research*, 1991; hereinafter Adams and Gelhar, submitted manuscript, 1991) is unique in that the large-scale ambient flow field exhibits strong nonuniformity and the aquifer is very heterogeneous. A superficial spatial moments interpretation, ignoring the flow nonuniformity, indicated a longitudinal dispersivity of around 70 m, whereas a more refined analysis that explicitly includes the influence of flow nonuniformity yields a dispersivity of around 7 m (Adams and Gelhar, submitted manuscript, 1991). This refined estimate is regarded to be of intermediate reliability because of the uncertainty regarding the mass balance at the Columbus site.

From the above reanalyses, all values of dispersivity calculated were smaller than the original values. We have higher confidence in these values because they are associated with solutions to the advection-dispersion equation with more realistic assumptions. In all cases we would rate the new values to be of intermediate reliability instead of low reliability. The reevaluated data are shown as solid symbols on Figure 3 connected to their original values by vertical arrows.

Based on the above reanalyses, we suspect that it is most likely that improved analyses would reduce many of the lower-reliability dispersivities in Figure 2. However, there are a few cases for which more appropriate observations and/or interpretations would most likely lead to larger dispersivities. For example, the Twin Lake natural gradient tracer test [*Moltyaner and Killey*, 1988*a*, *b*] was interpreted by using breakthrough curves at individual boreholes constructed as the average of breakthrough curves in three somewhat arbitrarily defined layers. We suspect that this kind of localized observation will produce a significantly lower dispersivity than would result from a spatial moments analysis which considers the overall spreading of the plume. The magnitude of the possible increase in the dispersivity cannot be assessed because the sampling network did not completely encompass the plume at the Twin Lake site.

Another example is that of the first Borden site natural gradient experiment [*Sudicky et al.*, 1983] which was analyzed using an analytical solution with spatially constant dispersivities. In the near-source region where dispersivities are actually increasing with displacement, this approach will tend to underestimate the magnitude of the dispersivity. *Gelhar et al.* [1985] reanalyzed the first Borden experiment using the method of spatial moments and found that the longitudinal dispersivity at 11 m was 2–4 times that found by *Sudicky et al.* [1983]. The resulting increase in the dispersivity is illustrated in Figure 3 connected to the original point by a vertical line. Because of the incomplete plume sampling and plume bifurcation in this test (only the "slow zone" was analyzed), this point is still regarded to be of intermediate reliability.

Dispersivities at small displacements will also be underestimated if based on breakthrough curves measured in localized samplers in individual layers. Such effects are likely, for example, in the Perch Lake [*Lee et al.*, 1980] and Lower Glatt Valley [*Hoehn*, 1983] interpretations. Later interpretation of the Lower Glatt Valley data using temporal moments [*Hoehn and Santschi*, 1987] shows values an order of

magnitude larger; these are connected with the original values by vertical lines in Figure 3.

As a further illustration of the uncertainty in the longitudinal dispersivity values in Figure 2, consider the data for the Hanford site. The tracer test [*Bierschenk*, 1959; *Cole*, 1972] interpreted from breakthrough curves at two different wells at roughly the same distance (around 4000 m) from the injection point produced values differing by 2 orders of magnitude (see dashed line in Figure 3). This difference illustrates the difficulty in interpreting point breakthrough curves in heterogeneous aquifers, even at this large displacement. The numerical simulations of the contamination plume [*Ahlstrom et al.*, 1977] extending to 20,000 m used a dispersivity of 30.5 m (100 feet) as identified by the bold arrow in Figure 3. Evidently this round number (100 feet) was popular in several different simulations of contaminant plumes.

In none of the cases of simulations of contamination events is there any explicit information on how the dispersivity values were selected or in what sense the values may be optimal. Consequently it is not possible to quantify the uncertainty in dispersivity values based on contamination event simulations. However, experience suggests that, because of the possible tendency to select large dispersivities which avoid the numerical difficulties associated with large grid Peclet numbers, some of the dispersivity values based on contaminant plumes are likely to be biased toward higher values. Such overestimates would occur mainly at larger scales.

The results of these reanalyses provide an explicit indication of the uncertainty in the dispersivity values in Figure 2 and suggest that for large displacements the low-reliability dispersivities are likely to decrease whereas for small displacements some increases can be expected.

Transverse Dispersivities

Although the data on transverse dispersivity are much more limited, they reveal some features which are important in applications. The data on horizontal and vertical transverse dispersivities are summarized in Figures 4 and 5, which show these parameters as a function of scale of observation. The data are portrayed in terms of reliability classification with the largest symbols identifying the high-reliability points.

In the case of the horizontal dispersivity, there appears to be some trend of increasing dispersivity with scale but this appearance results from low-reliability data which finds their origin largely in contaminant event simulations using two-dimensional depth-averaged descriptions. In these contamination situations the sources are often ill-defined; if the actual source area is larger than that represented in the model there will be greater transverse spreading which would incorrectly be attributed to transverse dispersion.

In the case of vertical transverse dispersion (Figure 5), the data are even more limited and certainly do not imply any significant trend with overall scale. Note that there are only two points of high reliability, those corresponding to the Borden [*Freyberg*, 1986] and Cape Cod [*Garabedian et al.*, 1988, 1991] sites. The estimate of the vertical transverse dispersivity for the Borden site is from the recent three-dimensional analysis of *Rajaram and Gelhar* [1991]. The vertical transverse dispersivity is seen to be much smaller than the horizontal transverse dispersivity, apparently reflecting the roughly horizontal stratification of hydraulic conductivity encountered in permeable sedimentary materials. All of the vertical dispersivities are less than 1 m and high-reliability values are only a few millimeters, this being the same order of magnitude as the local transverse dispersivity for sandy materials.

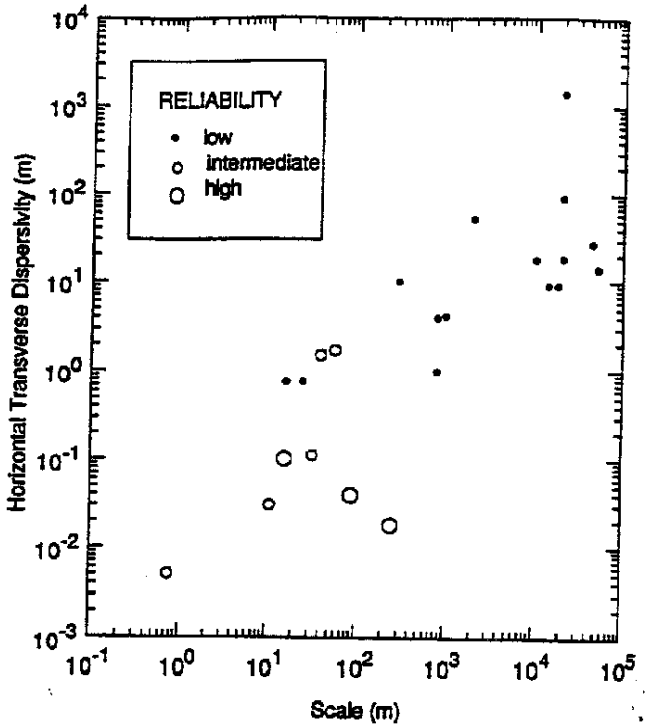

Fig. 4. Horizontal transverse dispersivity as a function of observation scale.

The ratio of longitudinal dispersivity to the horizontal and vertical transverse dispersivities is shown in Figure 6. This form of presentation is used because it is common practice to select constant values for the ratio of longitudinal to transverse dispersivities. For one thing, this plot illustrates the popularity of using, in numerical simulations, a horizontal transverse dispersivity which is about one third of the longitudinal dispersivity (the horizontal dashed line in Figure 6). There does not appear to be any real justification for using this ratio. We are not aware of any simulation work which systematically demonstrates the appropriateness of this value for the horizontal transverse dispersivity. The two high-reliability points show an order of magnitude higher ratio of longitudinal to horizontal transverse dispersivities. The vertical dashed lines in Figure 6 are used to identify three-dimensionally monitored sites for which all three principal components of the dispersivity tensor have been estimated. In all of these cases, the vertical transverse dispersivity is 1–2 orders of magnitude smaller than the horizontal transverse dispersivity. This behavior further emphasizes the small degree of vertical mixing which is frequently encountered in naturally stratified sediments. This small degree of vertical mixing is clearly an important consideration in many applications, such as the design of observation networks to monitor contamination plumes and the development of remediation schemes. Consequently, in order to model many field situations realistically, it will be necessary to use three-dimensional transport models which adequately represent the small but finite vertical mixing.

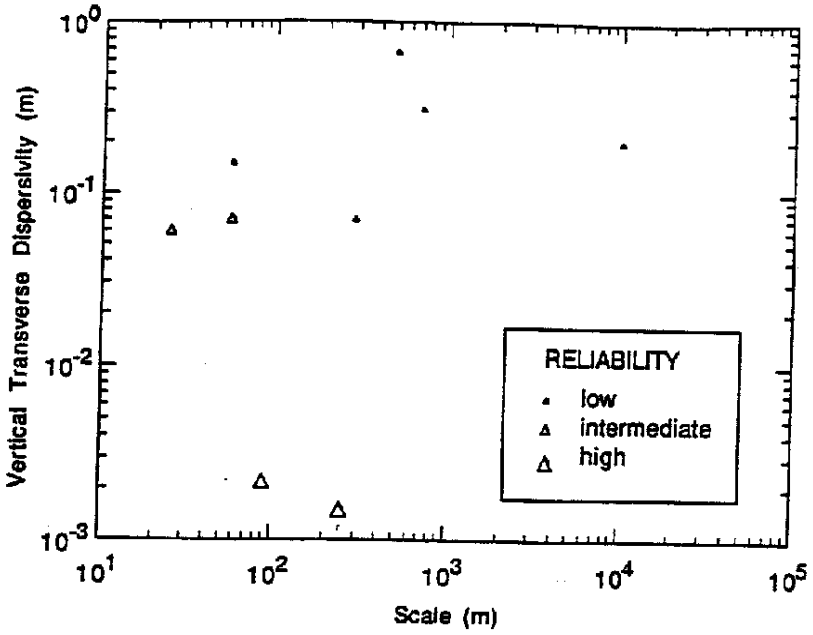

Fig. 5. Vertical transverse dispersivity as a function of observation scale.

INTERPRETATIONS

This review of field observations of dispersive mixing in aquifers demonstrates several overall features which are evident from the graphical and tabular information developed here. Taken in aggregate, without regard for reliability, the data indicate a clear trend of systematic increase of longitudinal dispersivity with scale. In terms of aquifer type (porous versus fractured media) the data at smaller scale may seem to be higher for fractured media but, in view of the lower reliability of the fractured media data, this difference is of minimal significance.

When the data on longitudinal dispersivity are classified according to reliability, the pattern regarding scale dependence of dispersivity is less clear (see Figure 2). There are no high-reliability points at scales greater than 300 m and the high-reliability points are systematically in the lower portion of the scattering of data. The lack of high-reliability data at scales greater than 300 m reflects the fact that the data beyond that scale are almost exclusively from contamination simulations or environmental tracer studies for which the solute input is typically ill-defined. Because of the very long period of time required to carry out controlled input tracer experiments at these larger scales, such experiments have not been undertaken.

Although the data shown in Figure 2 suggest that some overall trend of increasing dispersivity with scale is plausible, it does not seem reasonable to conclude that a single universal line [*Neuman*, 1990] can be meaningfully identified

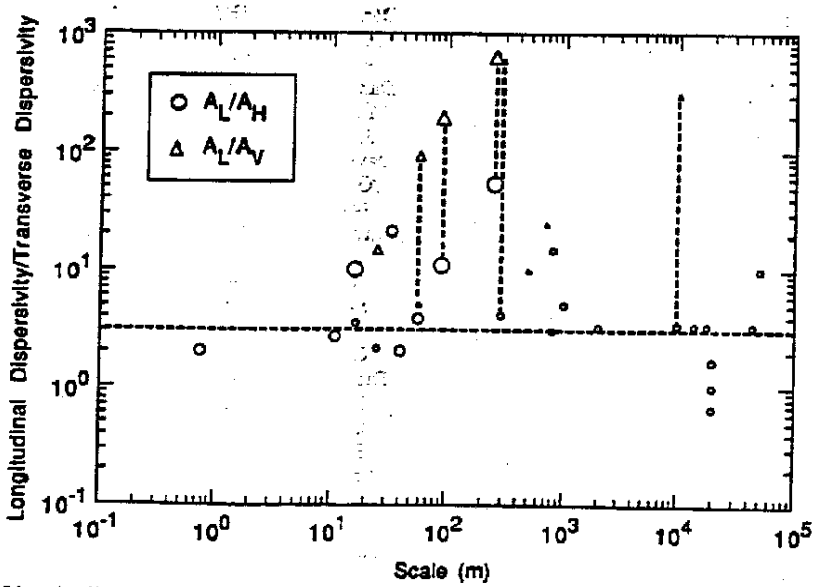

Fig. 6. Ratio of longitudinal to horizontal and vertical transverse dispersivities; largest symbols are high reliability and smallest symbols are low reliability. Vertical dashed lines connecting two points indicate sites where all three principal components of the dispersivity tensor have been measured. Horizontal dashed line indicates a ratio of A_L/A_T = 1/3, which has been widely used in numerical simulations.

by applying standard linear regression to all of the data. Rather we would expect a family of curves reflecting different dispersivities in aquifers with different degrees of heterogeneity. At a given scale, the longitudinal dispersivity typically ranges over 2–3 orders of magnitude. This degree of variation can be explained in terms of the established stochastic theory [e.g., *Gelhar and Axness*, 1983; *Dagan*, 1984] which shows that the longitudinal dispersivity is proportional to the product of the variance and the correlation scale of the natural logarithm of hydraulic conductivity. A compilation of data on these parameters [*Gelhar*, 1986] shows that they vary over a range that can easily explain the range of variation in Figure 2. The theoretical results for the developing dispersion process [*Gelhar et al.*, 1979; *Dagan*, 1984; *Gelhar*, 1987; *Naff et al.*, 1988] show that the longitudinal dispersivity initially increases linearly with displacement distance and gradually approaches a constant asymptotic value [see *Gelhar*, 1987, Figure 9]. One could visualize the behavior of Figure 2 as being the result of superimposing several such theoretical curves with different parameters characterizing aquifer heterogeneity.

The results of reanalyses for several of the individual sites serve to illustrate explicitly the uncertainty involved in the estimates of longitudinal dispersivity. The reanalyses indicate that, for the most part, improved analysis will lead to decreases in the longitudinal dispersivity except possibly for very small displacements where limited localized sampling can produce underestimates of the bulk spreading and mixing. In cases where the dispersivity estimates were based on numerical simulations of contamination events, the degree of uncertainty is likely large and ill-determined, but bias in some of the estimates toward the high side seems most likely.

From an applications perspective, the information assembled here should serve as a strong cautionary note about routinely adopting dispersivities from Figure 2 or a linear regression representation through the data. We feel that the preponderance of evidence favors the use of dispersivity values in the lower half of the range at any given scale. If values in the upper part of the range are adopted, excessively large dilution may be predicted and the environmental consequences misrepresented. In the case of transverse dispersivities, it is particularly important to recognize the very low vertical transverse dispersivities that have been observed at several sites. As a result, many contamination plumes will exhibit very limited vertical mixing with high concentrations at a given horizon. The recognition of such features is of obvious importance in designing monitoring schemes and implementing aquifer remediation. Horizontal transverse dispersivities are typically an order of magnitude smaller than the longitudinal dispersivity whereas vertical transverse dispersivities are another order of magnitude lower.

From a research perspective, the data reviewed here suggest a need for some skepticism regarding "universal" models which represent the scattered data of varying reliability by a single straight line. The presumption of such a universal model ignores the fact that different aquifers will have different degrees of heterogeneity at a given scale. The data suggest that there is a scale dependence of longitudinal dispersivity but reliable data must be developed at larger scales in order to establish the nature of the dependence. Clearly, there is a need for very large scale, long-term, carefully planned experiments extending to several kilometers.

Analysis of a Vertical Dipole Tracer Test in Highly Fractured Rock

by William E. Sanford[1], Peter G. Cook[2], and John C. Dighton[2]

Abstract/

The results of a vertical dipole tracer experiment performed in highly fractured rocks of the Clare Valley, South Australia, are presented. The injection and withdrawal piezometers were both screened over 3 m and were separated by 6 m (midpoint to midpoint). Due to the long screen length, several fracture sets were intersected, some of which do not connect the two piezometers. Dissolved helium and bromide were injected into the dipole flow field for 75 minutes, followed by an additional 510 minutes of flushing. The breakthrough of helium was retarded relative to bromide, as was expected due to the greater aqueous diffusion coefficient of helium. Also, only ~25% of the total mass injected of both tracers was recovered. Modeling of the tracer transport was accomplished using an analytical one-dimensional flow and transport model for flow through a fracture with diffusion into the matrix. The assumptions made include: streamlines connecting the injection and withdrawal point can be modeled as a dipole of equal strength, flow along each streamline is one dimensional, and there is a constant Peclet number for each streamline. In contrast to many other field tracer studies performed in fractured rock, the actual travel length between piezometers was not known. Modeling was accomplished by fitting the characteristics of the tracer breakthrough curves (BTCs), such as arrival times of the peak concentration and the center of mass. The important steps were to determine the fracture aperture (240 μm) based on the parameters that influence the rate of matrix diffusion (this controls the arrival time of the peak concentration); estimating the travel distance (11 m) by fitting the time of arrival of the centers of mass of the tracers; and estimating fracture dispersivity (0.5 m) by fitting the times that the inflection points occurred on the front and back limbs of the BTCs. This method works even though there was dilution in the withdrawal well, the amount of which can be estimated by determining the value that the modeled concentrations need to be reduced to fit the data (~50%). The use of two tracers with different diffusion coefficients was not necessary, but it provides important checks in the modeling process because the apparent retardation between the two tracers is evidence of matrix diffusion and the BTCs of both tracers need to be accurately modeled by the best fit parameters.

Introduction

Many tracer tests in fractured rocks are performed in well-defined fractured zones (Maloszewski and Zuber 1985; Himmelsbach et al. 1998; Jardine et al. 1999) where the injection and sampling occur in this zone and it is generally assumed that the tracer travels only through this zone. In this paper, we present the results of a tracer test using helium and bromide performed in the flow field of a vertical dipole established in a highly fractured metadolostone in the Clare Valley of South Australia (Figure 1). In this system, there exist five sets of fractures (Figure 2). With the injection and withdrawal occurring in relatively large screened sections (3 m), the analysis of the breakthrough data needs to account for tracer being injected into fractures not connected to the withdrawal well and tracer-free water mixing with tracer-tagged water in the withdrawal well. In addition, unlike most other tests, we do not know the actual length of the fracture connecting the two piezometers.

The purpose of this paper is to present a method to analyze breakthrough curves (BTCs) in highly fractured rock. We will show: (1) by fitting the characteristics of the BTCs, estimates of the effective field-scale flow and transport parameters can be made; (2) the use of multiple tracers is important to constrain the flow and transport parameters; and (3) the amount of dilution in the withdrawal well can be estimated.

Model Development

To model the transport of the two tracers, several assumptions need to be made at the beginning. First, it will

be assumed that the transport between the two piezometers is through a single fracture. Maloszewski and Zuber (1985, 1993) concluded that for short-term experiments on the order of tens of hours, the assumption of a single fracture is applicable. In several other works (Grove and Beetem 1971; Himmelsbach et al. 1998; Jardine et al. 1999) the tracer data was modeled as a single fracture partly because the tracer was injected and withdrawn from a well-defined fractured interval. A second assumption, following Grove and Beetem (1971) and Himmelsbach et al. (1998), is that the flow through the single fracture will follow a series of streamlines that would develop between a dipole of equal strength. A third assumption will be that the flow along each streamline will be considered at a constant velocity. This third assumption will be discussed in more detail later.

As shown in Figure 2, the rock is quite fractured. Each piezometer is screened over a 3 m section. (The height of the person on the scaffold in Figure 2 is approximately 2 m.) Therefore, it is likely that each piezometer intersects fractures that are not connected to the other piezometer. As a result, some of the tracer-tagged injection water may flow out fractures that are not connected to the withdrawal piezometer and the withdrawal piezometer may pull in water from nonconnecting fractures, causing a dilution of the tracer-tagged water that flows between each piezometer.

Another complicating factor for the situation at the field site is that the actual length of the fracture connecting the two piezometers is not known. It can be as small as 6 m (the distance from the bottom of the screened section of the upper piezometer and the top of the screened section of the lower piezometer) or any length greater than that.

To model the flow, we follow methods outlined in Grove and Beetem (1971) and Himmelsbach et al. (1998). In these papers, the flow was assumed to be through a single fracture and was modeled as a series of streamlines following the arcs of circles of different radii connecting the injection and withdrawal points. Grove and Beetem (1971) gave solutions for calculating the length and travel time along each streamline. The length (L) is given by

$$L = \frac{2\,a\,\alpha}{\sin\alpha} \tag{1}$$

where 2a is the spacing between injection and withdrawal points, and α varies between zero and π and is related to the angle at which each streamline leaves the injection point and enters the withdrawal point. The travel time along each streamline is given by

$$t = \frac{\pi\,m\,\theta_f\,(2a)^2}{Q\sin^2\alpha}\,[\alpha\cot\alpha - 1] \tag{2}$$

where Q is the pumping rate, θ_f is the fracture porosity, and m is the thickness of the aquifer.

Grove and Beetem (1971) and Himmelsbach et al. (1998) both modeled the transport through the fracture with one-dimensional analytical solutions. Each streamline represents the same proportion of flow between the wells and, assuming no flow across streamlines, each can be treated as a single flowpath. Himmelsbach et al. (1998) state that 35 streamlines are sufficient to accurately model the flow field of the dipole. Therefore, transport is calculated for each of the 35 streamlines with each contributing 1/35 of the flow. The contribution from each is summed at the times of interest in order to model the BTCs.

Transport modeling was done following the analytical solution of Sudicky and Frind (1982) for parallel fractures in the computer code CRAFLUSH. In this solution, steady-state flow occurs only in the fractures with diffusive exchange with the matrix. The values that are required for

specification are fracture aperture, ground water velocity, fracture spacing, dispersivity in the fracture, effective diffusion coefficient, fracture and matrix retardation, and matrix porosity. To model as a single fracture, we need to use a fracture spacing that is far enough to prevent interaction of neighboring fractures over the time scale of the experiment. Therefore, we chose a spacing of 10.25 m for use in the model, which is more than adequate to prevent the influence of neighboring fractures.

Typically, analytical solutions require the assumption of a constant velocity along the entire flowpath. The velocity along a streamline is not constant. Both Grove and Beetem (1971) and Himmelsbach et al. (1998) used analytical solutions but got around the need for a constant velocity by assuming that each streamline had a unique and constant Peclet number given by dividing the length of the streamline by the dispersivity in the fracture (dispersivity constant for all flowpaths). For the transport modeling in this paper, we will also assume a constant Peclet number along each streamline by using an average velocity determined by dividing the length of the streamline found using Equation 1 by the travel time found using Equation 2. These two approaches are essentially identical.

Accurate modeling of flow and transport through a fracture requires the coupling of the terms required for both. The fracture aperture can be calculated following Novakowski et al. (1985) and Himmelsbach et al. (1998) from

$$2b = \sqrt{\ln \frac{X}{r_w} \frac{4 \nu \tau_f X^2}{g\, t_0\, \Delta H}} \tag{3}$$

where

- X = length of shortest streamline, equal to 2a in Equation 1 (L)
- r_w = radius of bore (L)
- ν = kinematic viscosity of water (L^2/T)
- τ_f = fracture tortuosity (assumed as 1)
- t_0 = mean travel time along path X (distance between poles) (T)
- ΔH = difference in hydraulic head between piezometers (L).
- g = gravitational acceleration (L/T^2)

From Himmelsbach et al. (1998), the fracture porosity is determined by

$$\theta_f = \frac{3\, Q\, t_0}{\pi\, m\, X^2} \tag{4}$$

Substituting Equation 4 into Equation 2, we find that the travel time along a streamline is

$$t = \frac{3\, t_0}{\sin^2 \alpha} (\alpha \cot \alpha - 1) \tag{5}$$

Therefore, the average travel time between the wells along each streamline can be calculated independently of the proportion of the pumping rate that actually flows between wells.

Another term we need to estimate is the straight line distance between wells (X = 2a). To arrive at a first estimate, we will use an equation developed by Lever and Bradbury (1985) that calculates the time for the arrival of the peak concentration at a distance L for a pulse injection of tracer traveling through a single fracture (with parallel streamlines) in which matrix diffusion is occurring (their Equation 5.1):

$$t_{max} = \frac{K\, L}{v} + \frac{D_{eff}\, \theta_m\, L^2}{6\, v^2\, b^2} \tag{6}$$

where

- t_{max} = time of arrival of peak concentration (T)
- K = fracture retardation (here taken as 1)
- v = ground water velocity (L/T)
- D_{eff} = effective aqueous diffusion coefficient in the matrix (L^2/T)
- θ_m = matrix porosity
- b = half aperture of the fracture (L).

Letting L/v equal t_0 and K = 1, Equation 6 becomes

$$t_{max} = t_0 + \frac{D_{eff}\, \theta_m\, t_0^2}{6\, b^2} \tag{7}$$

The values for t_{max} and t_0 are selected from the tracer breakthrough data. The effective diffusion coefficient and matrix porosity are known, so Equation 7 is solved for the fracture aperture, 2b. The use of Equation 7 is important in that it relates the separation of the peak arrive time from the plug-flow time to the matrix diffusion parameters and to the contact time of the tracer with the rock matrix. This value of 2b is then used in Equation 3 to get a first estimate of the distance X.

There currently is no method to address the amount of dilution to be expected either in the modeling approach we have used or in a finite-element model because the entire fractured system would need to be known, which would be virtually impossible to do in this or other field sites. However, we can get around the effects of dilution by modeling characteristics of the BTCs of both tracers by reproducing the relative behavior of the two tracers. This is a similar approach to the use of partitioning tracers to examine NAPL concentrations in aquifers (Jin et al. 1995). It is not the total masses of tracers recovered that are important, it is the differences in their relative breakthroughs that provide information on the transport parameters between the injection and withdrawal wells. Therefore, our approach was to model the timing of the peak concentrations of both tracers, the times for the centers of mass of both tracers to arrive, and the inflection times on the leading and trailing edges of the BTCs. If there is dilution, the model will consistently produce relative concentrations higher than the data. Because dilution is affecting the concentrations only in the withdrawal well and not along the flowpath, an estimate of the amount of dilution can be made by determining the factor needed to reduce the modeled concentrations to fit the data.

Methods

Site Description

The Clare Valley is one of South Australia's wine-producing regions. Located 100 km north of Adelaide (Figure 1), it receives an average of 600 mm of rainfall per year. Ground water is used for irrigation of vineyards and, with an expanding wine industry, the demand is likely to increase. This increase has necessitated research into understanding the hydrogeology of the fractured rock aquifer to allow planning for sustainable use of ground water resources in the region. The Department of Water Resources, SA, installed a number of wells in the region to determine the water balance. Studies include natural ground water fluxes, use of environmental tracers to determine recharge, and examination of fracture connectivity (Cook et al. 1999; Cook and Simmons 2000).

The Clare Valley consists of low-grade metamorphosed, folded, and faulted sedimentary rocks of Proterozoic age (Morton et al. 1998). The major lithologies are sandstone, shale, quartzite, and dolomite. In this paper, data is presented from a field site (Wendouree) in the Saddleworth Formation (silty dolomite). The primary porosity of the dolomite has been measured to be 4.8% using mercury porosimetry. Outcrop mapping in an exposure approximately 70 m long and 6 m deep, located 3 km north-northwest of the field site, indicates five sets of fractures (Figure 2). For this site, on the western limb of the Hill River Syncline, the aquifers are on end, with the majority of fractures and bedding planes oriented vertically. The bedding comprises one vertical fracture set that strikes 151°. A second set of vertical fractures strikes 59°. A set of conjugate shear fractures has the same trend as the second set of vertical fractures with dips of ~60°. The only shallow dipping fracture set has a strike of 345° and a dip of 27°. The largest apertures measured in the outcrop are 600 μm. The highly fractured nature of the bedrock as seen in outcrop suggested that the vertical hydraulic conductivity of the aquifer due to vertical fracturing could be greater than the horizontal hydraulic conductivity.

At the field site, a 250 mm bore was drilled to 37.4 m depth, and a nest of six 50 mm PVC piezometers were installed in the bore, separated by bentonite and cement plugs. This paper discusses data from the three upper piezometers in this nest: 41497-6, 41497-5, and 41497-4, with screens at 9 to 12, 18 to 21, and 27 to 30 m below land surface (bls), respectively. Water levels vary seasonally between ~4 m depth in October–November and 7 m depth in July–August. At the time of the experiment, the water level was 6.0 m bls. Under ambient conditions, there is no measurable vertical head gradient at this site, indicating little or no vertical flow under nonpumping conditions.

Pumping Test

To first determine the approximate degree of connectedness of the piezometer levels, a pumping test was performed in which water was extracted with a submersible pump from piezometer 41497-5 at a rate of 15 L/min. Hydraulic heads were monitored in the piezometers located directly above (41497-6) and below (41497-4). Pumping continued until the heads in all three wells stabilized. The final drawdown in each piezometer was 0.26 m in 41497-4, 2.29 m in 41497-5, and 0.17 m in 41497-6. This difference in head response in the upper and lower piezometers suggests that there are fractures that intercept the withdrawal piezometer and one of the monitoring locations but not the other.

Tracer Test

The tracer test was designed to determine the actual volumetric flow rate between the two piezometers and to put constraints on field parameters such as average aperture size, ground water velocity, and the effects of matrix diffusion. The two tracers chosen were bromide and helium because of their conservative nature, ease of sampling and analysis, and their different aqueous diffusion coefficients (7.22×10^{-5} cm^2/sec for He vs. 2.01×10^{-5} cm^2/sec for Br^-). The bromide solution was made by dissolving approximately 750 g of KBr in 500 L of water in a rain water tank, achieving a bromide concentration of 864 ppm.

Helium was infused into the water through 100 m of 0.32 cm diameter silicon tubing following the method described by Sanford et al. (1996). Due to the length of time needed to charge the tracer water in this manner, the flow of helium was started five days before the tracer test. The water in the tank was mixed by turning on a submersible pump for a few minutes several times per day. The helium concentration in the injection water reached approximately 20% saturation. Complete saturation was avoided because of the concerns of the formation of bubbles due to degassing as the tracer solution came into contact with the slightly warmer ground water.

The injection system consisted of two 500 L tanks. One tank contained the tracer solution and the other contained local ground water. An outlet was placed near the bottom of each tank and fitted with 1.27 cm outer diameter (O.D.) copper tubing. Copper tubing was used to prevent the diffusive loss of the dissolved helium that can occur through the walls of plastic-type tubing. The tubing from each tank connected to a valve and then the two lines met at a tee. One line from the tee rose vertically through an in-line flowmeter. At the top of the flowmeter, a short section of tubing ran horizontally and was equipped with a septum port for collecting samples of the injection water. After this horizontal length, 1.27 cm O.D. copper tubing was used down to the screened section of 41497-5. At the bottom, a 60 cm length of 0.64 cm O.D. copper tubing was fitted to restrict the flow, with the outlet placed in the midpoint of the screened interval. Injection took place under gravity flow, with the valves being used to switch injection water between tanks. The flow rate was maintained at a constant rate of 4.7 L/min during the entire injection period.

The withdrawal portion of the doublet was established with an MP1 Grundfos® submersible pump centered on the midpoint of the screened interval of piezometer 41497-4. Attached to the pump was 1.27 cm O.D. copper tubing that ran to the surface. At the surface, the exit of the tubing was placed at a slightly upward angle to keep the outlet section completely filled with water at all times. The pumping rate was calibrated to equal that of the injection system.

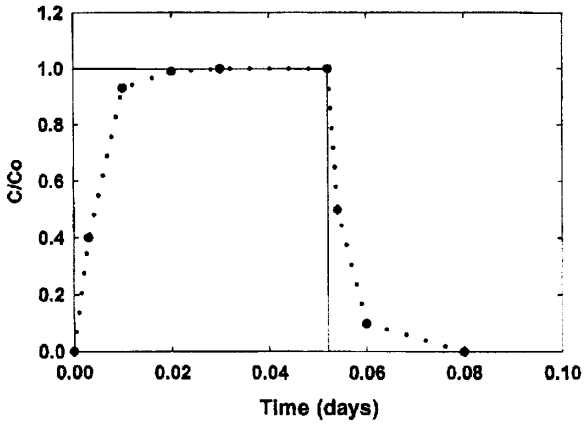

Figure 3. Injection pulse used in model to account for mixing in the injection bore. Solid line represents the theoretical injection with no mixing and the dotted line represents the modeled injection with mixing.

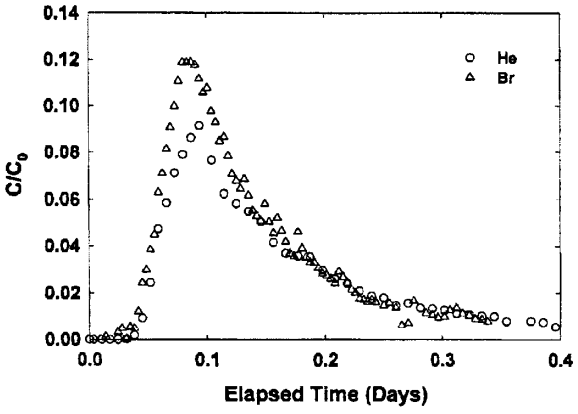

Figure 4. The breakthrough curves for helium and bromide.

The dipole was established prior to injection of the tracers by injecting tracer-free water until the hydraulic heads stabilized (approximately 30 minutes). The tracer solution was then injected for a total of 75 minutes, after which time the valves were switched so that only tracer-free water was injected. The test continued for an additional 510 minutes to recover the injected tracer. The total head difference between the two piezometers during the test remained constant at 0.6 m.

Samples of the tracer water were collected periodically during the injection through the port at the top of the injection line. Glass syringes fitted with needles were used to collect the water. For bromide samples, approximately 20 mL were collected and placed in a 100 mL plastic bottle. Helium samples were collected by slowly drawing water into the glass syringe to avoid the formation of bubbles. Once approximately 10 mL of water was collected, the needle was removed and a small rubber vial cap was placed over the luer-lock tip on the syringe.

Bromide samples from the withdrawal line were collected by placing 100 mL plastic bottles into the outlet stream and filling to approximately two-thirds full. Helium samples were collected by placing the needle on the glass syringe into the outlet pipe and slowly drawing in the sample, again avoiding the formation of bubbles. The syringes were capped as described previously. Sampling frequency was initially every five minutes for bromide and 15 minutes for helium for the first three hours of the test. After this time, helium was sampled every 20 minutes and bromide every 15 minutes.

The samples were taken to a nearby temporary laboratory for analysis. Bromide analyses were performed on 10 mL aliquots using an Orion® solid-state, ion-selective electrode with an Orion double-junction reference electrode. To extract helium from the water samples, water was removed from the syringe by placing a needle through the rubber cap until the volume left in the sampling syringe was equal to 8 mL. A headspace of 2 mL of high purity nitrogen (carrier gas) was added and the sample was shaken for 30 to 60 seconds. A 1 mL sample of the headspace was extracted and injected into a gas chromatograph equipped with a thermal conductivity detector and an 8 m molecular sieve column. See Sanford et al. (1996) for details on the gas chromatograph settings.

Wellbore Mixing

To handle the effects of wellbore mixing, an assumption of complete, instantaneous mixing within the volume was made. The concentration in the well volume at any time is given by

$$\frac{\partial C_w}{\partial t} = \frac{Q}{V}(C_i - C_w) \qquad (8)$$

where

C_w = concentration in well at time t (M/L^3)
t = time (T)
V = well volume (L^3)
Q = injection rate (L^3/T)
C_i = concentration of water entering the well (M/L^3).

The effect of wellbore mixing on the concentration in the injection well is shown in Figure 3. To account for this in the transport modeling, the source concentration was varied with time in such a way as to represent this modified injection pulse. The total amount of mass injected remained the same.

The distances, aperture, and velocities calculated from the preceding are used in the transport model with iterations made on the dispersivity and well spacing to find the best fit to the BTCs. The effects of dilution are handled as mentioned previously.

Results

The effects of matrix diffusion on the transport of the tracers are clearly evident in that the breakthrough of helium (the tracer with the largest effective diffusion coefficient) is retarded relative to the breakthrough of bromide (Figure 4). The center of mass of the bromide arrived at a relative volume (RV) of 2.59 and the center of mass of helium arrived at RV = 2.97. Mass recoveries of the tracers were determined to be 24.5% for helium and 28.4% for bromide.

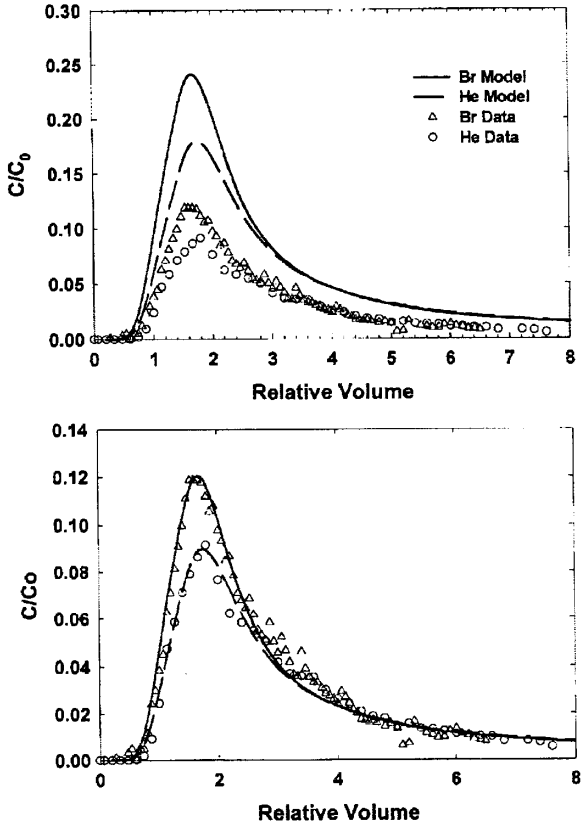

Figure 5. Best-fit results of the modeling. Relative volume is related to the volume of the injection pulse: (a) fit to the centers of mass, peak times, and inflection points; (b) fit to data by dividing concentrations in Figure 5a by 2.

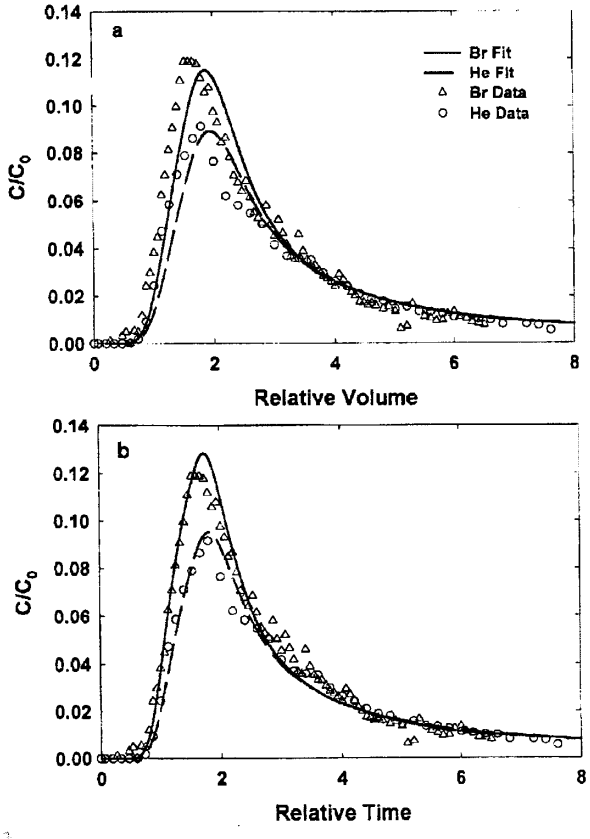

Figure 6. (a) Modeling of the data using a t_0 = 0.05 day; (b) Modeling of data using a dispersivity value of 0.2 m.

Modeling

The first step in modeling was to use Equation 7 to solve for the half width of the aperture. Again, the aim was to minimize the use of assumptions in producing the best modeling fit to the tracer data. The arrival time of the peak concentration was taken from the breakthrough data for the tracer with the largest diffusion coefficient, helium; hence, t_{max} = 0.094 day (Figure 4). The effective diffusion coefficients were taken from previous work (Sanford et al. 1996) and were given previously. The matrix porosity used was that measured (5%). The average travel time along the straight line path between the injection and withdrawal wells (t_0) was selected from the BTCs (Figure 4) as the time of first arrival of the tracers, resulting in t_0 = 0.04 day. Solving Equation 7 yields an aperture (2b) of 240 μm. This aperture value was then used in Equation 3 to solve for the length of the fracture, with the radius of the bore equal to 0.125 m. This resulted in a calculated length of 8.5 m and a velocity of 212 m/day. This length was substituted for 2a in Equation 1 to calculate the lengths of the streamlines and in Equation 2 to calculate the arrival times.

The calculated aperture, lengths, and velocities were used in the transport modeling. The only parameter not known, chosen from the BTC, or calculated for the transport modeling was the fracture dispersivity. Himmelsbach et al. (1998) present tracer data from dipole tests along a fracture with well spacings of 11.2 and 16.2 m. Their best fit dispersivities ranged from 0.17 to 0.25 m. Based on their results, the initial value of dispersivity used in the modeling was 0.2 m.

Centers of Mass Fit

The centers of mass of the modeled BTCs were compared to those of the tracers. With the spacing of 8.5 m, the modeled time for the peak to arrive for both tracers was too early, as were the centers of mass (RV = 2.08 for bromide and RV = 2.27 for helium). The next step then was to increase the fracture length, recalculate the streamlines, and remodel the BTCs.

Figure 5a presents the best fit to the breakthrough characteristics for both tracers using a spacing of 11 m, an aperture of 240 μm, a maximum velocity of 275 m/day, and a dispersivity of 0.5 m. For bromide, the center of mass of the model arrived at RV = 2.58. For helium, the center of mass of the model was RV = 2.96. Also note how the peak times and inflection points also correspond. The modeled concentrations are greater than the actual concentrations, with twice as much mass recovery modeled. If we divide the modeled concentrations by two, the resulting BTCs fit the data very well (Figure 5b). This indicates that there was an approximate 50% dilution in the withdrawal well.

Discussion

The fit to the data achieved by the method used here is a result of modeling the characteristics of the tracer BTCs and the relative differences between each tracer. Maloszewski and Zuber (1985) and Himmelsbach et al. (1998) stress the importance of the parameter that describes the matrix diffusion process, given by

$$a = \frac{\theta D^{1/2}}{2b} \tag{9}$$

during the fitting process. For our approach, we arrive at this relationship through the use of Equation 7. It can be shown that identical BTCs can be generated using the transport model as long as the value in Equation 9 is kept constant. For example, if the matrix porosity is doubled and the aperture is doubled and all other terms kept constant, identical BTCs will result. However, by doubling the aperture, the hydraulic relationship between the head difference and the arrival time is violated (Equation 3); for our case, the matrix porosity is known, so doubling it is not valid.

Obviously, the choice of t_0 is important. Because there is no other method available, it is best to choose the value from the BTC. An example of using a greater value of t_0 = 0.05 day is shown in Figure 6a. Here, the peak arrivals are late, as are the centers of mass (RV = 2.78 for bromide, RV = 3.12 for helium). The time difference between the first arrival and the peak concentration is too large compared to the data.

Figure 6b shows the results of using all the same parameters as in the best fit model except with a dispersivity of 0.2 m. For this representation, the timing of the peaks and arrival of the centers of mass are the same as the data, but the modeling fit is not as good.

Dilution

Once the breakthrough characteristics were fit for both tracers, it was necessary to reduce the modeled concentrations by half. This reduction suggests that half the water being drawn into the withdrawal well is from fractures not connected to the injection well. Reinspection of Figure 2 allows us to conclude that this is not unreasonable. For the tracers, only 25% of their injected mass was recovered. Two reasons account for this loss: First, in all models that were run, only 50% of the mass was recovered because, by using the streamline approach, some of the flowpaths have long distances and slow velocities. Therefore, some of the tracer injected into the fracture is traveling long distances and at slow velocities, so it never arrives at the withdrawal well during the time frame of the experiment. As a result, the maximum amount of tracer to be recovered if all mass was injected into the fracture would be about 50%. Himmelsbach et al. (1998) present the results of one of their dipole tracer tests and found that the mass recovery curve becomes asymptotic to 50% recovery. For our test, because only 25% was recovered, this suggests that only 50% of the tracer mass was injected into the fracture connecting the two piezometers. Second, with the streamline approach, the presence of a regional hydraulic gradient can result in additional mass loss.

Conclusions

A methodology for the analysis of a vertical tracer test in a highly fractured rock under dipole conditions was presented for conditions in which the injection and withdrawal occur over relatively large screen lengths. The assumptions made include streamlines connecting the injection and withdrawal point can be modeled as a dipole of equal strength, flow along each streamline is one dimensional, and there is a constant Peclet number for each streamline.

Because of the screen length (3 m), multiple fracture sets were intersected, some of which are not continuous between piezometers, and the actual travel length between piezometers was not known. By fitting the characteristics of the tracer BTCs, effective fracture aperture and the travel distance were estimated. The important steps were to determine the fracture aperture based on the parameters that influence the rate of matrix diffusion, which causes the lag between the arrival of the peak concentration and the average water velocity. The travel distance was then estimated by fitting the time of arrival of the centers of mass of the tracers. Dispersivity was determined by fitting the times that the inflection points occurred on the front and back limbs of the BTCs. An estimate of the amount of tracer that actually traveled between the two piezometers was estimated by determining the amount that the modeled concentration had to be reduced to fit the data. This step was a result of there being dilution in the withdrawal piezometer due to water being pulled in from fractures not connected to the injection piezometer.

The best fit modeling results for the active fracture connecting the two piezometers are a separation of 11 m, a fracture aperture of 240 μm, a maximum velocity of 275 m/day, a dispersivity of 0.5 m, and only approximately 50% of the injected tracer traveled through the connecting fracture and, of that, only 50% was recovered. These parameter values are not necessarily those to be used for every fracture in the system, but rather they provide a first approximation of the actual values.

Finally, the use of two tracers with differing diffusion coefficients was not necessary but was important for two reasons: First, the apparent retardation between the two tracers is evidence of matrix diffusion. Second, the BTCs of both tracers need to be accurately modeled by the best fit parameters. Therefore, multiple tracers provide important checks in the modeling process.

Analysis of Ground-Water Flow and Injection Fluid Transport in the Floridan Aquifer Near Pensacola, Florida

by David S. Ward, James W. Mercer, and Lisa L. August[a]

Abstract

Liquid waste has been injected into a permeable part of the lower limestone of the Floridan aquifer since 1963, raising hydraulic head in the injection zone throughout a region of northwestern Florida. The injection zone consists of a moderately permeable limestone, hydraulically isolated from overlying aquifers by a thick layer of clay. The formation fluid is saline, but becomes fresher up dip, northward where the limestone crops out. Numerical simulations were performed at regional and local scales to assess the regional pressure increase, to analyze the movement of the 10,000 mg/l total dissolved solids (TDS) isopleth (formation fluid) in the lower limestone of the Floridan aquifer, and to analyze the migration of the injection fluid, both historically and predictively, in the injection formation. This work is based largely on previous work by Merritt (1984), but uses the SWIFT code. Modifications to Merritt's work include increasing the hydraulic conductivity near the injection wells and using more recent injection rates; extensions include particle tracking and solute transport modeling. The simulations indicate that regional pressure increases should be much less than previously predicted. Using the new results, by the year 2033, the average movement of the 10,000 mg/l TDS isopleth due to injection is expected to be approximately 2200 ft (671 m). Additionally, by the year 2033, the indiluted injection fluid (95% of injection concentration) should migrate to an approximate diameter of 2.1 mi (3.4 km) from the injection wells.

Introduction

Liquid injection began near Pensacola, Florida in 1963. Today two facilities are injecting waste liquids, derived from the manufacture of synthetic fibers, into the Floridan aquifer (Vecchioli, 1979). Both sites are shown in Figure 1, which depicts both the injection wells and nearby monitor wells. This study is primarily concerned with Injection Site 1, where injection began in July 1963. Injection Site 2 is 8.5 mi (13.7 km) east-southeast of the first and began operation in June 1975; it is included in this study because the pressure buildup at Injection Site 2 affects the flow field.

After review of the site hydrogeology, including water quality, this paper describes three steps performed to estimate the environmental impact of injection: (1) numerical simulation of the regional ground-water flow system in the Pensacola area, (2) quantitative analysis of the movement of the 10,000 mg/l total dissolved solids (TDS) isopleth (i.e., the formation fluid) in the lower limestone of the Floridan aquifer, and (3) numerical simulation of the movement of the injection fluid, both historically and predictively, in the injection formation. This work is based largely on previous work by Merritt (1984), who performed numerical simulations of the regional ground-water flow system. His work was recreated using an updated version of the code (Ward, 1988) he used. The flow model was refined and used as the basis for subsequent analysis of the 10,000 mg/l TDS isopleth and injection fluid migration.

The purpose of this work is to refine the work of Merritt and to extend his work by considering solute transport. Specifically, the goal is to reasonably estimate the impact injection has on the natural flow system. This includes estimating injection fluid migration, as well as migration of saline water as defined by the 10,000 mg/l TDS isopleth (a regulatory consideration). The Pensacola area offers an opportunity to better understand the impacts of deep-well injection because the existing data base is much more extensive than those existing at most deep-well injection sites.

Site Description

Hydrogeology

The hydrogeology of this portion of northwest Florida has been studied extensively and is described by Barraclough (1966), Goolsby (1971), Foster and Goolsby (1972), Faulkner and Pascale (1975), and Pascale and Martin (1978). Regional data have been collected by the U.S. Geological Survey, with a summary provided by Hull and Martin (1982). The

Received September 1990, revised May and July 1991, accepted August 1991.

Discussion open until November 1, 1992.

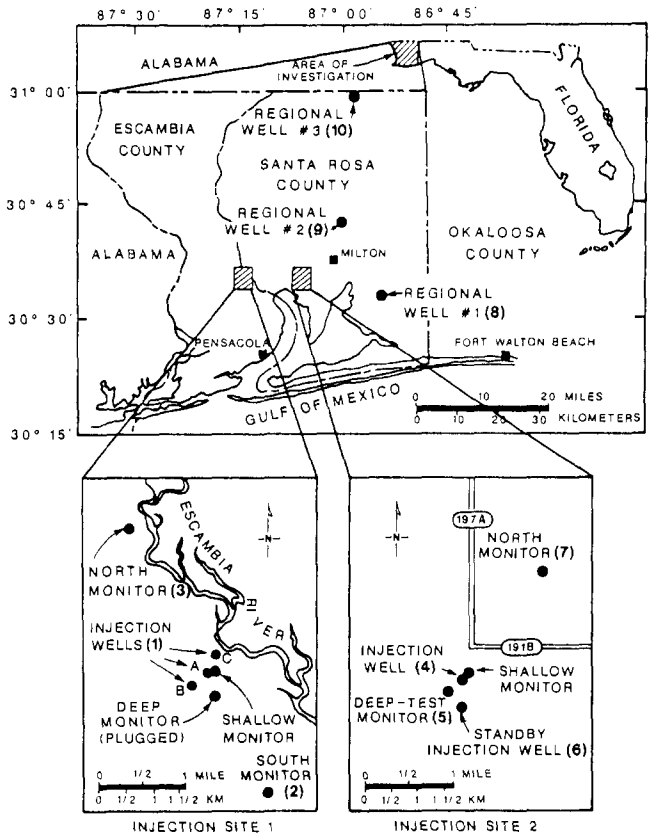

Fig. 1. Well location map for injection sites and vicinity (modified from Merritt, 1984).

geology of Escambia and Santa Rosa Counties is discussed by Marsh (1966). Early assessment of the two counties' water resources by Musgrove et al. (1961 and 1965) indicated that is was feasible to use the lower limestone portion of the Floridan aquifer for waste injection. As the hydrogeology of this region is discussed in these references and in Merritt (1984), only a brief description is provided here.

Waste is injected into the lower limestone of the Floridan aquifer, which dips southwest and, prior to injection, contained saline water in excess of 10,000 mg/l total dissolved solids at Site 1. Figure 2 provides a generalized north-south geological section showing Site 1. At this location, the top of the lower limestone is about 1,400 ft (427 m) below land surface. It is overlain by the 200-ft (61-m) thick Bucatunna Clay, which serves as a confining bed. The clay is overlain by the upper limestone of the Floridan aquifer, which also contains saline water at Site 1. Above the 230-ft (70-m) thick upper limestone lies the Pensacola Clay, a 400- to 500-ft (120-150-m) thick confining bed that separates a fresh-water aquifer above the Pensacola Clay from the saline upper limestone aquifer (Vecchioli, 1979). Fresh-water supplies for the area are obtained from the 300-400+-ft (90-120+-m) thick sand and gravel aquifer that overlies the Pensacola Clay and extends to land surface.

As shown in Figure 3, the Bucatunna Clay pinches out toward the east near Fort Walton Beach. It subcrops toward the south under the Gulf of Mexico and is offset by vertical faulting toward the west in Alabama. Toward the north, recharge occurs where the Floridan aquifer outcrops. Natural flow is generally from the recharge areas in the

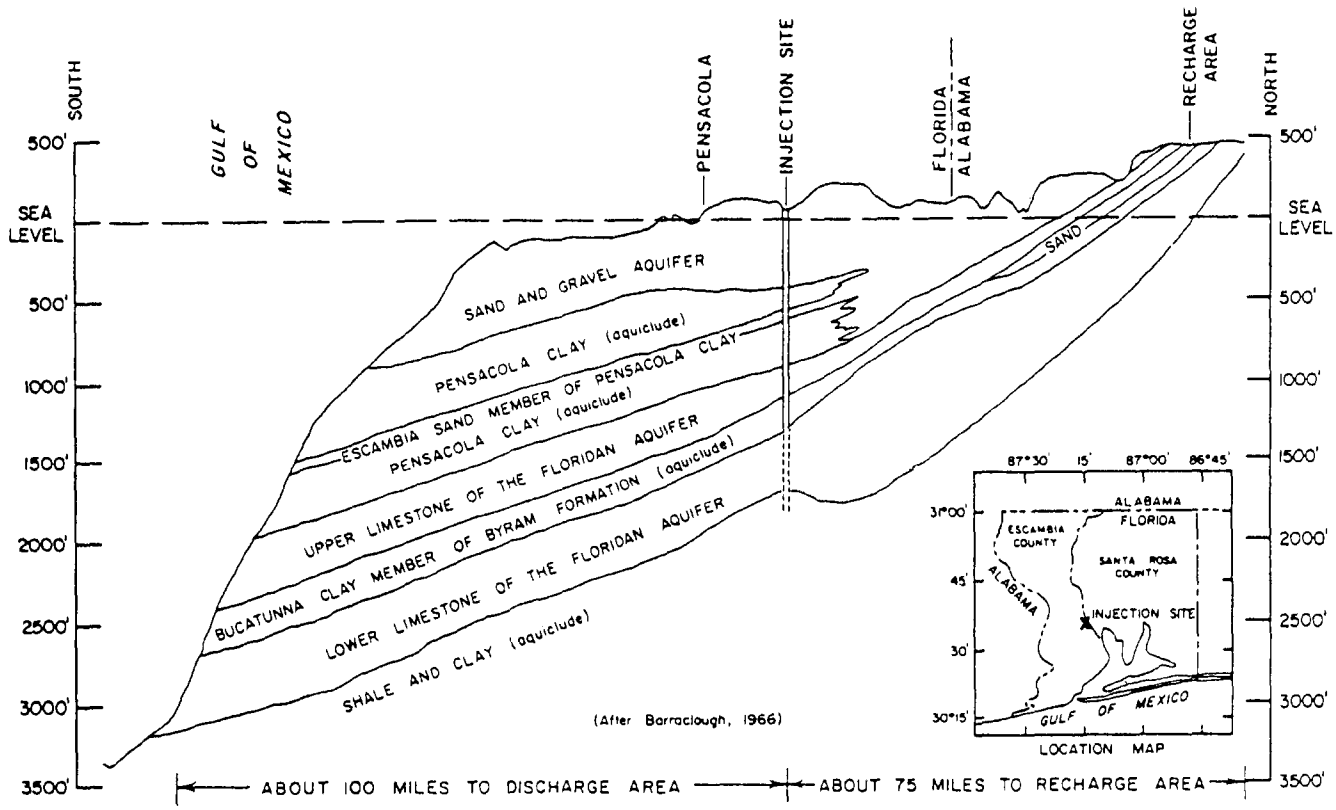

Fig. 2. Generalized north-south geological section through southern Alabama and northwestern Florida. The injection site indicated is Site 1 (from Goolsby, 1971).

north toward the Gulf of Mexico. Indications of the displacement of the limestone by faulting in an area northwest of the injection sites and of its thinning to the west and southwest of the injection sites suggest a partial or complete barrier to flow in these directions (Merritt, 1984).

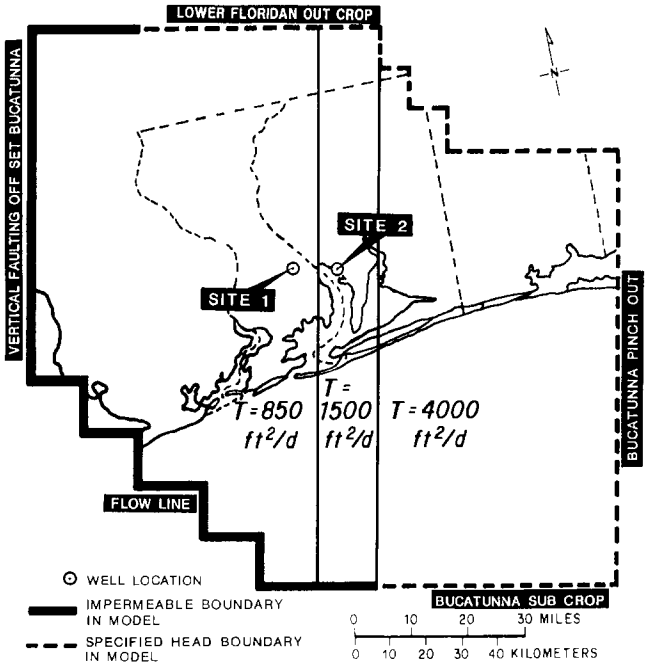

Fig. 3. Boundary conditions and transmissivity zones used in the regional flow model.

Water Quality

Beginning in 1963, the USGS conducted a ground-water sampling program in the lower limestone of the Floridan aquifer to collect data related to the geochemistry of subsurface injection. Chemical analyses are reported for ground-water samples from the wells shown in Figure 1. In addition, analyses are reported for both companies' injection fluids. Based on this information, viscosity and density differences between formation and injection fluids at Site 1 are negligible. Data collected from 1963 to 1980 are available for all sample points (Hull and Martin, 1982). Data for the 1981-1987 period also are available from USGS annual reports. Not all wells have a complete history of data, and only a fraction of the analyses are complete with respect to major cations and anions used in the classification and chemical characterization of ground water.

As a result, data from only nine sample sites of interest were selected for analysis. These included injection fluid from Site 1, and the site's north and south monitor wells; injection fluid from Site 2, and the site's deep-test and north monitor wells; and regional wells 1, 2, and 3. Although a limited number of samples from discrete zones have been reported, in general, the samples collected from well sites represent average water quality over an unknown aquifer interval.

The water-quality data are used to classify the water type at the sample sites. The major cations and anions, which define the water type (or facies), are plotted on Durov diagrams (Zaporozec, 1972; Katz and Choquette, 1991). The Durov plots created for samples from Injection Sites 1 and 2 are shown in Figures 4 and 5, respectively. A Durov plot for

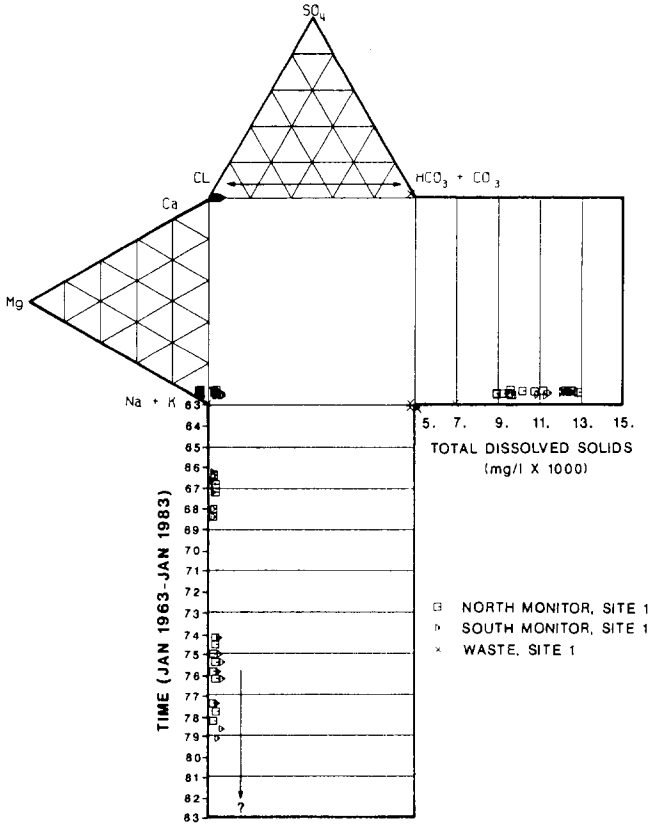

Fig. 4. Durov plots for Site 1 injection (1) fluid and monitor wells (2 and 3); time scale in years.

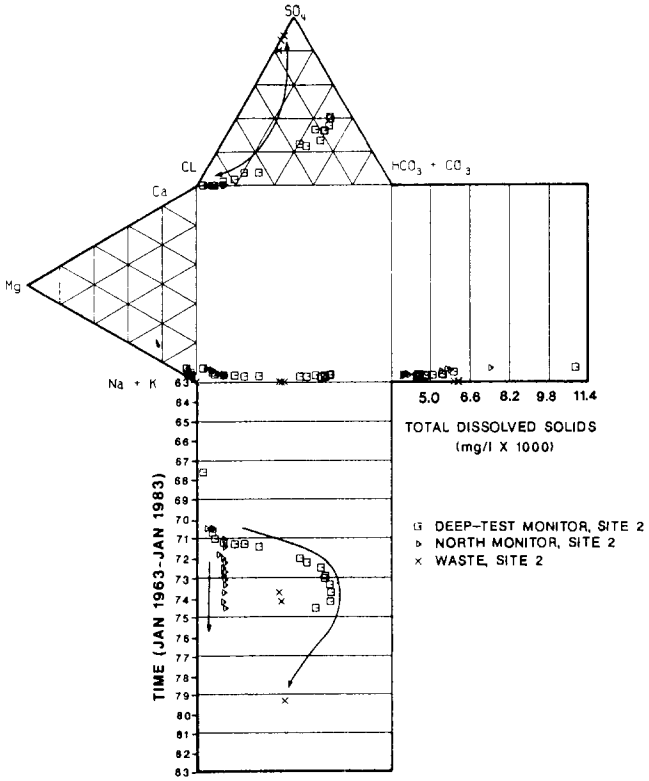

Fig. 5. Durov plots for Site 2 injection (4) fluid and monitor wells (5 and 7); time scale in years.

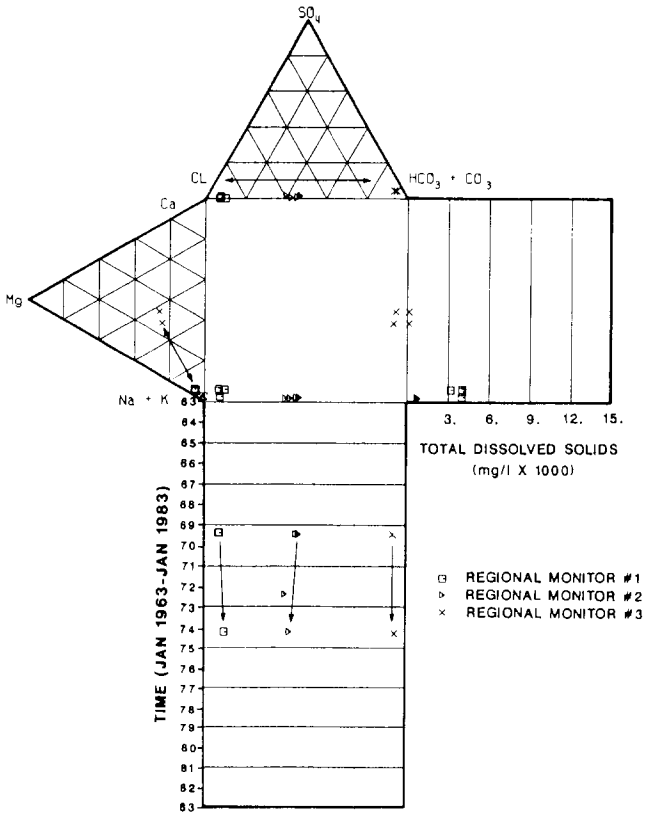

Fig. 6. Durov plots for regional wells #1(8), #2(9), and #3(10); time scale in years.

each regional well is shown in Figure 6. Total dissolved solids (TDS) in mg/l and the date of the sample are plotted on the adjacent rectangles. The date of the sample is plotted to illustrate possible changes in water composition over time.

As shown, the Durov plot consists of two triangles and three rectangles. The top triangle represents the anion composition, where the corners are 100% sulfate (SO_4), 100% chloride (Cl), and 100% bicarbonate ($CO_3 + HCO_3$). The triangle to the left represents the cation composition, where the corners are magnesium (Mg), sodium or potassium (Na + K), and calcium (Ca). Once a water analysis has been made, the percentage of the various cations and anions may be calculated and plotted as a point on the cation triangle and a point on the anion triangle. Multiple data may be plotted on the same plot. The water type is designated by the location of the sample points on the triangles. The points on the triangles may be projected onto the adjoining rectangles. The lines will intersect in the central rectangle, yielding a point that represents the major-ion composition for that sample on a percentage basis. These lines can be extended further into the adjacent rectangles. The rectangles are scaled and are used to compare changes in various samples. These two rectangles may be scaled in terms of two parameters selected from a number of possibilities, including total dissolved solids, ionic strength, hardness, pH, etc. For this application, the two rectangles are scaled in terms of total dissolved solids (right rectangle) and time (lower rectangle). Thus, an observance of these rectangles indicates how these parameters change with each sample or, in the case of the time scale, how the sample composition changes with time.

In Figure 4, the plots for the north and south monitor wells at Site 1 represent the native ground water as a sodium chloride water. The injection fluid (a slightly acidic waste) is represented as a sodium bicarbonate water. These two water types may be considered end members for water quality throughout the area of aquifer affected by injection. That is, the chemical composition of the ground water between the monitor wells and the injection well will plot along a line connecting the two end-member points. Because neither monitor well shows any significant change in composition over time, it is suggested that components of the injection fluid have not reached these wells. Pascale and Martin (1978), however, point out that the water samples from the south monitor well showed increases in bicarbonate concentrations from 282 mg/l to 636 mg/l and that dissolved organic carbon increased from 9 mg/l to 47 mg/l between September 1973 and March 1977. They further state that these increases at the south monitor well were accompanied by an increase in dissolved gas concentration and a distinctive odor like that of the injection fluid. Thus, it is not clear if waste components have reached the south monitor well.

It should also be pointed out that geochemical effects were detected in the deep monitor well (see Figure 1) about 0.25 mi (0.4 km) from the injection wells about 10 months after injection began (Goolsby, 1972). The geochemical effects included increases in calcium, total alkalinity, and the formation of nitrogen and methane gas. This well was subsequently plugged to prevent communication with overlying aquifers.

By contrast, in Figure 5, the deep-test monitor well at Site 2 changes in chemical composition over time. In this case, the north monitor well and the injection fluid represent the end-member water types as sodium chloride and sodium sulfate, respectively. The Durov plot shows the invasion of waste constituents at the deep-test monitor well by the movement of the composition point in the central rectangle along a line between the end members. As a general comparison of the two injection sites, it should be noted that the north monitor well at Site 2 shows a slightly lower chloride/bicarbonate ratio and a lower TDS content than the Site 1 monitor wells.

Figure 6 demonstrates the change in water quality over the region from a sodium chloride water at regional well 1 to a sodium bicarbonate water at regional well 3. The increase in calcium and magnesium and decrease in chloride at regional well 3 indicates an increase in fresh water due to the proximity of recharge waters where the lower limestone of the Floridan aquifer crops out. Note that waters from the Site 1 injection fluid and regional well 3 are classified under the same water type, although representative points on the composition triangles are significantly different. This emphasizes the broad range of this classification system.

In addition to Durov plots, time series plots of specific constituents were plotted to assess injection fluid movement and formation fluid movement. Although not presented, Site 1 monitor wells showed a scatter of points that suggests the variation is due to inconsistencies in sampling methods

and not individual analyses. Regional wells demonstrated a lack of data but did show that the chloride content of each well differs by an order of magnitude with chloride increasing to the south, down dip from the aquifer outcrop and recharge area.

In summary, the water-quality analysis is helpful in characterizing water types and provides general conclusions concerning injection fluid movement at Site 2 and trends in water salinity. Unfortunately, the water-quality analysis is not sufficient to indicate the movement of the injection fluid at Site 1 or movement of formation fluid.

Regional Flow Modeling

In this section, the work of Merritt (1984) is extended to simulate both steady-state and transient flow fields in the lower limestone of the Floridan aquifer using injection conditions representative of 1986 and projected for future years. The results of this work are used to define flow conditions and to assess the relative movement of the waste plume (injection fluid) and 10,000 mg/l TDS isopleth (formation fluid). In addition, the model is used to provide an estimate of the extent of pressure effects in the ground-water system resulting from injection. The computer code used in this application is Sandia Waste-Isolation Flow and Transport Code (SWIFT), a fully three-dimensional, finite-difference algorithm (Cranwell and Reeves, 1981; Reeves et al., 1986a, b). The code has been applied to a variety of geohydrologic problems (Finley and Reeves, 1982; Reeves et al., 1986c) and was developed under a rigorous quality assurance program (Ward et al., 1984).

Simulation Description

The pertinent data used for the regional flow model are listed in Table 1. Merritt's conceptual model was used with the following changes: Merritt assumes a minor density variation between native and injection fluids, but states that the assumption did not affect the regional hydraulic solution (Merritt, 1984, p. 43). Based on the negligible effect, a uniform equivalent fresh-water density [i.e., 62.4 lb/ft^3 (1 gm/cm^3)] is used throughout the system. The model developed by Merritt reproduced the effects of injection fairly accurately on a regional scale. Near-well pressure buildup, however, was overstimated because increased permeability near the injection well(s) (based on field measurement taken in 1982) was not incorporated into his model. A modification was made to the near-well permeability distribution in order to reproduce more accurately observed pressure buildup at the injection well(s). Except for the above changes, the assumptions of the regional flow model are consistent with Merritt's model.

The model developed herein is a two-dimensional, single-layer representation with flow confined from above and below. The finite-difference grid used for the model is shown in Figure 7. The boundary conditions, taken directly from Merritt's model, are illustrated in Figure 3. A specified head boundary (based on extrapolation of limited preinjection head data) is assigned to the eastern half of the grid, which represents the outcrop and pinchout boundary of the confining layer to the north and east, and the subcrop boundary to the south. The remaining boundary is considered impermeable and specified as a zero-flux boundary. This corresponds to permeability barriers to the northwest and west resulting from facies changes and faults. Figure 3 also shows the delineation of three transmissivity zones based on aquifer tests.

In addition to the three transmissivity zones presented in Figure 3 and Table 1, the model was modified to include near-well transmissivity zones. These zones are characterized by regions exhibiting increased transmissivity. The increases are assumed to have resulted from dissolution of the limestone as a result of the injection fluids and may extend several hundred feet into the formation. A field test performed at Site 1 in 1982, after 19 years of injection, indicated a permeability of 22 darcies, or a hydraulic conductivity of approximately 60 ft/d (18 m/d). Assuming an effective formation thickness of 60 ft (18 m), the corresponding transmissivity is 3600 ft^2/d (334 m^2/d). This value is approximately 4.2 times greater than the 850 ft^2/d (79 m^2/d) value determined in the early 1960s and used by Merritt.

A total of seven flow simulations were made and are summarized in Table 2. As shown, the first three simulations (cases 1, 2, and 3) were made to reproduce Merritt's regional simulation results. The next three simulations were sensitivity runs used to account for the increased hydraulic conductivity near the injection wells. The cases considered are described in Table 3 as cases A, B, and C. The final flow simulation uses information gained from the previous simulations and incorporates transient conditions with variable injection rates. This final flow simulation is used for the subsequent solute transport analysis. All seven simulations are described below.

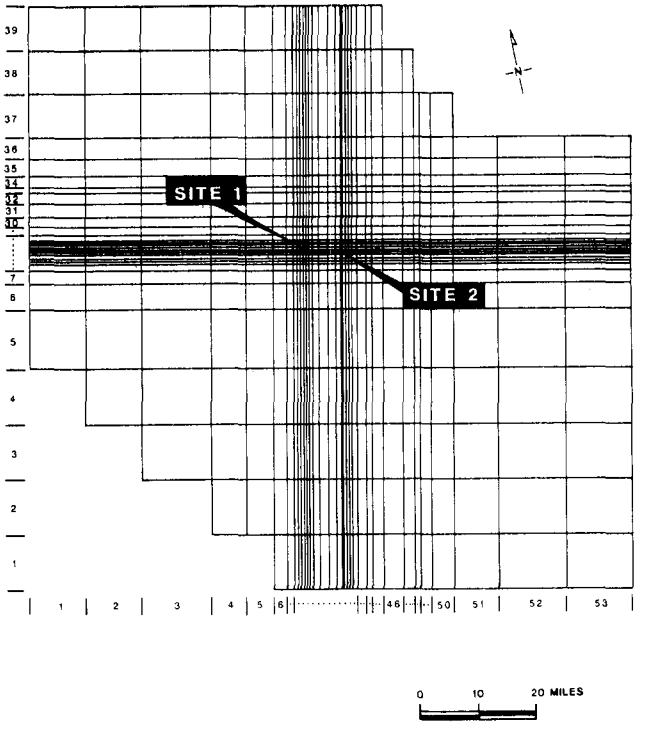

Fig. 7. Finite-difference grid used for regional flow model.

Table 1. Data Used for Regional Flow Model

Parameter	*Value*	*Source*
Porosity	0.28	Merritt (1984, p. 44)
Transmissivity[1]		Merritt (1984, p. 35)
Strip 1	850 ft^2/d (79 m^2/d)	
Strip 2	1500 ft^2/d (139 m^2/d)	
Strip 3	4000 ft^2/d (372 m^2/d)	
Water viscosity	0.76 cp	Merritt (1984, p. 18)
Water density[2]	62.4 lb/ft^3 (1 gm/cm^3)	
Well Index[3]		
Site 1	1406.8 ft^2/d (130.7 m^2/d)	
Site 2	2479.2 ft^2/d (230.2 m^2/d)	
Rock compressibility	3.5×10^{-5} psi^{-1} (5.07×10^{-9} Pa^{-1})	
Water compressibility	3.0×10^{-6} psi^{-1} (4.35×10^{-10} Pa^{-1})	

[1] The x-direction and y-direction transmissivities are equivalent. Location of the strips are presented in Figure 2. Transmissivity is based on the product of hydraulic conductivity and layer thickness.
[2] A uniform equivalent fresh-water density assumed throughout the system.

Steady-state (case 3)	1986 rates	No near-well zones	Reproduce Merritt's regional results
Steady-state	1986 rates	No near-well zones (case A)[2]	Sensitivity to est. near-well K increase
Steady-state	1986 rates	No near-well zones (case B)[2]	Sensitivity to est. near-well K increase
Steady-state	1986 rates	No near-well zones (case C)[2]	Sensitivity to est. near-well K increase
Transient	Step-wise[1]	No near-well zones (case C)[2]	Account for variation in injection rates

[1]Refer to Figure 7.
[2]Refer to Table 3.

In an effort to reproduce Merritt's results, three steady-state simulations are performed in which injection rates were varied to assess the changes in regional pressure (or head) distribution since the initiation of injection at Site 1. Case 1 represents preinjection conditions, where injection rates are set to zero. Case 2 represents steady-state conditions from 1963 to 1978. As discussed by Merritt (1984, p. 6), for the period 1963-1978, the Site 1 rate varied from a low of 550 gpm (2.1 m^3/min) in 1963 to a high of 2,605 gpm (9.9 m^3/min) in 1972. For this reason, Merritt simulated this time period using transient conditions. He points out, however, that most available water-level data were measured after 1971, so that history matching during this time period was difficult. From the commencement of injection at Site 2 in June 1975 until 1978, injection rates remained at nearly the same level at both sites, so a single average at each site was used during that period. For case 2, these average values were used and are referred to as the 1978 injection rates. They were determined from Merritt (1984) to be 2,295 gpm (8.7 m^3/min) and 550 gpm (2.1 m^3/min) for Sites 1 and 2, respectively. Because of the responsiveness of the limestone aquifer, the average rates provide a final pressure (head) result similar to the resultant head in Merritt's transient simulation. For case 3, average rates were also used and are referred to as the 1986 injection rates. These rates are 1,250

C*	4.2	2.1	1.0
Merritt	1.0	1.0	1.0

*Interpretation is based on field test performed in 1982 (oral communication from L. Brown, 1987).

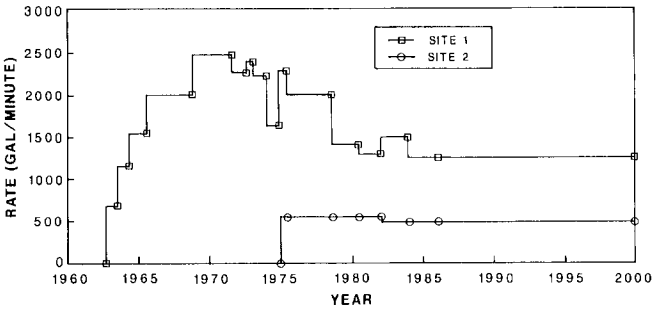

Fig. 8. Waste injection rates used in the transient flow simulations with 16 pumping periods. Data from Merritt (1984), with future rates at Sites 1 and 2 assumed to be 1250 gpm (4.7 m^3/min) and 500 gpm (1.9 m^3/min), respectively.

gpm (4.7 m^3/min) and 500 gpm (1.9 m^3/min) for Sites 1 and 2, respectively (oral communication, L. Brown, 1987). Due to source reduction efforts at Site 1, future injection rates are expected to decrease. The flow system responds very rapidly, thus calculating the steady-state potentiometric surface is a good approximation of the flow system. In the final simulations, this approximation is improved by using additional pumping periods.

To account for increased permeability near the injection wells, three refined steady-state cases are simulated, as presented in Table 3. The injection wells at Site 1 are assumed to be situated in the center of concentric zones that increase in transmissivity with proximity to the well. Three cases (A, B, and C) are used to simulate the steady-state flow field with 1986 injection rates. The three cases, presented in Table 3, are based on history matching against the observed pressure buildups at the injection wells. These refined cases were simulated after reproducing Merritt's regional results (i.e., cases 1, 2, and 3).

To more accurately account for variations in the injection rates, transient flow simulations also are performed using step-wise changes in the injection rates at Sites 1 and 2. The injection rates for each pumping period are time-averaged values and are provided in Figure 8. A summary of all simulations performed for the regional flow modeling is given in Table 2.

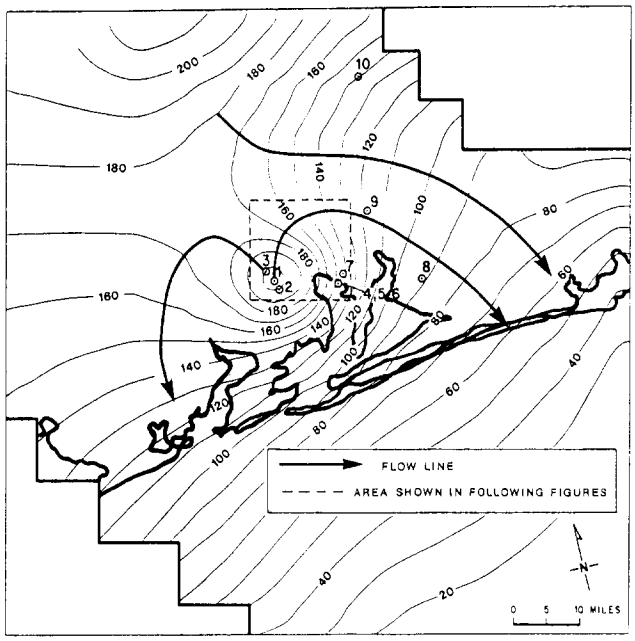

Fig. 9. Steady-state hydraulic head distribution (ft MSL) for 1986 injection conditions and case C transmissivity distribution.

Simulation Results

Results for steady-state cases 1 and 2 are not shown. The main purpose for simulating these cases was to reproduce the results of Merritt (1984). For both cases, head distributions showed good agreement with Merritt's results and the observed data. For preinjection conditions, the hydraulic gradient trends south-southeast over the region and grades approximately 3.8×10^{-4} ft/ft in the area of Site 1. Case 2 demonstrates a head increase over the region as a result of the injection. The head distribution for case 3, presented in Figure 9, shows a reduction in head (as compared to case 2) as a result of the decrease in injection rates. Also shown are generalized flow lines.

The data sets for the steady-state simulations were modified to include the refined transmissivity zones described in Table 3. The results of these simulations are reported for 10 locations, representing wells in the Floridan aquifer (see Table 4). The increased transmissivity zone locally impacts

the pressure buildup at the Site 1 injection well(s) only. Case B represents the greatest local increase in transmissivity and yields the smallest simulated head at Site 1. While case C yields the greatest buildup, it is thought to most accurately represent the near-well zone transmissivity based on comparison with field test (Table 3).

Model calibration was limited to near-well zone transmissivity. Calibration of transmissivity in other portions of the modeled area performed by Merritt (1984) appeared correct and were not changed. The steady-state calibration is good at Site 1 north and south monitor wells (2) and (3) and at Site 2 north monitor well (7). The difference in the observed and simulated heads at the regional wells is due to assumptions of steady flow and the effects of imposing a prescribed head boundary along the northern edge of the model.

Transient ground-water flow was simulated using the stepwise injection rates given in Figure 8. The computed hydraulic head in the lower limestone of the Floridan aquifer, for the beginning of years 1974, 1987, and 2033, is presented in Figures 10a-10c. These dates correspond to the year prior to beginning of Site 2 operation, the date of this study, and 70 years of operation at Site 1, respectively. Only a portion of the modeled grid is shown such that pressure buildups at both Sites 1 and 2 can be seen. Regionally (away from the area shown in Figure 10), the computed heads are similar to those computed in the steady-state simulations (Figure 9). By the year 1974 (Figure 10a), the pressure buildup at Site 1 exceeds 340 ft above sea level. By 1987 (Figure 10b), the head at Site 1 is reduced as a result of the decrease in the injection rate, and a buildup is evident at Site 2. In the year 2033 (Figure 10c), the predicted heads are similar to those in 1987 because the injection rates are the same.

The results of these simulations may be used to assess the extent of the hydraulic pressure effects of injection under different conditions. Though there are different ways to estimate the extent of pressure effects, one conservative way is to use the distance to the stagnation point, that is, the point where the hydraulic gradient reverses direction (see Figure 9, northwest of Site 1). On the southeast side of the saddle point, the gradient, hence flow direction, is toward

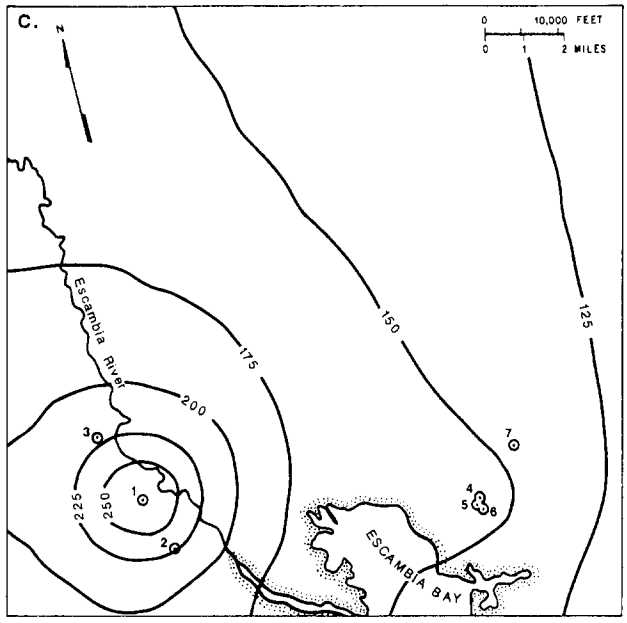

Fig. 10c. Partial display of the computed 2033 hydraulic head distribution (ft MSL) based on transient injection conditions (see Figure 8 for inset location).

the northwest. This flow changes direction at the stagnation point. The extent or distance of pressure effects would be different toward the northeast, but the stagnation point does provide a means to compare the relative extent of the head changes produced by different injection rates. Using the 1978 injection rates and steady-state conditions, the pressure front (defined by the saddle point and not shown) extends to the northwest approximately 25 mi (40 km) from the Site 1 injection wells. This is significantly less than the estimate of approximately 40 mi (64 km) made by Faulkner and Pascale (1975), who used an analytical approach with uniform properties and infinite boundaries. Using the 1986 injection rates and steady-state conditions, the current pressure front (defined by the saddle point) extends only 15 mi (24 km) (see Figure 9).

The extent of the pressure front using transient injection conditions is similar to, yet more accurate than, that produced by the steady-state simulations. Using transient analysis, the position of the stagnation point moves from the point of injection to the northwest. In 1987, the calculated pressure front using the transient simulation extends less than 15 mi (24 km) to the northwest. Because it is a more accurate representation, the transient flow analysis is used as the basis for salt-water front and waste plume movement described in the following sections.

After 2033, injection was assumed to be discontinued. The transient simulation was continued for another 100 years to 2133 with zero injection rates. Later results of this simulation are not shown; however, the head decreases rapidly and, within 10 years after stopping injection, the preinjection flow field is reestablished.

To account for possible future changes in the injection rates, a limited sensitivity analysis was conducted using the transient simulation. After 1986, the injection rate at Site 1 was assumed to increase 10% to 1375 gpm. Using this new rate, the head at the injection well increased from 437 feet to 471 feet. The increase of 34 feet relative to a preinjection head of 90 feet corresponds to approximately 10%.

Modeling the 10,000 mg/l Total Dissolved Solids Isopleth

The results obtained from modeling the salt-water front (formation fluid) in the lower limestone of the Floridan aquifer near Site 1 are presented in this section. The goal is to estimate the effects of injection on the formation fluid; more specifically, to estimate the relative movement of the salt-water front (as defined by the 10,000 mg/l TDS isopleth) caused by the injection. The 10,000 mg/l TDS isopleth is used because of regulatory considerations, where less than 10,000 mg/l TDS is defined as an underground source of drinking water. Definition and movement of the 10,000 mg/l total dissolved solids isopleth is complicated by data limitations and uncertainty associated with the processes of dispersion and density tilting (the tendency to have the denser salt water undercut the lighter fresh water, causing an interface between the two fluids to tilt). In addition, its location may vary with depth and the isopleth may move in response to recharge, regional pumping, and even as a result of past changes in sea-level elevation. In places, the natural water-quality contours are perpendicular to the preinjection flow system (Faulkner and Pascale, 1975). That is, the preinjection flow direction is toward the southeast, whereas chloride concentrations increase toward the southwest. This could be the result of complex subcropping of the Floridan aquifer under the Gulf of Mexico combined with changes in concentrations that are still occurring as a result of the last change in sea level. Due to these uncertainties, movement of the 10,000 mg/l TDS isopleth was simulated using particle tracking in the horizontal plane.

For the purpose of this study, the isopleth is defined as a vertical plane (ignoring significant density tilting) that separates ground water in the lower limestone of the Floridan aquifer that is less than 10,000 mg/l from ground water that is greater than 10,000 mg/l of total dissolved solids. There is considerable uncertainty as to where the isopleth occurs due to the sparseness of water-quality measurements. Because this interface was actually in dynamic equilibrium prior to 1963, an approach is taken in which the density-driven movements are assumed to be relatively insignificant and are, therefore, not considered. In this analysis, only hydraulically induced movement or forced convection is examined and only the relative or incremental movement of the isopleth, caused by injection, is computed.

The approach used is an extension of the regional flow model where calculated ground-water velocities are used to integrate the movement of the 10,000 mg/l TDS isopleth. Conservative assumptions include using the stepwise transient velocity field based on the injection rates presented in Figure 8. The movement of the 10,000 mg/l TDS isopleth was calculated by moving discrete particles. Twelve particle locations along the isopleth are initialized and calculations performed for 70 years. The initial 1963 10,000 mg/l TDS isopleth position is based on the inferred chloride distribution in Faulkner and Pascale (1975), where chloride is assumed to represent approximately 55% of the total dissolved solids. In this simulation, each particle trace is calculated for a given time step and the particles translated. Over the simulation period, the particles are translated hundreds of times. The model is based on the assumption that the aquifer is 60 ft (18 m) thick and has a porosity of 0.28. These are conservative estimates of the formation properties in that they represent a minimum volume for injection fluid to fill, causing the 10,000 mg/l TDS isopleth to migrate further for a given injection volume. As discussed in the next section, an aquifer thickness of 100 ft is a more representative value at Site 1.

Results of isopleth movement are shown in Figure 11. The 12 particles move at different rates and in different directions in response to the local ground-water velocity and direction of flow. Prior to injection, the regional flow in the Pensacola area was approximately to the south-southeast. Within a few years, the movement of each particle begins to be impacted by the injection wells. Another change in direction results from injection effects at Site 2, which began in 1975. This is demonstrated by the movement of the southeasternmost particle in Figure 11. The current (1987) average movement (average of the particles used in this analysis) of the 10,000 mg/l TDS isopleth is calculated to be approxi-

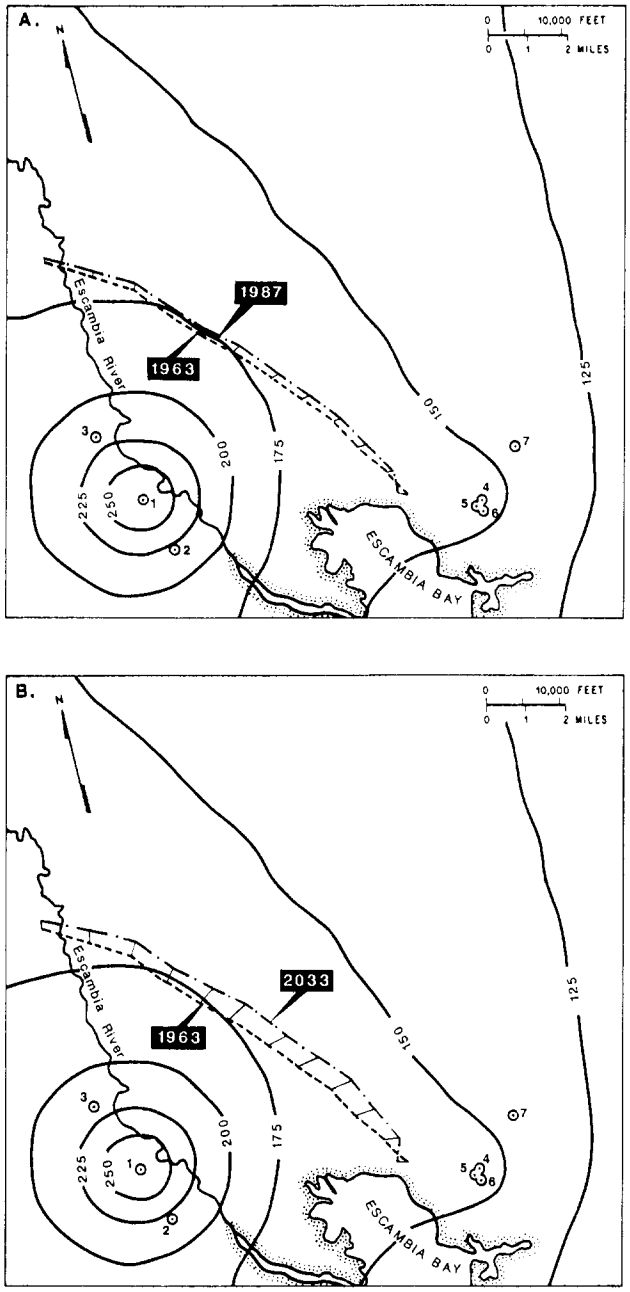

Fig. 11. Simulated movement of 10,000 mg/l TDS isopleth from 1963-1987(A) and 1963-2033(B). Potentiometric surface based on transient simulation with results shown for 1987.

mately 900 ft (274 m) from the initial position. By the year 2033, the average movement will be 2200 ft (671 m). These distances are substantially less than the average radius of the waste plume (discussed in the next section) because they are further from the region of head buildup near the injection wells.

Using a 10% higher injection rate at Site 1 after 1986 caused an increase in the integrated (1963-2033) particle travel distance of 6 to 9%, depending on the locations of the particles. Using velocities (from the flow modeling) after 2033 and cessation of injection, the particles drift slowly in a southeasterly direction in response to reestablishment of preinjection flow conditions. Therefore, the maximum displacement of the 10,000 mg/l TDS isopleth is observed in 2033.

Modeling Injection Fluid

A modeling study was performed to simulate the position of the injection fluid at Site 1. This study is based on the hypothesis that injection will continue for several more decades, probably at the current rate. Predictive simulations are performed from 1963 to 2033. The assumptions used in this study are conservative, i.e., adsorption and degradation are assumed to be negligible.

The approach used here is twofold, employing (1) a nested grid and (2) a radial grid. The first step is to nest a refined transport grid within a subsection of the regional flow grid (Figure 7). The regional flow effects are passed directly into the local transport grid through boundary conditions. This is based on the telescopic mesh refinement method (see Ward et al., 1987). For this study, three mesh refinements (not shown) were performed to create three local grids and to obtain an accurate transport solution. The local grids were square and measured 2500 ft (762 m), 5000 ft (1524 m), and 21,000 ft (6401 m) on a side. For each of these grids, steady-state ground-water velocities from the regional simulation (Figure 9) were interpolated on the local transport grids. Preliminary transport analyses were performed for 10 yrs of injection, and the waste plume evolved in a symmetric, radial pattern. As exhibited in the head distribution contours (e.g., see Figure 9), the symmetric pattern in hydraulic head extends over 5 mi (8 km) before regional impact is experienced. These results support and justify the use of a radial grid approach (described below) as the injection fluid is not expected to extend beyond a few miles.

Based on the above results, the final step in this analysis was simplified by using a radial grid. The assumption of radial symmetry is justified, based on the results from the nested gridding approach. The propagation of the pressure front from the injection well precedes that of the injection fluid. In Figures 10a-10c, the simulated 1974, 1987, and 2033 head contours for the lower limestone of the Floridan aquifer are presented, respectively. Based on volume calculations, the injected fluid is not expected to travel beyond the computed radial hydraulic head distribution by the year 2033, further supporting the radial transport analysis.

A transient simulation of the injection operations is performed using the rates in Figure 8. In this approach, ground-water velocities were calculated that vary with time and location. The radial grid is designed using 50 grid blocks ranging in width from approximately 80 ft (24 m) near the injection well(s) to 780 ft (238 m) near the perimeter of the 14,000-ft radius grid. Based on the work of Merritt (1984), an aquifer thickness of 60 ft (18 m) and a porosity of 28 percent were used. An additional simulation using a 100-ft (30-m) thickness was also performed, because studies at Site 1 indicate 100 ft (30 m) to be more representative of actual local conditions (oral communication, L. Brown, 1987).

The value of dispersivity in the hydrodynamic dispersion tensor used in the model was based on experience and, in part, a field test made at Site 2 for which a value of 33 ft (10 m) was determined. However, Beekman and Appelo

(1991) recently observed that during salt-water displacement by fresh ground water, the dispersivity was three times larger than for the reverse situation. Therefore, a value of 100 ft (30 m) is used and subject to some unknown degree of uncertainty. No attempts were made to calibrate the model because, as discussed in the section on water quality, waste breakthrough at the monitoring wells has not yet been observed to allow calibration.

Because the strata overlying and underlying the lower limestone of the Floridan aquifer are assumed to be impermeable, only waste concentration profiles for the injection zone are simulated. Results for the time periods displayed demonstrate the dispersed waste plume concentration as a function of distance from the injection well.

The undiluted waste body, defined as 95% of injection concentration, is predicted to enlarge to almost 3 mi (4.8 km) in diameter by the year 2033 for the case of the conservative estimate for aquifer thickness [60 ft (18 m)]. In the second case, an aquifer thickness of 100 ft (30 m) is used. Because of the greater thickness, the extent of the undiluted waste body is reduced by the ratio of the thicknesses in the two cases. By the year 2033, the undiluted body diameter is approximately 2.1 mi (3.4 km) in diameter. In both cases, by 1987, dispersed portions of the plume are in the vicinity of the south monitor well, which is consistent with some evidence discussed in the section on water quality. Plume contour plots are presented for 1987 for the 100-ft (30-m) aquifer thickness case in Figure 12. This shows the current waste body size relative to the regional monitor wells.

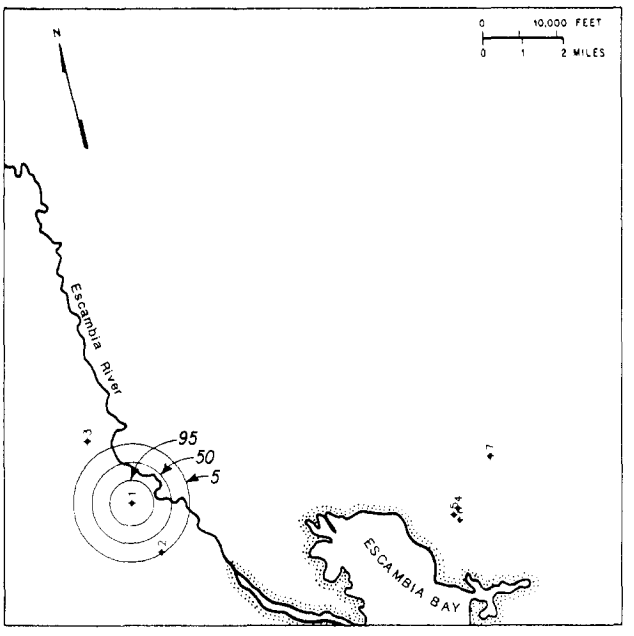

Fig. 12. Simulated plume contours (5, 50, 95% of injection concentration) in 1987 within a 100-ft thick injection zone.

Conclusions

Liquid injection in northwestern Florida has been analyzed. Water-quality data were helpful in defining water types and general trends, but did not show changes in water quality with time (except at Site 2), and therefore could not be used in transport model calibration. Flow model calibration had previously been performed by Merritt (1984), and his results were reproduced prior to making model refinements. These refinements consisted of increasing the hydraulic conductivity near the injection wells and using present injection rates.

Both steady-state and transient flow simulations were performed, with a transient flow simulation forming the basis for salt-water front (formation fluid) and injection fluid movement analysis. The salt-water front movement was analyzed using particle tracking, whereas injection fluid movement was analyzed using solute transport assuming cylindrical symmetry. The numerical simulations of groundwater flow and solute transport are used to support the following conclusions concerning injection Site 1 and vicinity:

- Based on the history match of available data, a two-dimensional transient representation of the regional groundwater flow system of the limestone aquifer provides an appropriate basis for subsequent analysis of injected waste transport.
- In order to match hydraulic head buildup near injection wells more accurately, increased zones of transmissivity were incorporated into the work of Merritt (1984) to represent zones of dissolutioning.
- For practical purposes, the pressure front associated with injection probably extends less than 15 mi (24 km). Because of reduced injection rates and a more accurate aquifer representation, the pressure buildup is much less than the 40 mi (64 km) extent predicted by Faulkner and Pascale (1975).
- The relative movement of the 10,000 mg/l TDS isopleth resulting from injection at Site 1 is very small, on a regional basis.
- Although the exact position of the 10,000 mg/l TDS isopleth is not known, the calculated average relative movement between 1963 and 1987 is approximately 900 ft (274 m) and between 1963 and 2033 is 2200 ft (671 m).
- The calculated undiluted injection fluid (95% of injection concentration) diameters range from 1.1 mi (2 km) to 1.5 mi (2.4 km) in 1987 and from 2.1 mi (3.4 km) to 3.0 mi (4.8 km) in the year 2033.

This modeling application demonstrates how various analysis tools are used to address different problems. Flow analysis required a regional model. Because the waste fluid migration was more limited geographically than the flow analysis, a simplified radial solute transport model was adequate to address waste migration issues (compare Figure 11 with Figure 10). Finally, the movement of formation fluid as represented by the 10,000 mg/l TDS isopleth was addressed using particle tracking. An attempt was made in each analysis to use an approach consistent with analysis goals and data availability. The simulation and analysis was motivated in response to regulatory concerns. Unlike many deep-well injection sites, however, the Pensacola area has relatively good spatial and temporal data coverage. Although each site is unique, the approach utilized in this study is applicable to other deep-well injection sites.

Acknowledgments

We would like to acknowledge the help of Laura Brown (formerly Monsanto, now U.S. Environmental Protection Agency) and Jerry Rinaldi (Monsanto) for their help in preparing this manuscript. We also acknowledge Mike Merritt (U.S. Geological Survey) for providing data sets used in Merritt (1984).

Abstract

A field-scale natural gradient tracer experiment with bromide, uranin and lithium was conducted in a heterogeneous aquifer at Krauthausen, Germany. The temporal and spatial evolution of the solute plumes was monitored over 398 days for bromide and 449 days for uranin and lithium. The spatial variability of basic aquifer parameters, hydraulic conductivity, and sorption parameters of the aquifer material was investigated in detail. Local Darcian velocities were measured using NH_4Br^{82} as a radioactive tracer in 33 observation wells. Vertical and horizontal correlation lengths of hydraulic properties were determined using variogram analysis. The magnitude of the local Darcian velocities was found to be lognormally distributed. In addition, the groundwater flow direction showed a clear trend in the vertical direction. The horizontal correlation length of the magnitude of Darcian velocity agreed with the correlation length of K estimated from grain size data. Batch experiments on aquifer sediments showed that sorption of uranin and lithium could be described by a Freundlich isotherm. The Freundlich n parameter of uranin sorption showed little variation with depth. The time evolution of the bromide plume was quantified in terms of spatial moments. The longitudinal effective dispersivity estimated from spatial moment analysis was within the range of calculated effective dispersivities,

1. Introduction

Mathematical models are increasingly used to describe the fate and mobility of pollutants in soils and groundwater, and to perform risk assessment of potentially hazardous substances. An accurate prediction of pollutant transport, however, requires knowledge of the spatial and temporal variation of transport properties, such as hydraulic, physico-chemical, and biological parameters. The spatial variation of soil and aquifer properties causes considerable fluctuations in solute concentrations in soils and aquifers, and leachate quantities from unsaturated soils (Dagan, 1989; Russo and Dagan, 1991). Theoretical and experimental investigations have shown that spatial variability of hydraulic conductivity, K, causes dispersive spreading of solutes, which is much larger than the spreading expected when using transport models with parameters determined from column experiments (Pickens and Grisak, 1981; Gelhar, 1986; Arya et al., 1988). Stochastic theories have been developed to relate this dispersive spreading to statistical properties of K (Gelhar and Axness, 1983; Dagan, 1984; Dagan, 1989; Gelhar, 1993; Jaekel and Vereecken, 1996, 1997). Some of these theories were compared with data obtained from large-scale field experiments, e.g., the Borden site tracer experiment (Sudicky, 1986), the Cape Cod tracer experiment (LeBlanc et al., 1991), and the Columbus tracer experiment (Boggs et al., 1992). Most of these studies and experiments investigated the transport of conservative tracers or substances assumed to undergo linear equilibrium or linear nonequilibrium sorption (Thorbjarnarson and Mackay, 1994; Zhang et al., 1998) in heterogeneous aquifers.

The tracer experiments at the Krauthausen field site were conceived to provide information on the transport of bromide as inert tracer and uranin and lithium as reactive tracers in a heterogeneous aquifer. Laboratory batch experiments and column displacement studies with sediment from the Krauthausen test site indicated that sorption of uranin and lithium may be described either by a Freundlich isotherm equation, hysteretic Freundlich sorption or linear nonequilibrium sorption (Vereecken et al., 1999b). Asymptotic analysis of uranin transport showed, e.g., that the value of the Freundlich n exponent derived from field breakthrough curves (BTCs) differed considerably from the values obtained in batch experiments. This indicates that a simple nonlinear equilibrium model is not appropriate to describe the field-scale behaviour of uranin. Which of the above sorption processes observed in column experiments is controlling the solute transport at the test site is presently not clear? Identification of the field-scale processes affecting transport of uranin and lithium requires, therefore, in a first step, detailed knowledge on the characteristics of the groundwater velocity field and the spatial variability of sediment properties.

In this study, the spatial variability of hydraulic conductivity, Darcian velocities, sediment properties and sorption parameters for lithium and uranin at the test site is

analyzed. Results of the large scale bromide tracer experiment are presented and evaluated using stochastic transport theory. In further work, the field-scale transport of lithium and uranin will be analyzed.

2. The field site

The Krauthausen test site is situated approximately 10 km northwest of the city of Düren and 6 km from the research center Jülich, Germany. The field site is located in the Lower Rhine Embayment and has an extension of 200×70 m (Fig. 1). A site specific geological profile was established on the basis of four drillings. These were conducted to a depth of 15 to 20 m (78–83 m above mean sea level (MSL)). The local base of the aquifer in which the tracer experiments were conducted is situated at a depth of 11–13 m (85–87 m above MSL) and consists of intermitting thin layers of clay and silt. Three different layers were distinguished in the aquifer (Döring, 1997): layer 1 corresponding to the Rur sediments (93–95 m above MSL); layer 2 corresponding to the upper part of the Rhine sediments (90–93 m above MSL); and layer 3 corresponding to the lower Rhine sediments (88–90 m above MSL).

The regional direction of groundwater flow is towards the NE with a hydraulic gradient of about 0.002. This gradient remained relatively constant in the period where tracer experiments conducted. Mean yearly precipitation in the area is about 690 mm. The groundwater table at the test site showed a significant seasonal variation. During summer, the groundwater level may be as low as 2.5 m below surface (95.5 m above MSL); and during winter, the level may rise up to approximately 1.0 m below surface (97 m above MSL).

Analysis of the groundwater quality (Fig. 1) showed high concentrations of chloride (70–100 ppm) prohibiting its use as a conservative tracer. The high nitrate concentrations (90–100 ppm) were caused by the intense agricultural activity in this region. The water is of the calcium-bicarbonate type with a relatively high amount of sulfate, the pH value is 6.7.

In order to ensure sufficient monitoring of the spatial and temporal distribution of the tracer substances as well as to obtain representative sediment materials for aquifer characterization, 68 observation wells with a diameter of 50 mm were installed to an elevation of 87 m above MSL (Fig. 1). A detailed specification of the installation procedure and observation well construction is given by Vereecken et al. (1999a). 58 observation wells were equipped with Multi-Level-Samplers (MLS) consisting of a bundle of 24 PE tubes (diameter 0.5 cm) attached to the outside wall of the observation well. The drilling diameter for all wells was 328 mm. The boreholes used for the installation of MLS were sealed at the bottom with clay and backfilled with gravel. The top part of the borehole was sealed with clay. Vertical distances between samplers range between 0.22 and 0.35 m. In order to prevent vertical mixing of the tracer substances in the fully screened wells (34 in total), large flexible silicon hoses were installed and operated under pressure in the course of the tracer experiments. These flexible tubes sealed the inside of the screened observation wells to prevent mixing and short cuts

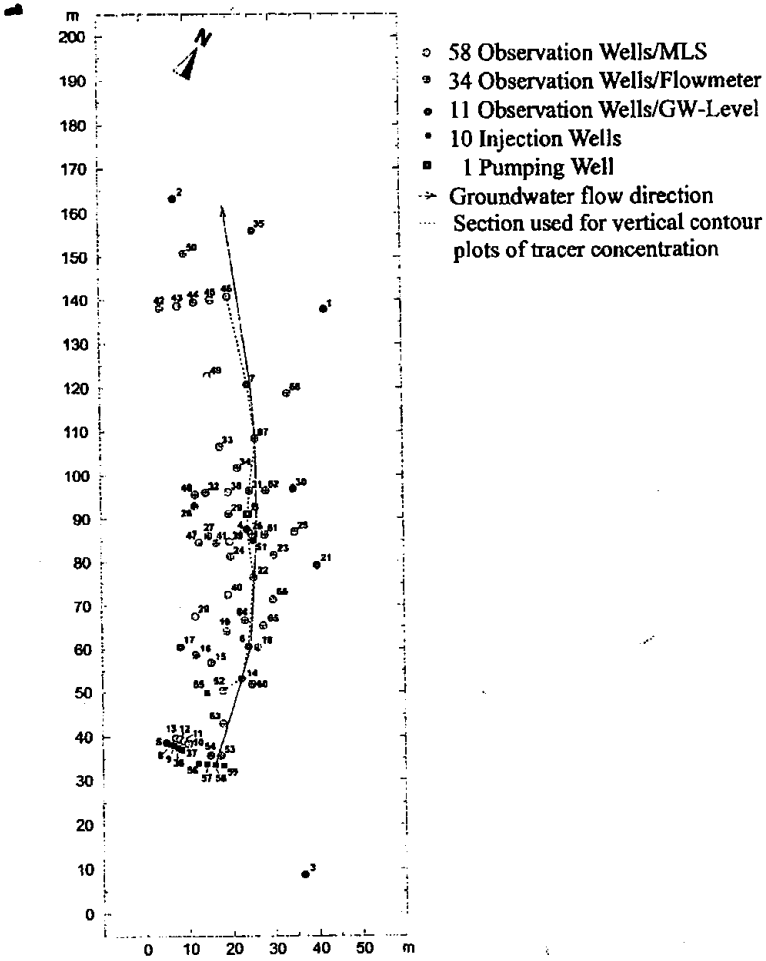

Fig. 1. Locations and category of the wells at the Krauthausen field site.

inside the wells. In various tests (Döring, 1997) the presence of these hoses showed no sorptive effect.

Two natural gradient field tracer experiments, one with lithium and uranin and one with bromide, were conducted at the test site Krauthausen. Evolution of the solute plumes was characterized by calculating spatial moments from 7 (bromide) and 12 (uranin and lithium) complete sampling rounds. In addition, BTCs were determined for 24 depths at each of 15 locations for a period of 449 days for the reactive tracers and 398 days for the bromide tracer. The number of data for the BTC ranged between 20 and 60. The heterogeneity of the aquifer material was characterized in terms of the spatial variation of sediment properties, hydraulic conductivity and sorption related parameters.

3. Determination of basic aquifer properties

3.1. Sediment properties

At the field site, 392 sediment samples were collected between soil surface and 87 m above MSL and analyzed for grain size distribution (12 fractions), organic carbon content (Corg), cation exchange capacity (CEC) and specific surface area (SSA). Of these 392 sediment samples, 250 samples (10 and 20 cm depth intervals) were obtained from undisturbed cores at locations 7, 22 and 32, while the remaining 142 sediment samples (20 cm depth intervals) were taken at 31 locations at three different elevation intervals (92–92.2, 91–91.2 and 90.4–90.6 m above MSL), which correspond to the depth of injection of the tracers.

Total porosity was determined on 83 soil cores collected at nine locations at the tracer site (Table 1). The majority of these 83 soil cores were taken at an elevation between 90 and 92 m above MSL. Total porosity was calculated from $\phi = 1 - (\rho/d)$ where ρ is the bulk density [ML^{-3}] and d is the sediment density [ML^{-3}]. Picnometer measurements on selected samples with varying porosity gave a mean value of 2.65 g/cm^3 for d with a standard deviation of 0.008 g/cm^3. The bulk density was obtained by drying and weighing the aquifer material at 10 cm core intervals. Since the top and bottom samples of each sediment core were disturbed during drilling, these samples were not considered.

The determination of the Corg was performed according to the method of Walkley–Black (Metson et al., 1979) on 1.2 g of sediment with a particle size < 2 mm. The CEC was determined by extracting 5 g sediment (< 2 mm) with an ammonium-acetate solution of pH 7. SSA was determined using a five-point BET method with nitrogen gas. Three to five replicate measurements on each sample were conducted. For one sample, 3.5 g sediment (< 2 mm) was used. Parameter values for the complete sediment fraction were obtained by correcting them by the weight percentage of the sediment fraction < 2 mm.

3.2. Hydraulic conductivity

Local scale variation of the hydraulic conductivity, K, was determined from flowmeter measurements and grain size data. Grain size data were determined from sieve analysis for the fractions larger than 50 μm (> 5 mm, 5–2 mm, 2–1 mm, 1 mm–500

Table 1
Statistics of the porosity for the different layers

	Height above mean sea level [m]	Mean porosity [%]	Standard deviation [%]	N
Layer 1	93–95	20	8	11
Layer 2	90–93	28	6	57
Layer 3	88–90	22	6	15
Layer 2+3	88–93	27	7	72
Overall	88–95	26	7	83

μm, 500–200 μm, 200–100 μm, 100–50 μm), while the pipette method was used to determine the silt and clay fractions (50–20, 20–10, 10–2 and <2 μm). K values were estimated from the grain size distribution data using two methods of Seiler (Seiler-I, Seiler-II) [1973], given by Eqs. (1) and (2):

$$K = c_1(u)\, d_{10}^2, \tag{1}$$

$$K = c_1(u)\, d_{25}^2, \tag{2}$$

where c_1 and c_2 are coefficients depending on the uniformity coefficient u, which is defined as d_{60}/d_{10}, where d_i is the ith percentile or quartile of the cumulative grain size distribution. Eqs. (1) and (2) are derived from experiments conducted by Seiler (1973) on glacial–fluvial sediments of aquifer located in Germany with an u-value ranging between 1 and 110. For values of u larger than 17, Eq. (2) (referred to as Seiler-II) proved to provide better estimates of the hydraulic conductivity than Eq. (1) and vice versa (Döring, 1997). The u-values of the sediments of the Krauthausen test site ranged between 5 and 30, suggesting that both Seiler methods may be equally suitable for the test site. The formula of Hazen was not used in this study because it only applies to sediments with u-values smaller than 5. Estimates of hydraulic conductivity using both equations of Seiler were, therefore, included in the analysis.

In addition to k-values estimated from grain size data, the borehole flowmeter method was used to characterize the small-scale variability of hydraulic conductivity. This method measures the vertical flow in a screened pumping well at different depth intervals. Details concerning the method can be found in Rehfeldt et al. (1992) and Molz et al. (1989). The layer-wise hydraulic conductivity was calculated from:

$$K_i = \frac{\Delta q_i}{\Delta q_d} K_p \tag{3}$$

where K_p is the hydraulic conductivity obtained from a large-scale pumping test, Δq_i is the inflow from the depth interval i, and Δq_d is the average of all inflow values obtained within one well. Similar approaches were successfully used by Molz et al. (1989), Rehfeldt et al. (1989) and Teutsch et al. (1991).

In the field, a mean pumping rate of 1500 l/h was imposed and the flowmeter measurements were started after the pumping rate became constant within an accuracy of ±4%. This was typically achieved after 15 min. This time duration is sufficient to warrant the use of Eq. (3) (Kabala, 1994). Measurements started at the deepest accessible point in the well and were made every 10 cm. For every depth, the average of 20 to 50 measurements was calculated subsequently.

3.3. Determination of local velocities

Single borehole measurements with a radioactive tracer (Fried et al., 1979; Klotz et al., 1979) were used to determine the variability in magnitude and direction of horizontal Darcian velocities at the field site. The procedure consisted of the following stages. $^{82}Br^-$ was injected and homogenized in a defined volume of a screened well, which was isolated by packers. This volume in our study was 1.0 dm^3 corresponding to a probed

layer thickness of 0.5 m. Due to the natural groundwater flow, $^{82}Br^-$ was transported and the dilution was measured with a scintillation detector as a function of time. From the dilution curve, the magnitude of the Darcian velocity was calculated. After the tracer had left the measuring volume, the flow direction was determined by locating the radioactive tracer plume. This was done with a lead-shielded scintillator, where a notch was left to allow radiation from a narrow sector to reach the detector. By rotating this arrangement, the direction with the maximum intensity gave the local flow direction.

Borehole measurements were performed in 33 out of the 34 wells designed for flowmeter measurements (Fig. 1) in the period from 12 to 14 March 1996. In 30 wells, the Darcian velocity was determined in two horizontal planes at 90.8 and 89.8 m above MSL. The packers were centered around these two depths. The elevation for measurement, thus, varied from 90.55 to 91.05 m and from 89.55 to 90.05 m above MSL. In addition, vertical velocity profiles were measured in locations 22, 32 and 53. Measurements started at 94.8 m above MSL with vertical increments of 0.5 m. In total, 82 measurements of groundwater velocity were performed. In some cases, the measuring device for flow direction could not be lowered to the required depth so that only 68 velocity measurements yielded data for flow direction.

3.4. Determination of sorption parameters

Sorption isotherms were determined on 47 samples using three equilibrium concentrations measured on eight batch samples. These samples were collected in layers 2 and 3. Uranin isotherms were determined using initial concentrations of 5 μg/l (three replicates), 50 μg/l (two replicates) and 500 μg/l (three replicates), the initial lithium concentrations were 90, 900 and 9000 μg/l with the same number of replicates as for uranin. Kinetic experiments showed that equilibrium conditions were obtained within 24

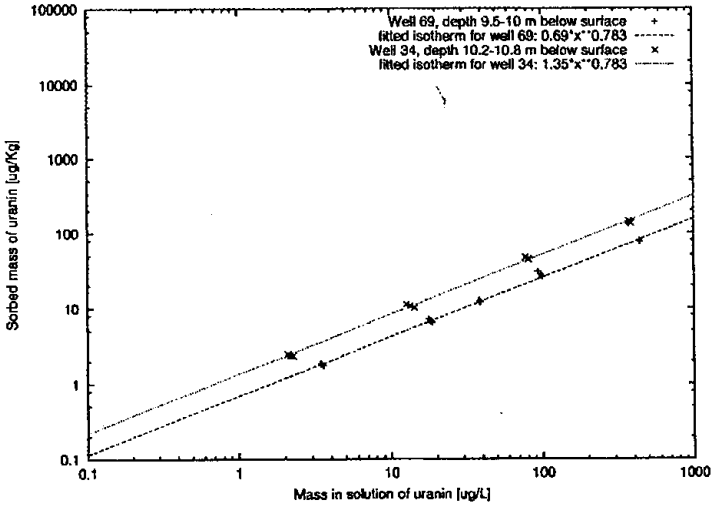

Fig. 2. Measured and fitted sorption isotherms for uranin.

h. This time scale was used to determine the sorbed concentration of uranin. Best fits of the measured isotherms for uranin and lithium were obtained with the Freundlich equation $s = kc^n$ where s is the sorbed mass and c is the solute concentration. This is shown in Fig. 2 for uranin for sediment taken at two different depths. The Freundlich equation was fitted to the 47 isotherms in order to derive the spatial variation of the Freundlich parameters in layer 2 + 3. Döring (1997) showed that the estimated k and n parameter values were not significantly different compared to estimates derived from batch experiments with six equilibrium concentrations. Details concerning the batch procedure, the selection of initial concentrations and the comparison of the two batch isotherm measurement procedures are given in Döring, (1997) and Döring et al. (1999). The k value of the complete sediment fraction was obtained by correcting it by the weight percentage of the fraction less than 2 mm of the whole sediment fraction.

To quantify the effect of differing Freundlich parameters on sorption and to facilitate comparison of sediment and sorption properties, the sorption capacity, S, was introduced. S is defined as the sorbed mass of lithium or uranin for a chosen solute concentration. For uranin and lithium, S was calculated for solute concentrations of 50 and 800 μg/l, respectively. These concentration values were assumed to be representative of concentrations observed at the field site after a travel distance of about 20 m.

4. Statistics of porosity and hydraulic conductivity

Results of the total porosity measurements are given in Table 1. The overall mean total porosity is 26%. Layer 2 has the highest mean porosity of 28% with a standard deviation of 6%. Lower values were found for layers 1 and 3. Table 2 lists the mean and variance of the estimated hydraulic conductivities using grain size data for the different layers of the aquifer. Both methods of Seiler (Section 3.2) gave comparable results for the mean and variance of $\ln K$ ($\sigma^2_{\ln K}$) on the complete dataset. Evaluating the layers separately, the Rur gravel (layer 1) is more heterogeneous than the other layers as indicated by large values of $\sigma^2_{\ln K}$. The $\sigma^2_{\ln K}$ value for the Rhine gravel (layer 2 + 3) is equal to 1.08 (Seiler-I) and 0.84 (Seiler-II). It is through this part of the aquifer that most of the tracer masses were transported. Layer 3 seems to be the most homogeneous with $\sigma^2_{\ln K}$ equal to 0.56 (Seiler-I) and 0.64 (Seiler-II). Vertical contour plots show that most of the tracer mass was probably transported through this part of the aquifer (see Section 10).

Table 2
The mean and variances of the hydraulic conductivities (m/s) of different layers using two indirect methods. The mean value $\langle K \rangle_g$ was calculated as the geometric mean

	$\langle K \rangle_g$	$\sigma^2_{\ln K}$	$\langle K \rangle_g$	$\sigma^2_{\ln K}$	$\langle K \rangle_g$	$\sigma^2_{\ln K}$	$\langle K \rangle_g$	$\sigma^2_{\ln K}$	$\langle K \rangle_g$	$\sigma^2_{\ln K}$

Seiler-II	1.0×10^{-3}	1.3	8.4×10^{-4}	3.1	1.3×10^{-3}	0.87	1.2×10^{-3}	0.84	9.4×10^{-4}	0.64

5. Spatial variation of hydraulic conductivity

5.1. Variogram analysis of hydraulic conductivities from grain size data

5.1.1. Vertical analysis

Vertical variograms of estimated hydraulic conductivities using the Seiler-I and Seiler-II method were calculated using the GEOPACK software by Yates (1989). The vertical variograms were based on 120 grain size distributions at locations 7, 22 and 32 for the layers 2 and 3. Layer 1 (Rur sediment) as well as the data points from the aquifer base below 88 m above MSL were excluded from the analysis. The exponential model as described by Journel and Huijbregts (1978) was fitted to the data points and gave a good description of the experimental variograms (Fig. 3). The estimated ranges were 0.6 and 0.4 m for the Seiler-I and Seiler-II methods, respectively, with a standard error of 0.3 m for both methods. The sill variance corrected for the nugget was 0.32 and 0.33 for Seiler-I and Seiler-II. The standard error of estimate was equal to 0.072 and 0.14, respectively. Both variograms showed a clear nugget of 0.32 and 0.24 with standard error of estimates of 0.076 and 0.15, respectively.

5.1.2. Horizontal analysis

3-D isotropic variograms of estimated hydraulic conductivities were calculated for layers 2 and 3 with GAMV3 (Deutsch and Journel, 1992) for irregularly spaced 3-D data. Variogram analysis of the data was done using an unit separation distance of 3.5 m and a lag tolerance of 1.75 m. The dip angle and the maximum acceptable horizontal deviation from the direction vector were set equal to 0.0 and 0.1 m, respectively.

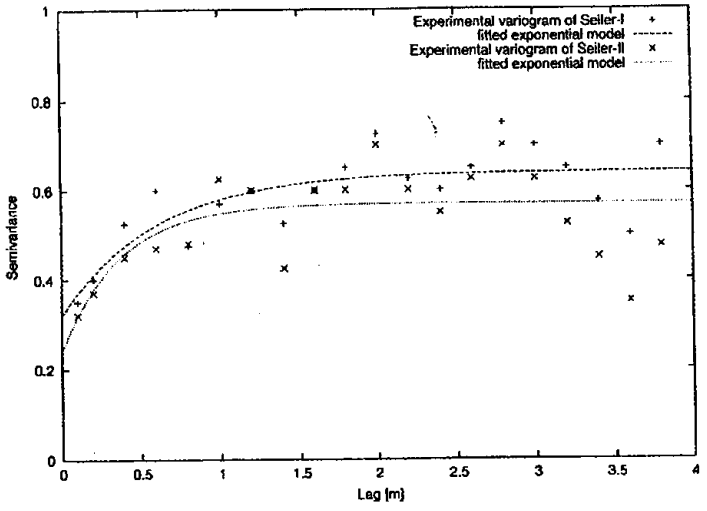

Fig. 3. Experimental and fitted exponential variogram of the estimated hydraulic conductivity in the vertical direction using the Seiler-I and Seiler-II method.

Analysis of the spatial variation of hydraulic conductivity estimates showed the presence of a linear trend, which could be described by:

$$\ln K(x,y,z) = 1.6 - 0.04x - 0.007y + 0.05z \tag{4}$$

where x, y and z are the space coordinates of the flow domain (y corresponds to the main flow direction of the groundwater). After substraction of this trend, an exponential variogram model with nugget was fitted to the hydraulic conductivity data obtained by the Seiler methods. Only for the Seiler-I model, a spatial correlation structure could be identified (Fig. 4). The estimated value of horizontal correlation length was 6.66 m with a standard error of estimate of 4.7 m. The estimated nugget value was equal to zero. The estimated sill variance was 0.88 with a standard error of estimate of 0.1.

5.2. Vertical variogram analysis of flowmeter data

Variogram calculations for separate vertical profiles are often inaccurate due to limited number of measurement points. This leads to a large uncertainty in the calculated semivariances, which are reflected by large scatter especially for large lag values. To overcome this limitation an overall vertical variogram was calculated using the K-values of all wells (not including replicate measurements). This was done by projecting the vertical profiles on to one transect where they were separated by a large lag distance to eliminate spurious correlations. In total 710 data points obtained from 23 wells were used to calculate the experimental variogram. The fitted exponential model gave a

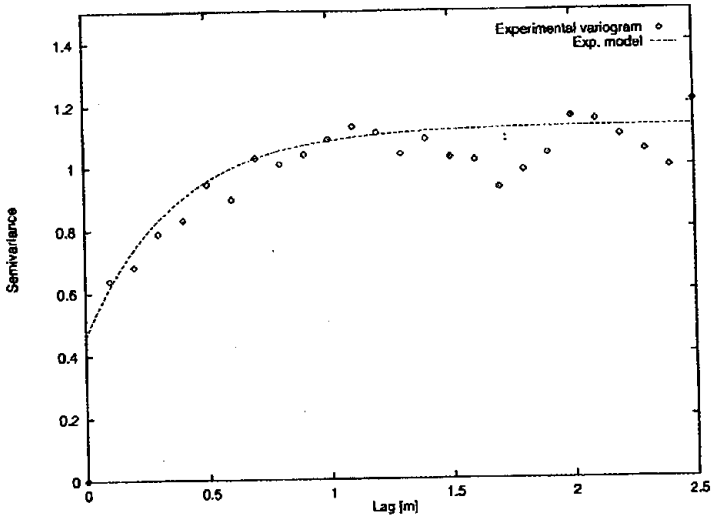

Fig. 4. Experimental and fitted exponential variogram of the hydraulic conductivity in the vertical direction using all locations projected on a transect.

correlation length of 0.37 m with a standard error of estimate of 0.09 m (Fig. 5). The value of the sill variance is 1.13, which is somewhat smaller than the sample variance of 1.3. The standard error of estimate is 0.11. The nugget is 0.46 with an standard error of estimate of 0.11. The estimated vertical correlation length is in good agreement with the value estimated from the Seiler-II (0.4 m) method. The Seiler-I method gave a correlation length that was a factor two times larger. This means that the vertical correlation length obtained from flowmeter measurements and grain size data estimates are quite similar. This is also supported by the findings of Rehfeldt et al. (1992).

5.3. Horizontal variogram analysis of flowmeter data

3-D experimental variograms of K values from flowmeter measurements were calculated using GAMV3 (Deutsch and Journel, 1992) in order to identify the horizontal correlation lengths of K. Numerous search schemes with different search directions, lag widths, dipping and tolerance angles were evaluated, but no spatial structure could be identified. The semivariances at small and large lag distances were of the same order of magnitude. This finding is in contrast to results of Rehfeldt et al. (1992), who succeeded in estimating the horizontal correlation length from flowmeter measurements. In their work, the ratio of vertical measurement interval and vertical correlation length was equal to 11, whereas, in our case, the ratio ranges between 2 and 3. At Cape Cod (Hess et al., 1992), the ratio ranged between 1 and 2.5. This small ratio may be one of the reasons why the experimental horizontal variograms presented in Hess et al. (1992) do not show such a clear spatial structure as those of Rehfeldt et al. (1992).

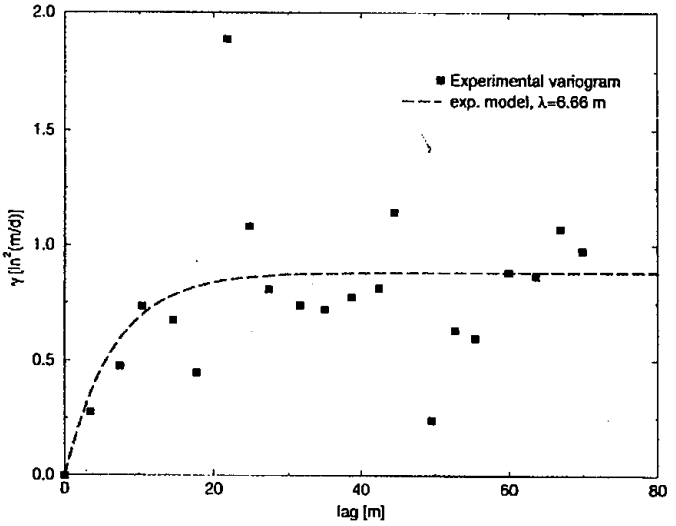

Fig. 5. 3-D experimental and fitted exponential variogram of estimated hydraulic conductivity using the Seiler-I method.

6. Spatial variation of local Darcian velocities

6.1. Univariate statistics of the local velocities

In Table 3, we show the statistics of the measured Darcian velocity U for two datasets (sets 1 and 2). Set 1 contains all data for which the magnitude of the Darcian velocity was available. In set 2, measurements were analyzed, which yielded both magnitude and direction of flow. The velocity components U_1 and U_2 were calculated by decomposing U along the mean flow path (340°N) and the direction perpendicular to it. Both datasets provide similar statistics of U. The Shapiro–Wilk test values for $\ln U$ are larger than 0.95 indicating that the observed data might come from a lognormal distribution. The geometric mean of U and overall variance of $\ln U$ in set 1 is 0.47 m/day and 1.86, respectively. Using an average porosity of 28% (layer 2), an average groundwater flow velocity of about 1.7 m/day is obtained. For set 2, the average groundwater flow velocity is 1.5 m/day. The calculated groundwater velocities on the basis of Table 2 (Seiler-I and Seiler-II, layer 2 + 3, layer 3, horiz.) range between 0.58 and 1.54 m/day. This indicates that the estimated groundwater velocities from the Seiler methods and the direct velocity measurements are of the same order of magnitude. Especially, the Seiler-II method is in good agreement.

The direction of measured groundwater velocities varied between 210°N and 90°N. The mean flow direction was at 340°N. Table 4 shows the change in magnitude and direction of U for the three wells for which a vertical profile was monitored. Large variations in the magnitude of the Darcian velocity occurred with depth. The values ranged between 0.47 and 7.87 m/day at location 22 and between 0.08 and 4.34 m/day at location 32. In addition, variations up to a factor of 9 occurred over a distance of 0.5 m. Further, the geometric mean of U varies considerably between wells with the lowest value of 0.24 m/day ($\exp(\ln K)$) at location 53 (Table 4). A second important observation is related to the direction of flow in the three observation wells. In these three wells, a systematic change in the flow direction was present. In layer 1, the direction of flow was towards the NNE and changed to N–W direction in layer 2. In

layer 3, the flow direction was towards NNE again. The change in flow direction corresponds to the three different hydrogeological layers distinguished on the basis of the geological survey. This variation is shown in more detail in Table 5. This table contains the means and variances of U_1 and U_2 ($\sigma^2_{U_1}$, $\sigma^2_{U_2}$) for the different hydrogeological layers (layer 1–3) and for the whole aquifer. U_1 is the velocity component in the direction of flow (340°N) and U_2 is the velocity component perpendicular to it. These components are obtained by straightforward decomposition of the measured groundwa-

Table 5
Mean and variance for the longitudinal and transversal velocity components U_1 and U_2 for different layers and layer 2+3. S–W test represents the Shapiro–Wilk test. Values in parentheses give the probability of finding a smaller value

		U_1, parallel to 340°	U_2, orthogonal to 340°
Layer 1 (10)	mean (m/day)	0.96	0.08

Overall (61)	mean (m/day)	0.70	0.12
	σ^2 ((m/day)^2)	2.2	3.0
	SW	0.48 (0.0001)	0.56 (0.0001)

ter velocities on the mean flow direction. Striking is the very high value of $\sigma^2_{U_2}$ (3.0) for the whole aquifer, which is even larger than $\sigma^2_{U_1}$ (2.2). In addition, the overall mean value of U_2 is positive, indicating a bias of the measurements of flow direction towards the eastern direction. The large variance in U_2 is a direct consequence of the trend present in the direction of the velocity. This trend may partly be removed by analysing the data according to the hydrogeological layers. For layer 1, the variance in U_2 is 0.6, which is about 31% of the variance in U_1. The mean value U_2 (0.08) is positive indicating that the flow directions were slightly biased in the eastern direction. For layer 2, the variance of U_2 (0.89) is larger than in layer 1 and its mean value is negative (-0.38), which indicates that the direction of the velocities was biased in the western direction. Finally, for layer 3, the velocity directions were heavily biased to the eastern direction again with a mean value of U_2 of 0.9. In addition, $\sigma^2_{U_2}$ (6.7) is almost twice as large as $\sigma^2_{U_1}$, showing that there was a considerable variation in the direction of flow. Thus, the high value for $\sigma^2_{U_2}$ in the whole aquifer was mainly caused by the strong variations in velocity magnitudes occurring in layer 3.

The above analysis shows that the main flow direction differs between the different hydrogeological layers. This variation seems to lead to large variances in velocity component perpendicular to the mean flow and may cause additional transverse dispersive effects. This may also partly explain the underestimation of transverse dispersivities observed at other test sites (at the Introduction) based on stochastic theories, which assume a constant mean velocity both in magnitude and direction.

6.2. *Spatial analysis of the local velocities*

Although the analysis of the direct velocity measurements showed a clear trend in the direction of the velocity (Section 6.1), the mean magnitude did not differ considerably between measurement planes. This was verified by comparing the mean velocity values of the two measurement planes combined with a trend analysis. Experimental variograms of $\ln U$ were, therefore, calculated using data from both measurement planes. Two experimental variograms were calculated using GAMV3 with a search angle of 340°N (case 1) and 310°N (case 2), respectively. The search direction of 340°N was motivated by the mean flow direction of the solute plumes (Section 12.4). The other search angle was chosen arbitrarily. The tolerance angle was 45°. An exponential correlation model was fitted through the experimental variograms of U (case 1, case 2). The correlation lengths are 4.2 m for case 1 and 6.9 m for case 2 (Table 6). Fig. 6 shows

Table 6
Results of variogram analysis for the magnitude of the measured Darcian velocities. Both exponential and spherical models are fitted. SSE is the sum of squared errors which is a measure for the goodness of fit; S.E. is the standard error of estimate, N is the number of data points; and L is the horizontal correlation length. The mentioned direction refers to the search angle of the variogram analysis

	L (m)	S.E.	Sill	S.E.	SSE	N
Case 1 (340°, magnitude)	4.19	2.16	2.10	0.18	2.63	53
Case 2 (310°, magnitude)	6.86	2.50	2.07	0.15	1.49	53

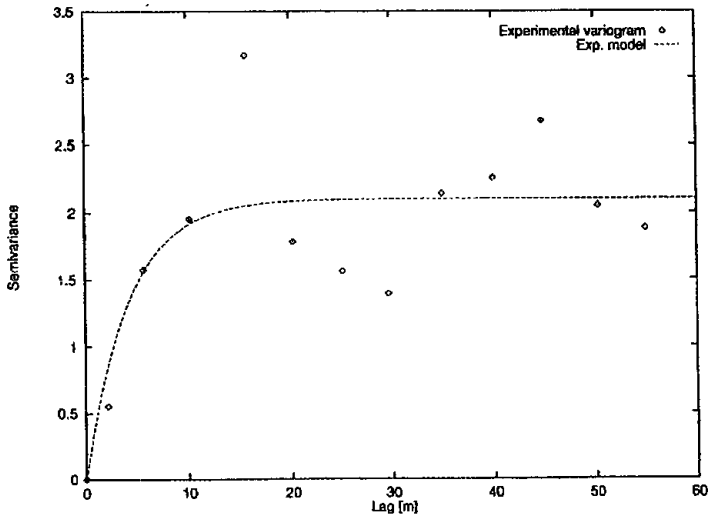

Fig. 6. Experimental and fitted exponential variogram of the horizontal velocity magnitude for a search direction of 340°N.

a fit of the exponential model to the experimental variogram obtained for case 1 (340°N). The experimental variogram was calculated for lag distances of 5 m centered at 2.5 m. Compared to the K-values of the flowmeter measurements for which no horizontal spatial structure could be found (Section 5.3), a clear spatial correlation was found for the Darcian velocities. As discussed previously for the flowmeter data, this may be due to the fact that the measurement interval of 0.5 m was more appropriate than the interval used in the flowmeter measurements to detect the horizontal correlation length.

The variogram analysis of the local velocities showed that the spatial dependence may be described by an exponential variogram function with a correlation length of 4.2 m. This correlation length is similar to the correlation length obtained from the K-values from grain size distribution (6.66 m, Section 5.1).

7. Spatial variation of Freundlich parameters for uranin and lithium

Mean (M), standard deviation (ST.DEV.) and measurement errors (ME.ER) for k and n of uranin and lithium in the Rhine gravel (layer 2 + 3) are listed in Table 7. For both substances, the measurement errors of k and n parameters are considerably lower than their observed spatial variation expressed by ST.DEV. Therefore, the measured variation is due to spatial variation in the estimated sorption parameters. For uranin in layer 2 + 3, the mean value of n and k (total sediment) are 0.83 and 0.35, respectively. The mean values of n for layer 2 (0.85) and 3 (0.81) are significantly (at 95% confidence interval) different. The mean value of k differs by a factor two to three between layers and is

Table 7

Lithium, tot. sed.						
M	6.7	0.53	8.4	0.49	3.2	0.61
ST.DEV.	±4.5	±0.08	±4.8	±0.06	±1.0	±0.05
ME.ER.	±1.3	±0.02	±1.6	±0.02	±0.6	±0.02

statistical different at 95% confidence. Lithium sorption is strongly nonlinear as indicated by the low values of n, ranging between 0.49 and 0.61 (Table 7). Mean k values of the total sediment range between 3.2 and 8.4. The mean values of k and n for layer 2 and layer 3 are statistically different at a confidence level of 95%. Due to the limited number of data and the clear difference in mean values between layers, no spatial analysis of n and k was performed.

8. Correlation analysis of sorption and aquifer parameters

8.1. Correlation between hydraulic conductivity and sorption parameters

Correlation coefficients are calculated between hydraulic conductivity, K, and sorption parameters, n and k, for lithium and uranin (Table 8). Hydraulic conductivities were estimated from grain size data using the method of Seiler-II (Section 3.2). The

Table 8
Correlation coefficients for uranin and lithium sorption parameters and hydraulic conductivity K

correlation coefficients are very low both for uranin and lithium and this for both types of sediment fraction. The largest correlations were found between n and $\ln K$ with values ranging between 0.30 and 0.65 for uranin and between -0.35 and -0.65 for lithium. The difference in correlation signs between uranin and lithium may indicate that different sorbents are responsible for the interaction. By recalculating the data for the whole sediment the correlation between k and $\ln K$ increased to values ranging between -0.40 and -0.65 for uranin and lithium. Only in one case (lithium, total sediment, layer 2) no correlation was found. Similar results were found using the method of Seiler-I. The low correlations agree with the findings of Robin et al. (1991), who reported weak negative correlations between the log transformed distribution coefficient of strontium, $\ln K_d$, and $\ln K$.

8.2. Correlations between Freundlich parameters and sediment properties

Correlation coefficients between k, n, S of uranin and sediment properties are given in Table 9. The sediment sorption capacity, S, mainly determined by k, was investigated for all layers. The n parameter does not show any significant correlation with the aquifer properties for layer 2 + 3. The sorption capacity determined for the whole sediment fraction is positively correlated with log transformed values of clay content, CEC and the amount of fines. No correlation with Corg was found. The correlation coefficients between parameters differed for layers 2 and 3 when analysed separately. The values of the coefficients for layer 3 were similar to those found for layers 2 and 3 together (Rhine gravel). For layer 2, n was, however, negatively correlated with all measured sediment properties, especially with the fine sediment fraction. This is probably due to the fact that uranin sorption occurs at different sorption sites in layers 2 and 3. The larger correlation coefficient between k and the log transformed clay fraction for layer 3 compared to layer 2 indicates that the clay fraction is the major sorbent for layer 3. For layer 2, other properties than clay minerals, such as oxides, most likely control the sorption of uranin.

Table 10 gives the correlation coefficients for lithium sorption data with the sediment properties. The values of k and n are negatively correlated. For layer 2 + 3, n is positively correlated with the log transformed sediment properties and S. The largest correlations coefficients for n are found in layer 3 with log transformed clay content and fines. These values are different from the values found for uranin. First, only weak correlations (Table 9) were found in layer 3 for n of uranin with clay and fines. Secondly, only negative correlations for n of uranin were found with sediment parameters in layer 2. The value of k for lithium sorption is weakly correlated with the log transformed properties of the sediment. This is again in contradiction with the observation made for uranin.

The differences in correlation coefficients of uranin and lithium sorption parameters with sediment properties may be explained by different sorbing materials in the sediment layers and the chemical nature of uranin and lithium. Uranin is a large organic anion with carboxylic groups whereas lithium is a small cation. Therefore, it is expected that uranin sorption occurs on positively charged oxides (e.g., Goethite), which from their size may belong to the clay fraction. On the basis of the correlation coefficient with Corg, there was no evidence of uranin sorption with organic carbon. For lithium, sorption probably occurs on the basis of ion exchange processes with clay minerals.

9. Tracer injections

Three different tracers were injected into groundwater: uranin ($C_{20}H_{20}Na_2O_5$) and lithium chloride (LiCl) on 30 August 1994 and sodium bromide (NaBr) on 3 April 1996. Eosin ($C_{20}H_6Br_4Na_2O_5$) was used in a pretest to obtain estimates of groundwater flow direction and velocity with the purpose of defining the locations of observation wells (Döring, 1997). The spatial and temporal evolution of Li^+ (hereafter referred to as lithium) and uranin were then monitored for 449 days. Chloride was not used as a tracer substance due to the high background concentration in the groundwater. The spatial and temporal evolution of Br^- (hereafter referred to as bromide) was monitored for 398

days. Preliminary batch experiments with sediment from different depths showed that bromide behaved as an inert (conservative) tracer. Uranin and lithium were used as reactive tracer substances.

120 kg LiCl and 2 kg uranin (55% purity) dissolved and well mixed in 4500 l of groundwater were injected. The tracer solution was equally distributed over the three injection wells (57, 58, 59) (Fig. 1) and injected at a depth between 6 and 7 m below the surface (91.4–92.4 m above MSL). The injection lasted for 5 h. During this time, concentration and temperature of the injection solution were monitored. The initial concentrations of uranin and lithium were 240 and 4100 mg/l, respectively. The water temperature was constant at about 17.2°C, the groundwater temperature was 10°C. The injected solution had a density of 1.015 g/cm^3, which was about 1.5% higher than the density of the groundwater.

The injection of 135.9 kg of NaBr dissolved in 8000 l of groundwater lasted for 10.8 h. To minimize downward movement of the solute plume due to a higher mass density compared to the groundwater, the solution volume and injection time were doubled compared to our earlier tracer experiments with LiCl and uranin.

10. Monitoring of solute concentrations

During the tracer tests with uranin and lithium, which were monitored for 15 months, 7468 lithium and 19,386 uranin samples were collected and analyzed. For the bromide, 12,616 samples were analyzed. To characterize the spatial extent of the uranin and lithium clouds, 12 sampling rounds were done. For bromide, seven measurement rounds were done. Uranin BTCs were measured for every sampler at 15 locations. Bromide and lithium concentrations were determined on every second sample. The number of lithium and bromide samples analysed were smaller than uranin because their detection was more complicated and expensive than uranin. Groundwater samples were collected with a 12-channel peristaltic pump. Two volumes of a sampler tube (200 ml) were removed before a sample of 10 ml was taken. Testing of the PE tubes showed that no sorption of the substances occurred. The samples were stored at the field site in dark conditions at 8°C and transported to the laboratory at the end of the day.

Bromide was measured using ion-chromatography with a detection limit of 0.02 mg/l and a relative measurement error of 5%. The natural background concentration of bromide was about 0.25 mg/l. Uranin was analyzed using fluorescence spectroscopy with synchron scan (Schaefer, 1995). Concentrations of 200 ng/l could be detected but due to the antecedent use of eosin, an uranin detection level of 2 μg/l was set. Samples containing both uranin and eosin were analyzed by fitting two Gaussian curves, one for uranin and one for eosin, to the observed spectrum. The area below the uranin curve was then determined and transformed into concentrations using calibration curves. Lithium was analyzed using ICP-MS. This method allows the detection of lithium to about 20 μg/l. But since the natural background of lithium varied between 2 and 20 μg/l, a cutoff value of 50 μg/l was set.

As previously stated, this paper focuses on the analysis of bromide transport using spatial moment analysis. The measured bromide BTCs will be discussed and interpreted

in a paper by Vanderborght and Vereecken (2000) using classical CDE analysis and temporal moment analysis. Field BTCs of uranin were analysed by Vereecken et al. (1999b) using asymptotic analysis. The results of the field-scale analysis were compared with results from local scale BTCs. In addition to the determination of the tracers, the major cation and anion concentration were determined in samples collected along the tracer flow path. Work is on its way to interpret the transport behaviour of lithium using observed BTCs of these anions and cations.

11. Contour plots of bromide plume

Horizontal and vertical contour plots were calculated using the SURFER software (Version 5.02, 1994). Horizontal interpolation was performed by Kriging using a linear variogram model without nugget, a rotation angle of $-30°$ and an anisotropic ratio of 0.5. Interpolation in the vertical plane was done with Kriging using a linear variogram. Horizontal contour plots of vertically averaged bromide concentrations are shown in Figs. 7 and 8. After 138 days, the longitudinal extension of the plume is about 100 m.

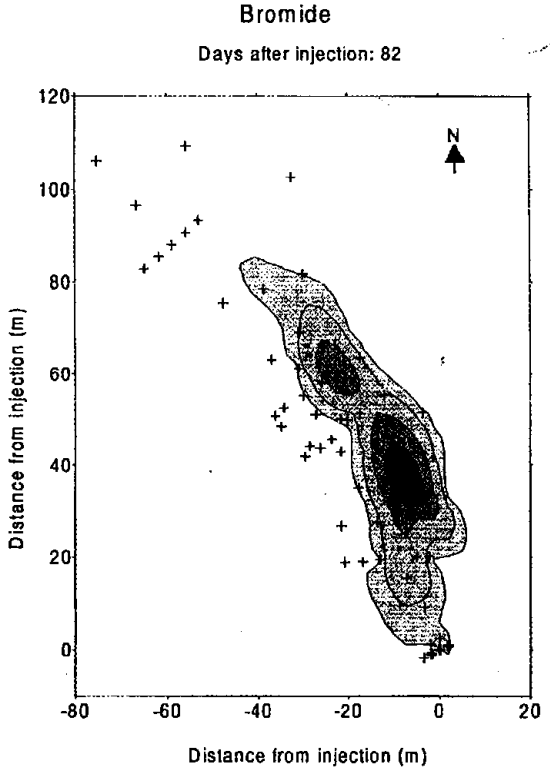

Fig. 7. Horizontal contour plots of the vertical averaged concentrations of bromide for 82 days after injection.

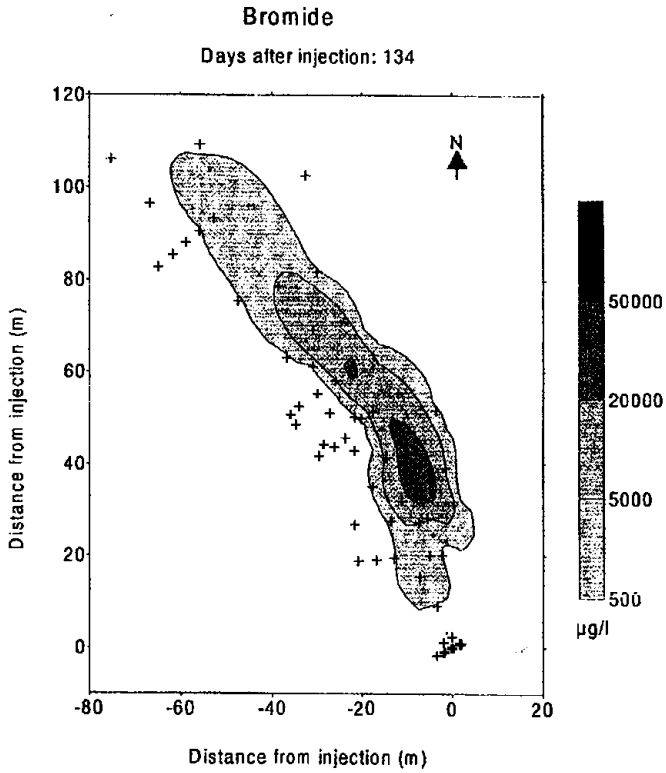

Fig. 8. Horizontal contour plots of the vertical averaged concentrations of bromide for 134 days after injection.

For larger times, a part of the bromide mass is transported beyond the field site. This is also illustrated by the steady decrease of the total recovered mass (see Section 12.2.1). Vertical contour plots (between 88.4–95.4 m and 87.4–95.4 m above MSL) of the solute concentrations along a transect in the mean groundwater flow direction were constructed for four sampling dates (Fig. 1). The vertical contour plot (Fig. 9) shows that bromide partly sank below the depth of injection (91.4–92.4 m above MSL). In addition, the contour lines are not closed at the bottom suggesting that tracer mass was lost below the deepest sampler. This sinking of the plume was most likely caused by the higher density of about 1.5% of the injected solute than groundwater.

12. Spatial moment analysis

12.1. Calculation of the spatial moments

The calculation of spatial moments of the tracer plumes is one of the most frequently used methods to compare experimental data with predictions from stochastic theories

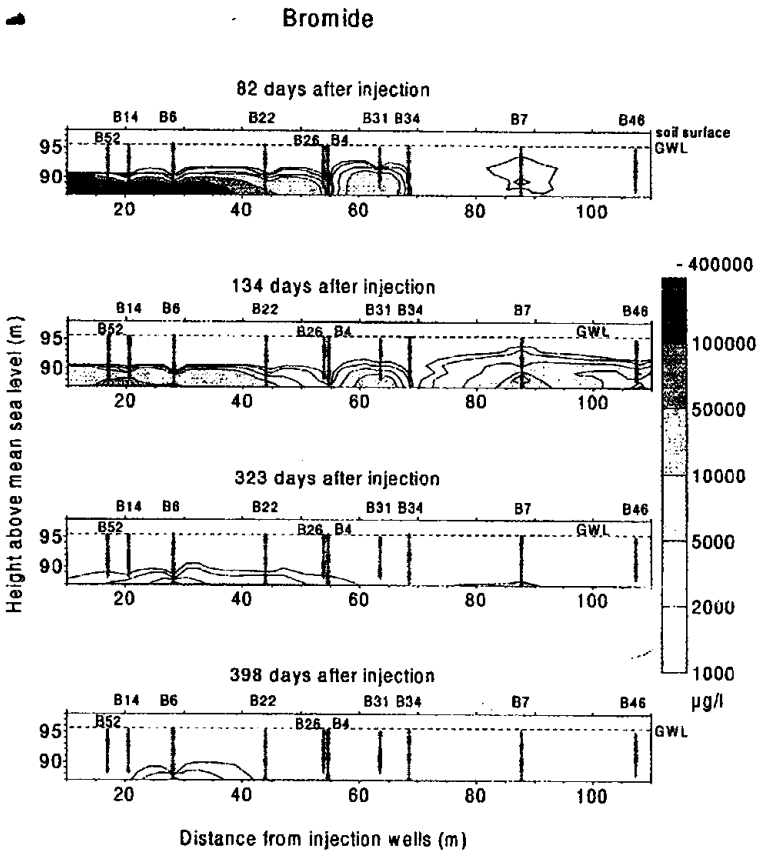

Fig. 9. Vertical contour plots of bromide concentrations along a transect in the direction of groundwater flow.

(Freyberg, 1986; Garabedian et al., 1991). Spatial moments for the dissolved phase are defined as:

$$M_0 = \int\int\int n(\vec{x})\, c(\vec{x},t)\, \mathrm{d}\vec{x}, \tag{5}$$

$$M_1 = \frac{1}{M_0}\int\int\int \vec{x} n(\vec{x})\, c(\vec{x},t)\, \mathrm{d}\vec{x}, \tag{6}$$

$$\Sigma = \frac{1}{M_0}\int\int\int (\vec{x} - M_1)(\vec{x} - M_1)^T n(\vec{x})\, c(\vec{x},t)\, \mathrm{d}\vec{x}, \tag{7}$$

where M_0 is the zeroth-order moment representing the mass of solute; M_1 is the first-order moment representing the position of the center of mass; Σ is the second-order central moment representing the spread of the plume, $c(\vec{x},t)$ is the concentration of the dissolved phase at time t and spatial coordinate $\vec{x}$ and n is the porosity of the medium.

The integrals in Eqs. (5)–(7) were evaluated numerically. The vertical direction of the integration domain extended from 87.0 to 95.5 m above MSL. Extrapolation of concentration values was needed in a few samplers to assign values to nodal points belonging to wells, which did not reach the lower boundary of the integration domain. We used the extrapolation algorithm proposed by Freyberg (1986), which involved halving the concentration for each stepwise increase in vertical sampling distance. Eigenvalues and eigenvectors of Σ (Eq. (7)) were calculated using routines from the NAGlib to obtain the principal components of the variance tensor. Eigenvectors can be used to calculate the orientation of the plume axis with respect to the original coordinate system. In this study, we only considered the orientation of the plume in the horizontal plane with respect to the original coordinate system.

12.2. Analysis of spatial moments

12.2.1. Zeroth-order spatial moment

The zeroth-order moment representing the mass of dissolved substance in the domain was calculated using a mean porosity of 26% for the whole aquifer. The bromide tracer shows a systematic decrease of mass in solution (Fig. 10). The recovered mass remains roughly constant over a period of 110 days after injection. The decrease in dissolved mass was most likely caused by a density driven downward movement of the tracers. Similar downward driven movements due to higher densities of the injected volume were observed at the Cape Cod (LeBlanc et al., 1991) and Columbus (Boggs et al., 1992) tracer experiments. The zeroth-order moments for uranin and lithium (not shown) indicated an even more drastic decrease of the recovered mass with time. It is anticipated that in addition to the downward movement of the plumes, sorption of

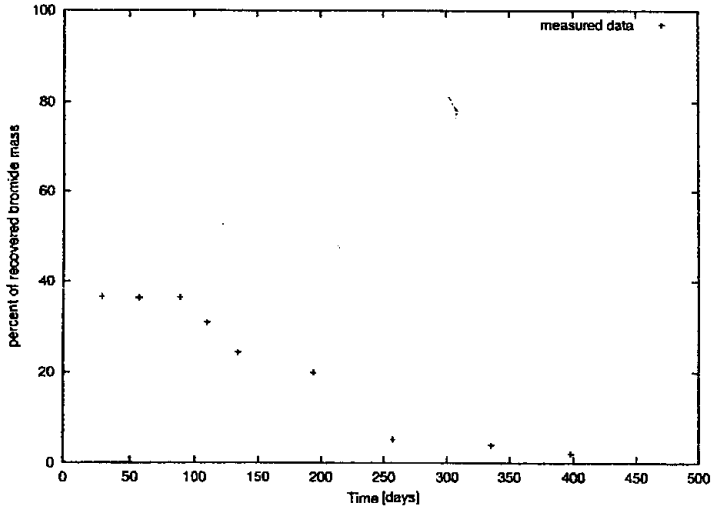

Fig. 10. Variation of mass recovery of bromide with time.

lithium and uranin occurs on the sediment. This is supported by the findings from the batch experiments (Section 3.4). However, it is not clear whether nonlinear equilibrium sorption is the main driving sorption process. Column experiments conducted on sediments from the field site with uranin and lithium showed that other sorption mechanisms may play a role. Interpretation of the uranin and lithium field-scale transport will be subject of further work. In the following, we focus on the spatial moments of bromide and restrict our evaluation to the period of constant mass recovery of bromide.

12.3. First-order spatial moments

From the first spatial moment, the mean solute velocity of the bromide tracer was determined (Fig. 11). 110 days after injection, the mean average solute plume velocity of bromide was 0.5 m/day. This velocity is in agreement with the effective velocities derived by time moment analysis of bromide BTCs, which range between 0.41 and 0.84 m/day, depending on the method of calculating flux-averaged concentrations (Vanderborght and Vereecken, 2000), but is lower than the estimates obtained from local velocities (1.7 m/day) and grain size data methods using Seiler-I and Seiler-II (0.72 and 0.92 m/day). The estimates from the grain size data are in good agreement with the velocities derived from the field BTCs of bromide. The velocities derived from the grain size data were obtained by multiplying the K-values with the mean hydraulic gradient (0.002) and dividing the product by the mean overall porosity (0.26). Evaluation of the orientation of the tracer cloud main axes calculated from the first spatial moment showed that the mean flow direction of the bromide plume was 330°N.

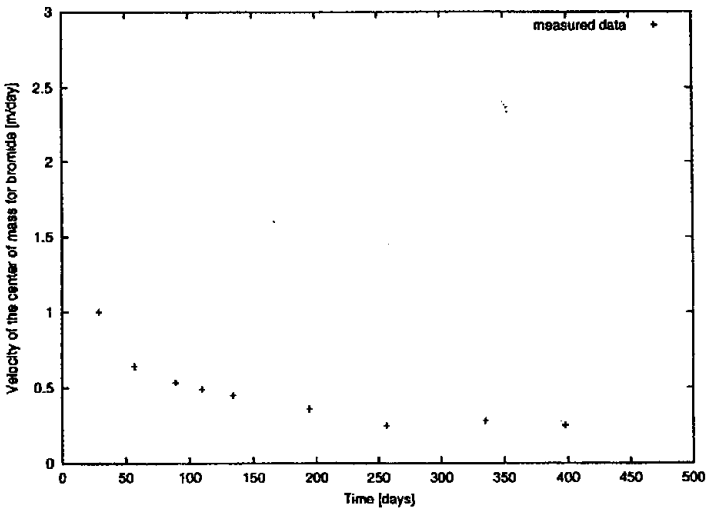

Fig. 11. Change of mean velocity from spatial moment analysis for bromid.

12.4. Second-order spatial moments

The second-order centered longitudinal moment (longitudinal variance) of bromide is shown in Fig. 12. An almost linear increase of the moment with time is observed up to a value of 470 m^2 after 134 days. Thereafter, the calculated values of the moment are fluctuating with two large values above 1100 m^2 on days 323 and 398. For the initial 110 days after injection, the longitudinal dispersion and the mean velocity were 1.82 m^2/day and 0.5 m/day, respectively. This results in a longitudinal dispersivity, α_L, of 3.64 m. This value should be considered as a lower estimate because asymptotic behaviour may not have been reached yet. This value is of the same order of magnitude as observed at the Columbus field site experiment, which was found to range between 5 and 10 m (Adams and Gelhar, 1992). The variance of $\ln K$ at this site was 4.5 with a correlation length of 4.8 m. Lower longitudinal dispersivities were observed at the Borden site ($\alpha_L = 0.43$ m) and the Cape Cod site ($\alpha_L = 0.96$ m). Both test sites are less heterogeneous with variances of $\ln K$ ranging between 0.14 (Borden site) and 0.29 (Cape Cod). The variance of $\ln K$ at the Krauthausen test site obtained from grain size data for layer 2 + 3 ranges between 0.84 and 1.08 (Table 2). This is larger than the values from Borden (0.29) and Cape Cod (0.14–0.24), but smaller than the value from the Columbus site. Correlation lengths for K at Borden and Cape Cod were 2.8 m and 5.1 m. Our estimated horizontal correlation length on the basis of grain size data was equal to 6.7 m with a standard error of estimate of 4.7 m.

Using the theory of Gelhar and Axness (1983), an estimate of α_L for the Krauthausen field site is obtained from the equation $\alpha_L = \sigma^2_{\ln K} I_{\ln K}$ where $\sigma^2_{\ln K}$ is the variance of $\ln K$ and $I_{\ln K}$ is the correlation length. With $\sigma^2_{\ln K} \approx 1.08$ (Table 2, Seiler-I) and a correlation length of 6.7 m, we obtain a dispersivity $\alpha_L \approx 7.2$ m. This is twice as large

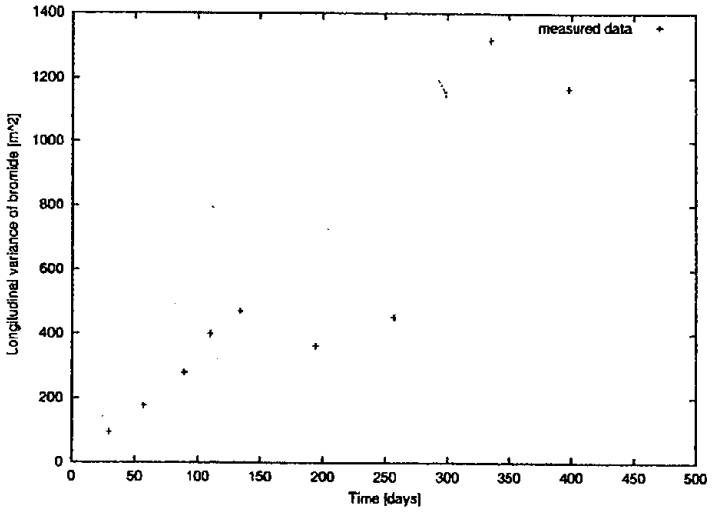

Fig. 12. Change of longitudinal variance of the bromide solute plume with time.

as the observed value of 3.64 m. Two reasons can be invoked to explain this difference. One possibility may be that the asymptotic regime is not yet obtained. The maximum travel distance for the plume was about 170 m, which corresponds to 25 correlation lengths of $\ln K$. The evaluation of the spatial moments was, however, restricted to a smaller distance due to mass loss. This may have provided too few correlation lengths needed to obtain asymptotic behaviour. The other reason may be the overestimation of $\sigma^2_{\ln K}$. The vertical contour plots of bromide suggest that most of the solute mass travelled through the bottom part of the flow domain, which corresponds to layer 3. The estimates of $\sigma^2_{\ln K}$ for this layer are smaller than for the layer 2 + 3 with a value of 0.56 (Seiler-I, Table 2). Using this value would give an estimate for α_L of 3.75, which is in better agreement with the value obtained from spatial moments. The observed dispersivity value of 3.64 m is, however, within the range of estimated dispersivity values when the standard error of estimate for the correlation length of $\ln K$ is taken into account. Due to this large uncertainty, the evaluation of stochastic solute transport theories becomes difficult. In addition, truncation of the solute plume may affect the reliability of the moments based on spatial moment evaluation in terms of an underestimation of effective dispersivities (Miralles-Wilhelm and Gelhar, 1996).

The second-order centered transverse moment (transverse variance) (Fig. 13) provides information on the transverse macrodispersivity. The transverse variance of bromide increased to a value of 9.8 m^2 after 29 days and reached an almost constant value of about 20 m^2 after 57 days. These values need to be corrected for the initial extent of the plume in the horizontal direction. The plume was injected over a width of about 6 m, which corresponds to a variance of about 3.0 m^2 in the transverse direction. The transverse variance was, therefore, equal to about 17 m^2 after 57 days. This almost constant tranverse variance suggests that a small or even zero asymptotic value for the

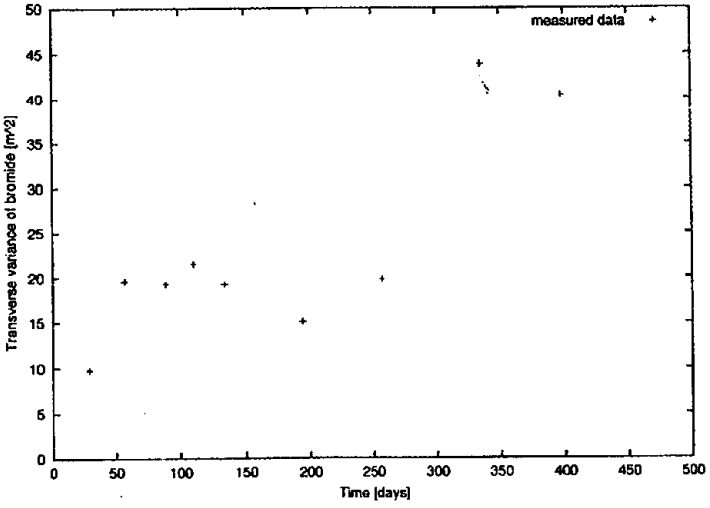

Fig. 13. Change of transversal variance of the bromide solute plume with time.

effective horizontal dispersivity may be appropriate. This finding is in agreement with the Borden site experiment where a small or zero asymptotic value for horizontal dispersivity was found also not to be inappropriate (Freyberg, 1986). At the Borden site, this asymptotic behaviour occurred after 300 to 650 days of travel time, which corresponds to a travelled distance of 27 to 59 m and corresponds to 9.6 to 21 correlation lengths of $\ln K$. For the range of groundwater velocities (0.4 to 0.92 m/day) observed at the Krauthausen test site and using $I_{\ln K} = 6.7$ m, an asymptotic regime seems to be obtained after 3.4 to 7.8 correlation lengths of $\ln K$. The results at the Borden and Krauthausen site differ from the findings at Cape Cod. At this site, the transverse horizontal variance was found to increase linearly over a travel distance of 200 m suggesting that a zero asymptotic value for the horizontal macrodispersivity was not yet obtained after 39 correlation lengths. In terms of statistics of $\ln K$, the Cape Cod site is the most homogeneous ($\sigma^2_{\ln K} = 0.14$–0.24) with $I_{\ln K} = 5.1$ m, which is close to the value for the Krauthausen site (6.7 m). A straight forward comparison between the sites in terms of asymptotic behaviour is, however, frauded with difficulties and can only be indicative because these estimates are uncertain due to estimation errors in the values of $\sigma^2_{\ln K}$ and $I_{\ln K}$. These uncertainties are caused by the limited spatial resolution of the sampling grid and the different results provided by the various methods used to derive the statistics of $\ln K$. In addition, mass loss of bromide at the Krauthausen combined with a trend in the groundwater flow direction complicates the picture. Further research at the test site will, therefore, focus on the use of new geophysical techniques (Kulessa et al., 2000) to monitor in a noninvasive manner the spreading of solutes and to avoid the limitations of spatial resolution.

13. Conclusions

The following findings were obtained from the experimental work conducted at the tracer field site Krauthausen.

(1) The vertical spatial correlation of hydraulic conductivity, K, derived from grain size data was described with an exponential variogram model with a correlation length of 0.4 and 0.6 m, depending on the choosen grain size data method. The vertical correlation length of K values obtained from flowmeter measurements was 0.37 m and agrees with the estimates from grain size data methods.

(2) The horizontal correlation length of K from grain size data based on the Seiler-I method was 6.7 m. No horizontal correlation length for K could be derived from flowmeter measurements.

(3) The magnitude of local Darcian velocities at the test site was found to be lognormally distributed with a geometric mean value of 0.47 m/day and a variance of 1.86. The local flow direction measurements showed a clear trend in the groundwater flow direction. This trend may lead to an enlarged dispersive effect on solute transport, which is not accounted for in stochastic theories. The spatial dependence of local velocities was described by an exponential variogram with a correlation length of 4.2 m. This correlation length is in good agreement with the correlation length obtained from the K-values from grain size distribution (6.7 m).

(4) The sorption isotherms of uranin measured in batch experiments could be described by a Freundlich equation with an n exponent varying between 0.71 and 0.95 within two standard deviation in layer 2 + 3. The lithium isotherms determined in batch experiments could also be described by a Freundlich isotherm. The value of the n parameter varied within one standard deviation between 0.37 and 0.69. In contrast to uranin, the n exponent of lithium sorption showed a clear correlation with clay content and CEC.

(5) Weak correlations between Freundlich sorption parameters obtained for the sediment fraction < 2 mm and $\ln K$, estimated from grain size data, were obtained both for uranin and lithium. This is in agreement with earlier findings in literature. A negative correlation $\ln K$, and Freundlich k of uranin pertaining to the whole sediment fraction was found, in which values ranged between -0.5 and -0.65. For lithium, both the k and n parameters were negatively correlated with $\ln K$.

(6) Spatial moment analysis showed a systematic decrease of the mass recovery for bromide. This is explained by the density driven vertical movement of the plumes below the MLS and mass loss due to the fact that the plume left the field site.

(7) The calculated longitudinal dispersivity at the test site was 3.64 m. Using the theory of Gelhar and Axness (1983), $\sigma^2_{\ln K} = 1.08$ and a correlation length of 6.7 m, the estimated longitudinal dispersivity is 7.2 m. Due to large uncertainties in the estimated correlation length and variance of $\ln K$ and the tracer mass loss, the quality of the estimates based on the theory of Gelhar and Axness could not be verified.

GLOSSARY OF TERMS

A	Area [L^2]
A_{eff}	Effective area [L^2]
b	Thickness of the flow zone [L]
C	Solute concentration [M/L^3]
C_i	Solute concentration in injected water [M/L^3]
C_n	Solute concentration in native water [M/L^3]
c	Volumetric solute concentration in the aquifer fluid [M/L^3]
c'	Volumetric solute concentration in the injected fluid [M/L^3]
D_d	Molecular diffusion coefficient [L^2/T]
$\underline{D}_m$	Dispersion tensor [L^2/T]
d	Characteristic length [L]
dh_i	Head change in the *i-th* high-permeability zone [L]
d_r	Change in distance from the pumping well [L]
g	Gravitational acceleration vector [L/T^2]
$\underline{I}$	Identity tensor [dimensionless
K_i	Hydraulic conductivity of the *i-th* high-permeability zone [L/T]
k	Intrinsic permeability of the aquifer [L^2]
k_H	Horizontal permeability of the aquifer material [L^2]
k_V	Vertical permeability of the aquifer material [L^2]
n	Apparent porosity of the aquifer [dimensionless]
p	Fluid pressure [M/LT^2]
ρ	Fluid density [M/L^3]
ρ_i	Density of injected water [M/L^3]
ρ_n	Density of native water [M/L^3]
Pgh	Hydrostatic pressure [M/LT^2]
Q	Flow rate through the flow zone [L^3/T]
Q'	Volumetric injection rate per unit area of aquifer [L/T]
Q_i	Representation of flow components from the different aquifer high-permeability zones where $i = 1,2,3$ [L^3/T]
Q_p	Mass of fluid injected or withdrawn per unit time per unit volume of aquifer [M/L^3T]
Q_T	Total flow rate through the well [L^3/T]
q	Specific discharge [L/T]
R_e	Reynolds number [dimensionless]
r	Radial distance [L]
T_i	Transmissivity of the aquifer [L^2/T]
t	Time [T]
μ	Dynamic viscosity of the fluid [M/LT]
V	Fluid kinematic viscosity [L^2/T]
v	Average pore-water velocity [L/T]
z	Elevation above a reference datum [L]
α_L	Longitudinal dispersivity of the aquifer [L]
α_T	Transverse dispersivity of the aquifer [L]
Δt	Time step [T]
∇	Gradient operator [1/L]

Analysis of Tests of Subsurface Injection, Storage, and Recovery of Freshwater in the Lower Floridan Aquifer, Okeechobee County, Florida

By Vicente Quiñones-Aponte, Kevin Kotun, *and* Joseph F. Whitley

Abstract

A series of freshwater subsurface injection, storage, and recovery tests were conducted at an injection-well site near Lake Okeechobee in Okeechobee County, Florida, to assess the recoverability of injected canal water from the Lower Floridan aquifer. At the study site, the Lower Floridan aquifer is characterized as having four local, relatively independent, high-permeability flow zones (389 to 398 meters, 419 to 424 meters, 456 to 462 meters, and 472 to 476 meters below sea level). Four subsurface injection, storage, and recovery cycles were performed at the Lake Okeechobee injection-well site in which volumes of water injected ranged from about 387,275 to 1,343,675 cubic meters for all the cycles, and volumes of water recovered ranged from about 106,200 to 484,400 cubic meters for cycles 1, 2, and 3. The recovery efficiency for successive cycles 2 and 3 increased from 22 to 36 percent and is expected to continue increasing with additional cycles.

A comparison of chloride concentration breakthrough curves at the deep monitor well (located about 171 meters from the injection well) for cycles 1, 4, and test no. 4 (from a previous study) revealed unexpected findings. One significant result was that the concentration asymptote, expected to be reached at concentration levels equivalent or close to the injected water concentration, was instead reached at higher concentration levels. The injection to recovery rate ratio might affect the chloride concentration breakthrough curve at the deep monitor well, which could explain this unexpected behavior. Because there are four high-permeability zones, if the rate of injection is smaller than the rate of recovery (natural artesian flow), the head differential might not be transmitted through the entire open wellbore, and injected water would probably flow only through the upper high-permeability zones. Therefore, observed chloride concentration values at the deep monitor well would be higher than the concentration of the injected water and would represent a mix of water from the different high-permeability zones.

A generalized digital model was constructed to simulate the subsurface injection, storage, and recovery of freshwater in the Lower Floridan aquifer at the Lake Okeechobee injection-well site. The model was constructed using a modified version of the Saturated-Unsaturated **TRA**nsport code (SUTRA), which simulates variable-density advective-dispersive solute transport and variable-density ground-water flow. Satisfactory comparisons of simulated to observed dimensionless chloride concentrations for the deep monitor well were obtained when using the model during the injection and recovery phases of cycle 1, but not for the injection well during the recovery phase of cycle 1 even after several attempts. This precluded the determination of the recovery efficiency values by using the model.

The unsatisfactory comparisons of simulated to observed dimensionless chloride concentrations for the injection well and failure of the model to represent the field data at this well could

be due to the characteristics of the Lower Floridan aquifer (at the local scale), which is cavernous or conduit in nature. To test this possibility, Reynolds numbers were estimated at varying distances from the injection well, taking into consideration two aquifer types or conceptual systems, porous media and cavernous. For the porous media conceptual system, the Reynolds numbers were greater than 10 at distances less than 1.42 meters from the injection well. Thus, application of Darcy's law to ground-water flow might not be valid at this distance. However, at the deep monitor well (171 meters from the injection well), the Reynolds number was 0.08 which is indicative of laminar porous media flow. For the cavernous conceptual system, the Reynolds numbers were greater than 2,000 at distances less than 1,000 meters from the well. This number represents the upper limit of laminar flow, which is the fundamental assumption for the application of Darcy's law to free flow.

Results from the study suggest that to simulate recovery efficiency for the Lower Floridan aquifer at the Lake Okeechobee injection-well site might require the application of a free-flow type model (conduit flow or fracture flow). This type of model may produce a more realistic representation of the actual fluid motion in the Lower Floridan aquifer and could provide appropriate estimates of the recovery efficiency.

INTRODUCTION

Lake Okeechobee is the second largest natural freshwater lake in the United States, encompassing about 1,813 km^2 (square kilometers). The lake is the principal source of potable water for southern Florida and is part of the flood-control system for the area (fig. 1). A serious contamination problem to Lake Okeechobee is posed by phosphate loads from tributary canals, such as Taylor Creek and Nubbin Slough (fig. 1), which might accelerate eutrophication of the lake (Lake Okeechobee Technical Advisory Committee, 1986). The Lake Okeechobee Technical Advisory Committee proposed a study to determine the feasibility of reducing phosphate loads into Lake Okeechobee.

From April 1991 to September 1994, the U.S. Geological Survey, in cooperation with the South Florida Water Management District, conducted a study to: (1) assess the feasibility of subsurface injection, storage, and recovery as a mechanism for reducing phosphate loads in the canal water; (2) examine the chemical behavior of the canal-water and native aquifer water mix during subsurface injection, storage, and recovery, focusing on the fate of orthophosphate; and (3) estimate the recovery efficiency of injected canal water from the Lower Floridan aquifer. A report by Quiñones-Aponte and Whitley (1996, in press) analyzed the application of phosphate mass-balance approaches to assess the feasibility of subsurface injection, storage, and recovery as a tool for reducing phosphate loads in the canal water. This report assesses the recoverability of injected canal water from the Lower Floridan aquifer.

Purpose and Scope

The purposes of this report are to: (1) describe a series of freshwater subsurface injection, storage, and recovery tests conducted at an injection-well facility near Lake Okeechobee; (2) present the analyses of the subsurface injection, storage, and recovery tests; and (3) assess the recoverability of injected canal water from the Lower Floridan aquifer using field data and digital model analyses. This report combines information and results from a previous study (CH_2M Hill, 1989) and the present study to characterize the Lower Floridan aquifer at the Lake Okeechobee injection-well site; these characteristics include lithostratigraphic units, hydrogeologic units, aquifer properties, potentiometric levels, and ambient water quality. Recovery efficiencies from actual field subsurface injection, storage, and recovery tests were estimated and are included in this report to measure the success of a subsurface injection, storage, and recovery cycle. A summary of the governing ground-water flow and solute transport equations is also included with a description of the digital model development and its application to evaluate recovery efficiency at the Lake Okeechobee injection-well site. Finally, simulations were made using a digital model code (QSUTRA) to study the effects of the aquifer characteristics on the recoverability of the injected canal water.

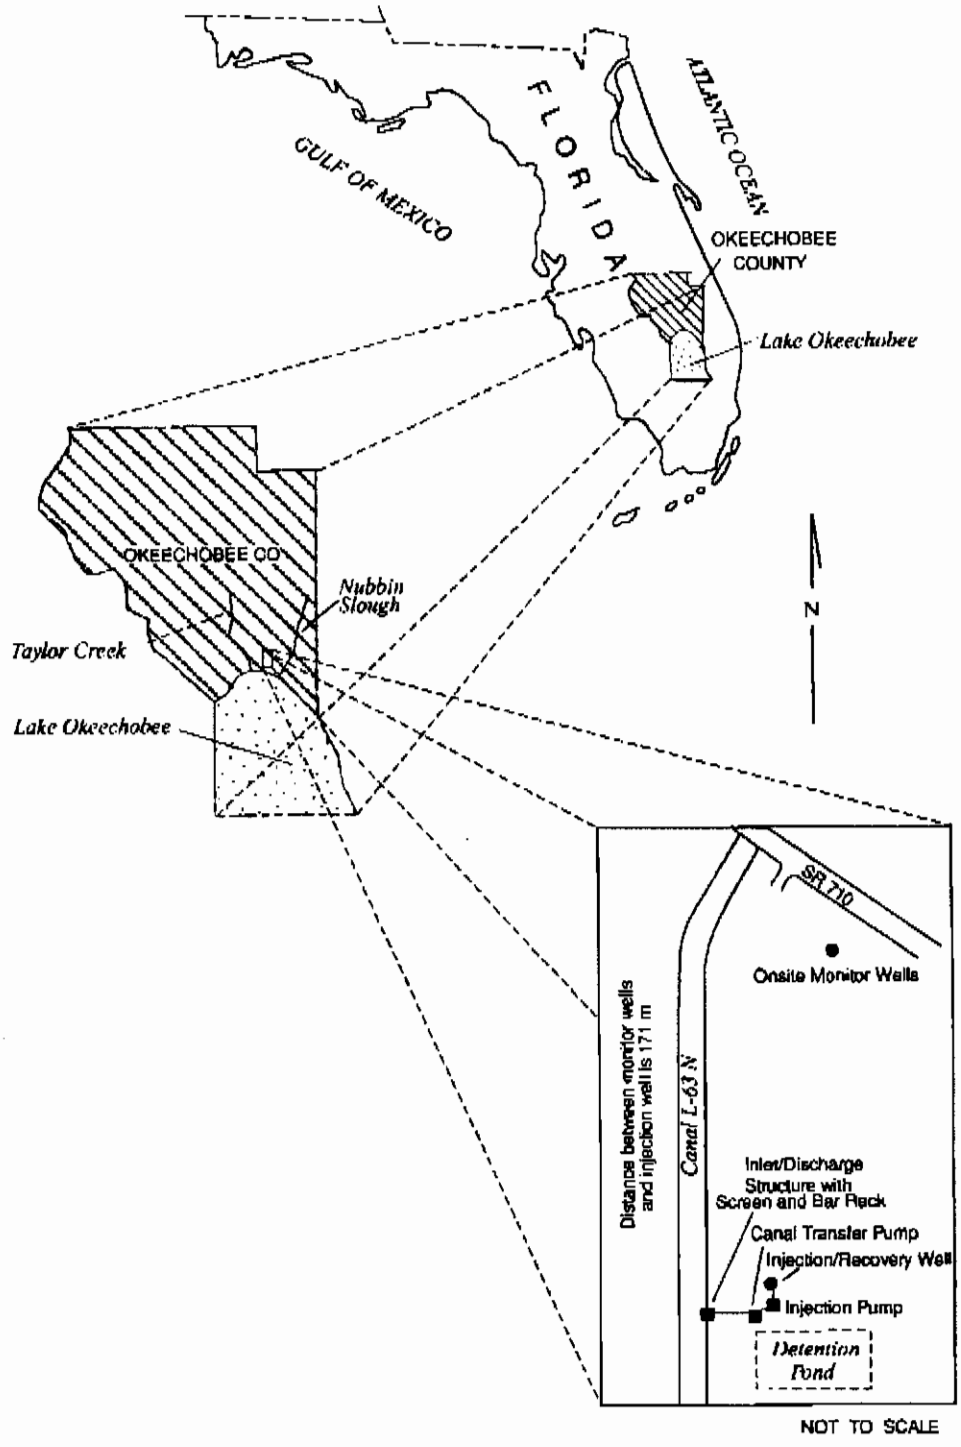

Figure 1. Location of the Lake Okeechobee injection-well site and the contributing canals.

Description of Study Area

The study area is located at existing well facilities near the northern shore of Lake Okeechobee at the intersection of State Road 710 and Canal L-63N in Okeechobee County, Fla. (fig. 1). The facilities were designed and constructed by CH_2M Hill (1989), under an agreement with the South Florida Water Management District, and consist of a canal inlet/discharge structure to withdraw water from Canal L-63N, chlorination facilities (not used for the present study), a detention pond, an injection well, pumps, and two nested monitor wells located about 171 m (meters) from the injection well (fig. 1). All the wells are characterized by artesian heads. Initial testing at this well site was conducted by CH_2M Hill (1989).

The general hydrogeologic characteristics of the injection well site are briefly described in the subsequent sections, including lithostratigraphic and hydrogeologic units. The description of the aquifer hydraulic characteristics focuses on the Lower Floridan aquifer, which is the hydrogeologic unit considered in this study.

Hydrogeologic Setting

The geology of Okeechobee County and the Lake Okeechobee injection-well site has been described by previous investigators, including Sellards (1912), Parker and others (1955), Puri and Vernon (1964), Miller (1986), CH_2M Hill (1989), and Lukasiewicz (1992). The upper 550 m of sediments at the injection-well site are comprised of the upper part of the Oldsmar Formation of lower Eocene age, the Avon Park Formation (formerly termed the Lake City Limestone) of middle Eocene age, the Ocala Limestone of upper Eocene age, the Tampa Limestone of Miocene age, the Hawthorn Formation of Miocene age, the Tamiami Formation of Pliocene age, and the Anastasia Formation of Pleistocene age (fig. 2).

The Oldsmar Formation, Avon Park Formation, and Ocala Limestone are present in the Floridan aquifer system (fig. 2). The Ocala Limestone and the upper part of the Avon Park Formation constitute the Upper Floridan aquifer, the middle part of the Avon Park Formation constitutes the middle semiconfining unit, and the lower part of the Avon Park Formation and the upper part of the Oldsmar Formation constitute the Lower Floridan aquifer (Miller, 1986). The middle semiconfining unit separates the Upper Floridan aquifer from the Lower Floridan aquifer within the Floridan aquifer system. The Oldsmar Formation is characterized by off-white to light-gray, micritic to finely pelletal limestone interbedded with gray to tan to light-brown, fine to medium crystalline, commonly vuggy dolomite (Miller, 1986). The Avon Park Formation is characterized by pelletal but locally micritic cream, tan, or light-brown, soft to well-indurated limestone sediments (Miller, 1986) with fauna typical of Eocene age and also contains large amounts of lignite and carbonaceous plant material (Puri and Vernon, 1964). Overlying the Avon Park Formation is the Ocala Limestone containing marine fauna and foraminifera throughout and chert beds in places. The cavernous Ocala Limestone produces large volumes of water and is the source of many springs in Florida that originate from the Floridan aquifer system (Parker and others, 1955).

The Tampa Limestone and Hawthorn Formation are present in a confining unit (about 162 m thick) between the surficial aquifer and the Floridan aquifer system (fig. 2) and consist of sand, silts, and limestones of marine origin. Limestones are predominant in the lower part of the Tampa Limestone (Puri and Vernon, 1964). At the Lake Okeechobee injection-well site, the Tampa Limestone is characterized as a soft loosely consolidated limestone, rich in phosphorite (fig. 2). The base of the Tampa Limestone is considered the top of the Floridan aquifer system and is identified by increased consolidation and occurrence of arenaceous limestone. The Hawthorn Formation overlying the Tampa Limestone contains many types of deposits, including carbonate with quartz sand and phosphatic clayey dolostones. The Tamiami Formation and Anastasia Formation are present in the surficial aquifer (fig. 2). At the Lake Okeechobee injection-well site, the Tamiami Formation consists of fine silty sand, shell fragments, low phosphorite, and interbedded clay (CH_2M Hill, 1989). The Anastasia Formation is generally composed of coquina, quartz sand, calcareous quartz sandstone, and shelly marl (Sellards, 1912) but consists of unconsolidated sand with fine shell fragments at the injection-well site (CH_2M Hill, 1989).

Hydraulic Characteristics of the Lower Floridan Aquifer

The Lower Floridan aquifer at the Lake Okeechobee injection-well site is characterized by two flow zones under confined conditions isolated from each other by an intermediate dolomite confining unit (CH_2M Hill, 1989; and Lukasiewicz, 1992). The upper

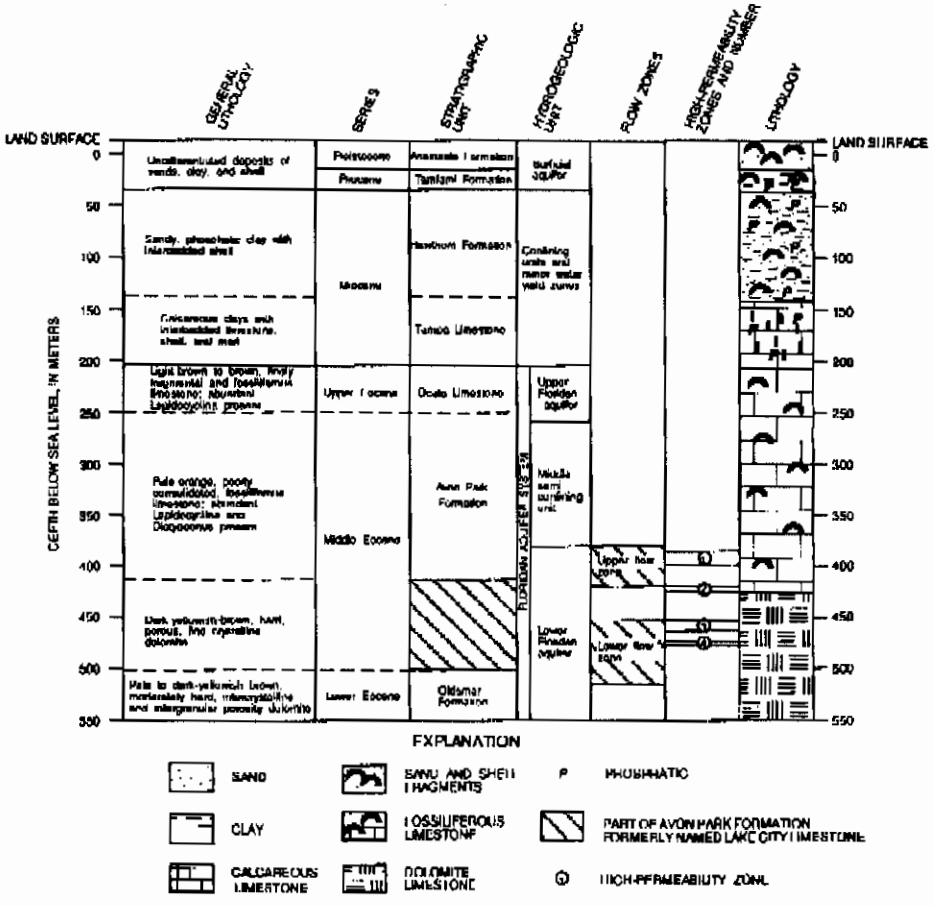

Figure 2. Geologic column of the Lake Okeechobee injection-well site showing stratigraphic units, hydrogeologic units, and lithology. Modified from CH_2M Hill (1989).

flow zone occurs from about 380 to 419 m below sea level, the intermediate confining unit occurs from about 419 to 456 m below sea level, and the lower flow zone occurs from about 456 to 518 m below sea level (fig. 2). At local scale, high-permeability zones occur along some intervals in the upper and lower flow zones (CH_2M Hill, 1989). Local high-permeability zones were present along two intervals in the upper flow zone (389 to 398 m below sea level and 419 to 424 m below sea level) and along two intervals in the lower flow zone (456 to 462 m below sea level and 472 to 476 m below sea level).

Field data and model simulation results from Lukasiewicz (1992) were used to estimate the direction and magnitude of the regional ground-water flow gradient at the Lake Okeechobee injection-well site. The direction of flow was estimated at about 45 degrees northeast from true north and the background hydraulic gradient was about 0.047 m/km (meter per kilometer). The four local high-permeability zones occurring within the upper and lower flow zones were identified by CH_2M Hill (1989) using data from geophysical logs (caliper, flow velocity, fluid resistivity, and fluid temperature) during pumping conditions. The percent of flow from the individual local high-permeability zones (table 1) was estimated from caliper/velocity (flow meter) borehole logs conducted during pumping or flowing conditions (CH_2M Hill, 1989).

CH_2M Hill (1989) estimated the hydraulic characteristics of the open-hole interval of the injection well and the middle semiconfining unit above the flow zones. The estimated transmissivity of the aquifer at the injection well was about 71,000 m^2/d (meters squared per day) for the interval between 377 and 509 m below sea level, which is equivalent to an average hydraulic conductivity of 540 m/d (meters per day).

Table 1. Hydraulic characteristics of the Lower Floridan aquifer at the Lake Okeechobee injection-well site

[Percent of flow estimated using caliper and flow-meter borehole logs]

High-permeability zone	Depth interval (meters below sea level)	Thickness (meters)	Percent of flow from this zone	Horizontal hydraulic conductivity (meters per second)	Horizontal intrinsic permeability (square meters)
1	389-398	9.0	60	5.48×10^{-2}	5.57×10^{-9}
2	419-424	5.0	11	1.81×10^{-2}	1.84×10^{-9}
3	456-462	6.0	22	3.01×10^{-2}	3.06×10^{-9}
4	472-476	4.0	7	1.44×10^{-2}	1.46×10^{-9}

The hydraulic characteristics of the middle semiconfining unit were estimated from a packer test conducted at a depth interval of between 349 and 365 m below sea level. This middle semiconfining unit (fig. 2) confines the aquifer considered in the subject study at its upper limit. Transmissivity values in this unit ranged from 65.6 to 273.2 m^2/d, which is equivalent to a hydraulic conductivity range of between 4.1 and 17.2 m/d.

The hydraulic characteristics of the individual high-permeability zones of the two flow zones in the Lower Floridan aquifer at the Lake Okeechobee injection-well site can be estimated using the following mathematical procedure:

$$Q_T = Q_1 + Q_2 + Q_3 + Q_4 \qquad (1)$$

where:

Q_T is the total flow rate through the well, and

Q_i (i = 1,2,3,4) represents the flow components from the different aquifer high-permeability zones.

For radial flow through each flow zone, Darcy's law can be expressed as:

$$Q_i = 2\pi r T_i \frac{dh_i}{dr} \qquad (2)$$

where:

r is the radial distance from the pumping well,

T_i is the transmissivity in the *i-th* high-permeability zone,

dh_i is the head change in the *i-th* high-permeability zone, and

dr is the change in distance from the pumping well.

Assuming a very small difference in head gradient among the high-permeability zones, $dh_i/dr = dh/dr$, and uniform head distribution in the well-bore, equation *(2)* becomes:

$$Q_T = 2\pi r\left(T_1 + T_2 + T_3 + T_4\right)\frac{dh}{dr} = 2\pi r T \frac{dh}{dr} \qquad (3)$$

and:

$$T = T_1 + T_2 + T_3 + T_4 = K_1 b_1 + K_2 b_2 + K_3 b_3 + K_4 b_4 \qquad (4)$$

Based on the previous assumptions, $Q_i/Q_T = T_i/T$ and $T_i = K_i b_i$. The average hydraulic conductivity of each high-permeability interval i can be estimated if the thicknesses (b_i) of the high-permeability zones are known. The hydraulic conductivity values K_i for the four high-permeability zones, given in table 1, were estimated using the flow terms Q expressed as a percentage (where Q_T = 100), assuming that all flow comes from the four high-permeability zones, and using the transmissivity value estimated at the injection well (71,000 m^2/d).

Aquifer matrix permeability (k_i, intrinsic permeability) values, given in table 1, were computed using:

$$k_i = \frac{\mu K i}{\rho g} \qquad (5)$$

where:

μ is the dynamic viscosity of the fluid [M/LT],

ρ is fluid density [M/L^3], and

g is the gravitational acceleration vector [L/T^2].

Subsurface Injection, Storage, and Recovery Concept

Subsurface injection, storage, and recovery of freshwater in brackish or saline aquifers is a water supply storage strategy that has received increased attention in recent years. The subsurface injection, storage, and recovery concept is suited for southern Florida where there is: (1) a surplus of freshwater during the wet season; and (2) a lack of suitable surface storage reservoirs because of the cost of land, limits of topography, and high rates of evapotranspiration and seepage losses. The suitability of a particular aquifer to store surface water is determined through subsurface injection, storage, and recovery tests from which the recovery efficiency (ability of the well/aquifer system to retrieve some fraction of the injected water) is determined.

The success of subsurface injection, storage, and recovery of freshwater is measured by the recovery efficiency. The recovery efficiency is defined as the volume of mixed injected and native aquifer waters recovered that meets a prescribed chemical standard, expressed as a percentage of the volume of water initially injected (Meyer, 1989). Most recent studies of subsurface injection, storage, and recovery have assumed the recommended level of 250 mg/L (milligrams per liter) for chloride concentration as the standard (Florida Department of Environmental Protection, 1993). However, in this study a limit of 1,385 mg/L of chloride and a limit of specific conductance of 5,000 µS/cm (microsiemens per centimeter) were established because the potential use (agricultural irrigation) of the recovered water tolerates this salinity level. This salinity level is the upper limit that can be tolerated by most crop types.

Merritt and others (1983) and Merritt (1985) describe a number of physical mechanisms that control the recoverability of freshwater injected into the Floridan aquifer system. They determined that buoyancy stratification, mixing due to hydrodynamic dispersion, and downgradient displacement of the injected freshwater with the native water were the three dominant processes that affected the recovery efficiency.

Buoyancy stratification is the process in which the lighter freshwater rises through the aquifer while moving outward from the injection well and overrides the denser, native saltwater or brackish water. Buoyancy stratification can be very significant especially during long storage periods. During recovery, native saltwater in the lower part of the injection zone is drawn into the well, whereas freshwater remains in the upper part of the zone. Buoyancy stratification is controlled by the density contrast between native and injected waters, permeability of the injection zone, and thickness of the injection zone (Merritt, 1985). Studies by Merritt and others (1983) and Merritt (1985) indicate that thin aquifers of moderate permeability are less affected by buoyancy stratification, and therefore, best suited for subsurface injection, storage, and recovery of freshwater. Confinement of the injection zone by low-permeability hydrogeologic units can also aid in limiting the upward movement of freshwater.

Hydrodynamic dispersion describes the mixing of solutes due to molecular diffusion and mechanical dispersion. Molecular diffusion is the process that describes the movement of solute particles from areas of high solute concentration to areas of low solute concentration. The effect of molecular diffusion is independent of the fluid velocity. Mechanical dispersion is caused by mixing of solutes due to variations in fluid velocities at the microscopic scale. Enhanced mechanical dispersion or macrodispersion is caused by velocity variations resulting from local differences in hydraulic conductivity. At the relatively large velocities during injection and recovery, the effects due to mechanical dispersion are generally far greater than those due to molecular diffusion. During long-term storage, however, molecular diffusion may become the dominant mixing process.

A transition zone is created during the mixing of the native and injected waters. The extent of the transition zone depends on the rate of injection, length of injection period, and the difference in solute concentration between the native and injected waters. Because velocities are higher near the well, most of the mixing occurs at the start of the injection process. As injection continues, the transition zone moves outward at continually decreasing velocities, leading to decreasing dispersive mixing at the interface between the native and injected water.

The effect of downgradient displacement of the injected freshwater body on recovery efficiency depends on the length of the injection-recovery cycle and the regional ground-water flow velocities. For subsurface injection, storage, and recovery cycles of relatively short duration (with respect to the size (scale) of the aquifer system), this effect can be considered negligible because the local hydraulic gradient due to injection is much greater than the regional gradient.

Clogging of the aquifer around the injection wellbore is another factor that can affect the recovery efficiency. Clogging can be caused by bacterial growth, suspended sediments in the injected water, and chemical precipitation of solutes due to reactions between the injected water and the aquifer matrix or native water. At the Lake Okeechobee well facilities (fig. 1), the injection well is open hole from 377 to 509 m below sea level and the aquifer is characterized as cavernous. None of the aforementioned clogging problems are likely to occur for such a well-aquifer system. However, geochemical models can be used to predict the reactions that would most likely occur during rock-water interaction and mixing of injected and native waters.

TESTS OF SUBSURFACE INJECTION, STORAGE, AND RECOVERY OF FRESHWATER

A series of freshwater subsurface injection, storage, and recovery tests were conducted at the Lake Okeechobee injection-well site to assess the recoverability of injected canal water from the Lower Floridan aquifer. The injected water was withdrawn from the L-63N canal, which collects water from Taylor Creek and Nubbin Slough (fig. 1). The canal water is composed of runoff and local ground-water discharge from shallow infiltration. According to Quiñones-Aponte and Whitley (1996, in press), the injected canal water and the water in the Lower Floridan aquifer are of similar major inorganic composition.

The subsurface injection, storage, and recovery facilities have been previously described in this report and consist of an injection well that is 60.96 cm (centimeters) in diameter and a nest of two monitor wells, one shallow and one deep, located about 171 m from the injection well (fig. 1). The injection well is cased to a depth of 377 m below sea level and open hole to 509 m below sea level in the Lower Floridan aquifer. The shallow and deep monitor wells were used to observe water-quality changes due to mixing of the injected canal water and native aquifer water in the Lower Floridan aquifer. The shallow well is 15.2 cm in diameter and open to the middle semiconfining unit of the Floridan aquifer system from 292 to 318 m below sea level. The deep well completed in the Lower Floridan aquifer is 3.8 cm in diameter and is open to the aquifer from 379 to 539 m below sea level.

Background water-quality data were collected prior to the subsurface injection, storage, and recovery cycles. CH_2M Hill (1989) used a straddle packer to conduct hydraulic testing and collect water samples from four depth intervals (349 to 365 m, 383 to 403 m, 401 to 450 m, and 460 to 497 m below sea level). These depth intervals do not necessarily coincide with the high permeability zones included in table 1, but some may include the high-permeability zones. The data, presented in table 2, indicate that chloride, specific conductance, and total dissolved solids values were significantly different between zones and increased with depth. This suggests that there is some degree of semiconfinement among the high-permeability zones.

Initial testing was conducted by CH_2M Hill (1989) at the Lake Okeechobee injection-well site to: (1) estimate the maximum feasible injection rate, (2) determine if pretreatment by chlorination would be necessary to eliminate potential fecal coliforms in the injected water, and (3) evaluate the recoverability of the injected canal water. Results indicated that water can be injected into the Lower Floridan aquifer through the injection well at a rate from 18,925 to 37,850 m^3/d (cubic meters per day). Chlorination had little effect on coliform concentrations in the brackish environment of the Lower Floridan aquifer. CH_2M Hill (1989) further reported that water can be withdrawn from the well (under the natural and built-up artesian pressures of the aquifer) at a rate from 10,976.5 to 16,275.5 m^3/d. CH_2M Hill also indicated that the recoverability of the injected canal water could be enhanced by increasing the volume to be stored and/or backplugging the deeper saline zone of the aquifer that is open to the injection well (456 to 509 m below sea level). However, actual testing of this hypothesis was beyond the scope of the study (CH_2M Hill, 1989). CH_2M Hill (1989) indicated that density might affect the recovery efficiency. Most of their tests were affected by the relatively small volumes injected, about 94,600 to 344,185 m^3 (cubic meters), and the duration of the storage period (0 to 28 days). Such

Table 2. Background water-quality data for the canal water and native-aquifer water at the Lake Okeechobee injection-well site

[Data from CH_2M Hill (1989); straddle packer used to conduct tests in monitor well test hole]

Water type	Straddle packer test depth interval (meters below sea level)	Representative high-permeability zones (from table 1)	Chloride (milligrams per liter)	Field specific conductance (microsiemens per centimeter)	Total dissolved solids (milligrams per liter)	Static water-level altitude (meters, sea level)
Canal			290	1,140	729	
Native aquifer	349-365	Middle semiconfining unit	131	1,155	656	13.3
	383-403	1	1,800	7,850	4,000	12.4
	401-450	2	2,500	10,890	5,740	12.1
	460-497	3,4	2,920	12,763	6,710	11.9

conditions precluded recovery of meaningful quantities and impeded the interpretation of the test results in terms of the recovery efficiency. When the amount of injected water is small (relative to the size of the aquifer), the conditions represented by the data do not actually represent the aquifer, but the well/aquifer interface. CH_2M Hill (1989) could not make any projections or a conclusive assessment of the recovery efficiency potential because of the relatively small volume injected.

Four subsurface injection, storage, and recovery cycles were conducted for the present study, as was the case for the study by CH_2M Hill (1989). Cycle 1 consists of injection and recovery phases; cycles 2 and 3 consist of injection, storage, and recovery phases; and cycle 4 consists only of an injection phase. The injection, storage, and recovery phases are explained below:

- Injection: Phase in which canal water is injected through the well into the formation using a pump.
- Storage: Period in which the well is shut-in, and
- Recovery: Phase in which water is withdrawn from the aquifer (through the injection/recovery well) by natural artesian flow. A 35.6-cm diameter valve was open, discharging at rates ranging from 16,460 to 18,532 m^3/d. The water was discharged into a detention pond and later released into the L-63N canal (fig. 1).

The volumes of water injected ranged from 387,275 to 1,343,675 m^3 in the present study and ranged from 94,600 to 344,185 m^3 in the study by CH_2M Hill (1989). A preestablished water-quality limit (5,000 µS/cm of specific conductance, which is equivalent to a chloride concentration of 1,385 mg/L) was used to end the recovery cycle and determine the recoverability of water. Recovery was terminated when these water-quality criteria were met at the injection well. The results of the four injection, storage, and recovery cycles for the present study are discussed in the subsequent sections of this report.

Cycle 1

Cycle 1 consisted of injection and recovery phases. A preinjection phase was conducted for cycle 1, during which background water-quality conditions were established when specific conductance and chloride values were 10,400 µS/cm and 3,100 mg/L in the injection well, 7,930 µS/cm and 2,200 mg/L in the deep monitor well, and 1,280 µS/cm and 210 mg/L in the shallow monitor well. The amount of water discharged from the flowing well into the detention pond before reaching the background water-quality conditions was about 1,890 m^3. Corresponding constituents in water samples collected from the injection well and from the straddle packer test at an interval of between 383 and 403 m below sea level in the deep monitor well (table 2) were similar to background chloride and specific conductance values.

The injection phase of cycle 1 was conducted over a 35-day period in spring 1991 (April 17 to May 22), and the volume of water injected was 686,324 m^3. During this period, the injection rate ranged from 16,400 to 21,700 m^3/d and averaged 20,186 m^3/d (fig. 3A and table 3). The specific conductance and chloride values in the injected water were 709 µS/cm and 150 mg/L, respectively. All water samples were collected at the wellhead; the reason being that water

levels in the injection, deep, and shallow monitor wells rise above land surface due to the artesian condition of the respective aquifers.

The recovery phase was conducted over a 7-day period (May 22-29, 1991) when the preestablished water-quality limit (5,000 µS/cm of specific conductance, which is equivalent to a chloride concentration of 1,385 mg/L) was reached at the injection well. Chloride concentrations in the injection well (and the shallow and deep monitor wells) for the injection and recovery phases of cycle 1 are shown in figure 4. During the recovery phase, an average flow rate of about 17,700 m^3/d was maintained (fig. 3B and table 3). The volume of water recovered prior to achieving the preestablished chloride concentration limit (fig. 4B) was 106,200 m^3, and the estimated recovery efficiency was about 15 percent (table 3).

Cycle 2

Cycle 2 consisted of injection, storage, and recovery phases. Background water-quality conditions were not preestablished for this cycle. The buffer zone, which was created by the mixing of native aquifer water and residual water injected during cycle 1, served as reference conditions for cycle 2. This procedure is described in the literature as a "successive cycle" (Merritt, 1985). Preinjection sampling indicated that specific conductances and chloride concentrations were 4,220 µS/cm and 1,100 mg/L in the injection well, 2,020 µS/cm and 480 mg/L in the deep monitor well, and 959 µS/cm and 140 mg/L in the shallow monitor well.

The injection phase of cycle 2 was conducted over a 63-day period in summer 1991 (June 24 to August 26), and the volume of water injected was 1,294,784 m^3. During this period, the injection rate ranged from 19,077 to 21,800 m^3/d and averaged 20,552 m^3/d (fig. 5A and table 3).

A storage period of about 8 days (August 26 to September 3, 1991) was allowed before the beginning of the recovery phase of cycle 2. The recovery phase was conducted over a 17-day period (September 3-20, 1991) prior to achieving the preestablished water-quality limit (5,000 µS/cm of specific conductance which is equivalent to a chloride concentration of 1,385 mg/L). Chloride concentrations in the injection well (and the shallow and deep monitor wells) for the injection and recovery phases of cycle 2 are shown in figure 6. During the recovery phase, the flow rate ranged from 16,460 to 17,545 m^3/d and averaged 16,892 m^3/d (fig. 5B and table 3). The volume of water recovered prior to exceeding the preestablished chloride limit at the injection well (fig. 6B) was 287,162 m^3 and the estimated recovery efficiency was about 22 percent (table 3).

Cycle 3

Cycle 3 also consisted of injection, storage, and recovery cycles. Background water-quality conditions were not preestablished for this cycle. The buffer zone water quality established by previous successive cycles of injection and recovery (described in the previous section) served as reference conditions for cycle 3. Preinjection sampling indicated that specific conductances and chloride concentrations were 5,020 µS/cm and

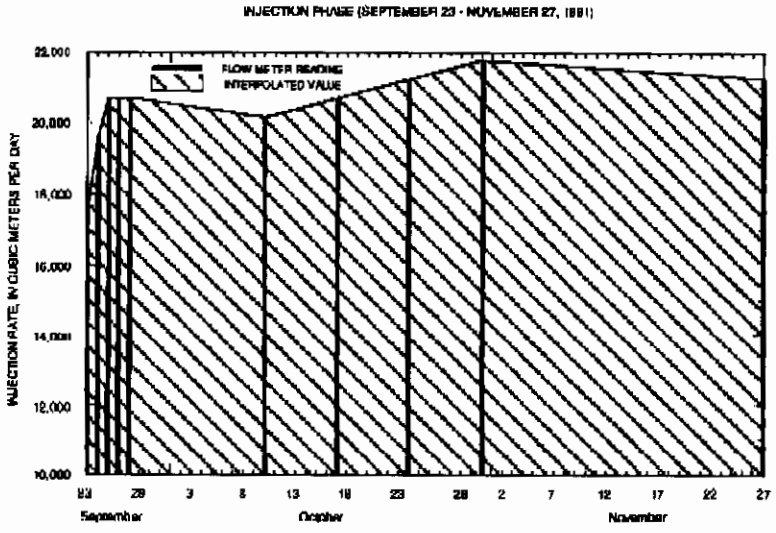

Figure 7. Rates of injection for cycle 3.

1,400 mg/L in the injection well, 1,410 µS/cm and 300 mg/L in the deep monitor well, and 929 µS/cm and 150 mg/L in the shallow monitor well.

The injection phase of cycle 3 was conducted over a 65-day period in autumn 1991 (September 23 to November 27), and the volume of water injected was 1,343,675 m^3. During this period, the injection rate ranged from 17,400 to 21,800 m^3/d and averaged 21,043 m^3/d (fig. 7 and table 3).

A storage period of about 5 days (November 27 to December 2, 1991) was allowed before the beginning of the recovery phase of cycle 3. The recovery phase was conducted over a 28-day period (December 2-30, 1991). Specific conductances and chloride concentrations at the end of the recovery period were about 4,700 µS/cm and 1,297 mg/L at the injection well. Chloride concentrations in the injection well (and the shallow and deep monitor wells) for the injection and recovery phases of cycle 3 are shown in figure 8. The recovery flow rate was not measured because of mechanical problems with the flow meter, but an average rate of 17,300 m^3/d was estimated using flowmeter readings from cycles 1 and 2. The specific conductance and chloride data were extrapolated through time because the chloride concentration limit of 1,385 mg/L was not reached at the end of the cycle. The volume of water recovered for the preestablished chloride limit (fig. 8B) was 484,400 m^3, and the estimated recovery efficiency was about 36 percent (table 3).

Cycle 4

Cycle 4 was used to define the dynamics of the aquifer system during the injection phase. Before injection, the valve at the wellhead was opened and water began flowing under natural artesian conditions. This backflow phase was conducted in an attempt to reestablish background water-quality conditions. Natural artesian flow was maintained for 161 days (January 27 to July 6, 1992). The natural artesian flow rate decreased with time during the test from more than 16,000 m^3/d to about 6,500 m^3/d. This may be an indication of pressure buildup in the aquifer during the injection phase. After 161 days of natural artesian flow, background water-quality conditions had not yet been reestablished at the injection and deep and shallow monitoring wells (fig. 9). The attempt to reestablish background water-quality conditions was abandoned because at least five additional months might have been required, and time constraints precluded continuation of the process (fig. 9). As a result, the reference water-quality conditions for cycle 4 consisted of lower chloride concentrations than those representing native aquifer water. The reference chloride concentrations (estimated from specific conductance readings) were about 2,700 mg/L at the injection well, 1,750 mg/L at the deep monitor well, and 240 mg/L at the shallow monitor well.

The injection phase of cycle 4 was conducted over a 26-day period in summer 1992 (July 8 to August 3), and the volume of water injected was 387,275 m^3.

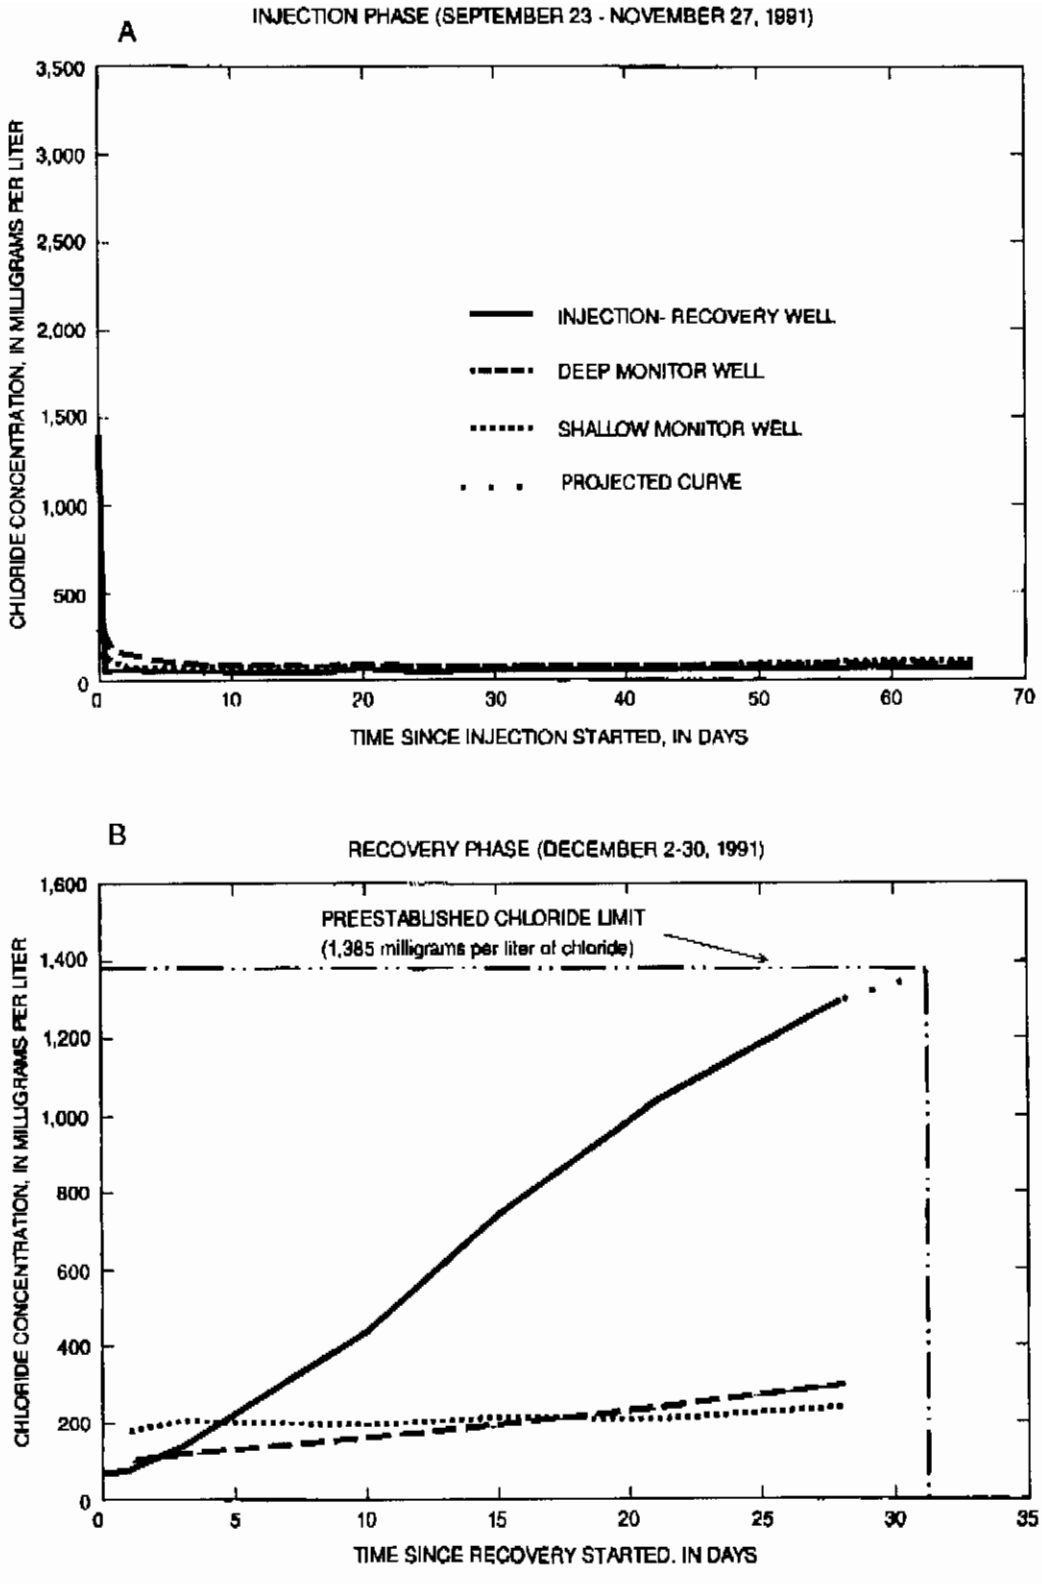

Figure 8. Chloride concentrations in the injection-recovery well and shallow and deep monitor wells during the injection and recovery phases of cycle 3.

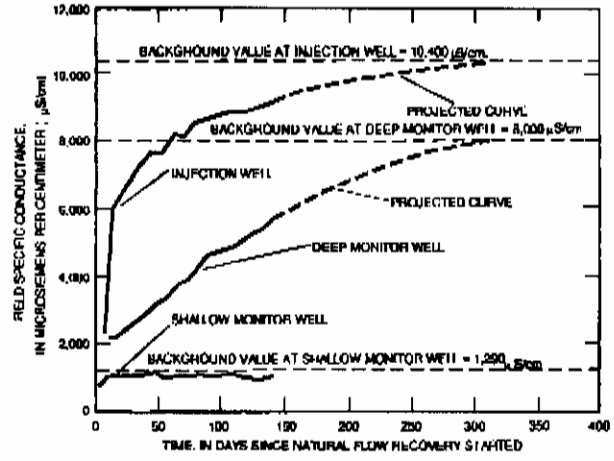

Figure 9. Specific conductance at the injection, deep monitor, and shallow monitor wells during the natural flow recovery period for reestablishing background water-quality conditions.

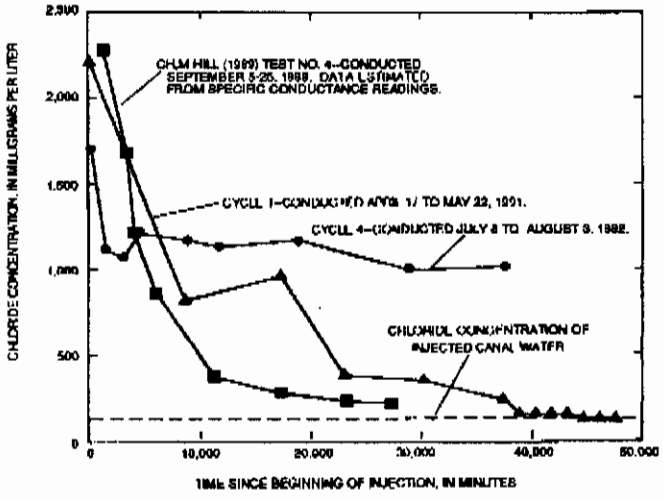

Figure 10. Chloride concentration breakthrough curves at the deep monitor well for the injection phase of cycles 1 and 4 from the present study and test no. 4 from a previous study.

An average injection rate of 14,549 m^3/d was maintained during this period (table 3). A storage period and a recovery phase were not conducted for cycle 4 due to the nature of the test.

Chloride concentration breakthrough curves were developed for the injection phase of cycles 1 and 4 (at the deep monitor well) from the present study data and test no. 4 from previous study data (CH_2M Hill, 1989). A comparison of the curves (fig. 10) reflects unexpected differences, especially considering that all three tests were conducted under similar background conditions. For example, it is expected that the chloride concentration curve reach an asymptote at a chloride concentration equal to that representative of canal water. Although it could be expected that the asymptote was reached at different times, for a conservative ion such as chloride, the asymptote should reach the same canal-water chloride concentration (chloride concentration of the injected water, approximately 120 mg/L). Several explanations of the hydrogeologic and hydraulic conditions at the injection well that may help explain this unexpected behavior are provided below.

1. Background chloride concentrations increased significantly with depth in the four high-permeability, relatively independent zones of the Lower Floridan aquifer. Chloride concentrations were 1,800 mg/L from 389 to 398 m below sea level (high-permeability zone 1),

2,500 mg/L from 419 to 424 m below sea level (high-permeability zone 2), 2,900 mg/L from 456 to 462 m below sea level (high-permeability zone 3), and 2,900 mg/L from 472 to 476 m below sea level (high permeability zone 4). These differences in background concentrations may have contributed to the anomalous patterns of the breakthrough curves (fig. 10).

2. Water-level altitudes, representative of the high permeability zones, were estimated from measurements using a straddle packer (CH_2M Hill, 1989) (table 2) and indicated a hydraulic gradient from the upper to the lower high-permeability zones. These data suggest that water from the upper high-permeability zone (1,800 mg/L of chloride concentration) might be flowing through the wellbore into the lower high-permeability zones (2,920 mg/L of chloride concentration). Hence, a mixing of the waters from the different high-permeability zones would occur, and the chloride concentration at which the asymptote of the breakthrough curve is reached would change (affected by the degree of mixing between the waters from the different zones).
3. The fact that the average injection rate for cycle 4 (14,549 m^3/d) was less than the natural artesian discharge rate (16,000 to 17,000 m^3/d) may have produced a greater degree of mixing at the deep monitor well (fig. 11). Figure 11A shows that if the injection rate (QINJECTED) were equal to or greater than the natural artesian flow (QNATURAL), all four high-permeability zones would transmit the injected water to the deep monitor well, and therefore, the chloride concentration value observed at the monitor well would be similar to that of the injected water. However, if QINJECTED were less than QNATURAL, the head differential might not be transmitted through the entire open wellbore, and injected water would probably flow only through the upper high-permeability zones (fig. 11B). As a result, chloride concentration values observed at the deep monitor well would represent a mix of water from the different high-permeability zones (fig. 11B), and therefore, would be higher than the concentration of the injected water.

ANALYSIS AND SUMMARY OF TEST CYCLES

Four subsurface injection, storage, and recovery cycles were conducted at the Lake Okeechobee injection-well site. Cycle 1 included injection and recovery phases; cycles 2 and 3 included injection, storage, and recovery phases; and cycle 4 included only an injection phase. The injection phases of each cycle were conducted over selected time periods in 1991 and 1992, and the volumes of water injected ranged from 387,275 to 1,343,675 m^3. The injection rate for cycles 1, 2, and 3 was similar and averaged about 20,600 m^3/d. The injection rate for cycle 4 was 14,549 m^3/d.

The recovery phases of cycles 1, 2, and 3 were conducted during variable time periods in 1991 when the preestablished water-quality limit was achieved at the injection well. The preestablished water-quality limit (5,000 µS/cm of specific conductance, which is equivalent to 1,385 mg/L of chloride concentration) was achieved for cycles 1 and 2 and projected for cycle 3. The average recovery flow rate ranged from 16,892 to 17,700 m^3/d for the three cycles. The volume of water recovered prior to achieving the preestablished water-quality limit ranged from 106,200 to 484,400 m^3, and the resulting recovery efficiency ranged from 15 to 36 percent.

The variability of the injection and recovery rates is shown in figures 3, 5, and 7 and can be due to several factors. Three of these factors include measurement device error (flow meter), change in background pressure, and electrical power failure (for the case of injection).

A comparison of the recovery efficiency for cycles 1, 2, and 3 in this study and test no. 4 from a previous study (CH_2M Hill, 1989) has been made, and the results are shown in figure 12. The recovery efficiency for successive cycles 2 and 3 increased from 22 to 36 percent and is expected to continue increasing with additional cycles. Cycle 1 and test no. 4 were conducted under similar background conditions (background conditions equal to native-aquifer water conditions or no residual injected water from a previous test). The volume of water injected for cycle 1 was 686,324 m^3 and the volume injected for test no. 4 was 344,185 m^3. Results indicated that the recovery efficiency was 24 percent for test no. 4 and 15 percent for cycle 1, suggesting that the recovery efficiency decreases with increasing injected volumes of water for tests conducted with no residual injected water from previous tests (background conditions equal to native-aquifer water conditions). All of these results are in agreement with those from previous studies by Tibbals and Frazee (1976) and Quiñones-Aponte and others (1989).

Cycle 4 was conducted in 1992 to define the dynamics of the aquifer system during the injection phase. A comparison of chloride concentration breakthrough curves at the deep monitor well (about 171 m from the injection well) for cycles 1 and 4 and test no. 4 reflects unexpected differences, especially considering that all three tests apparently were conducted under similar background conditions. One major difference was that the asymptote, expected to be reached at

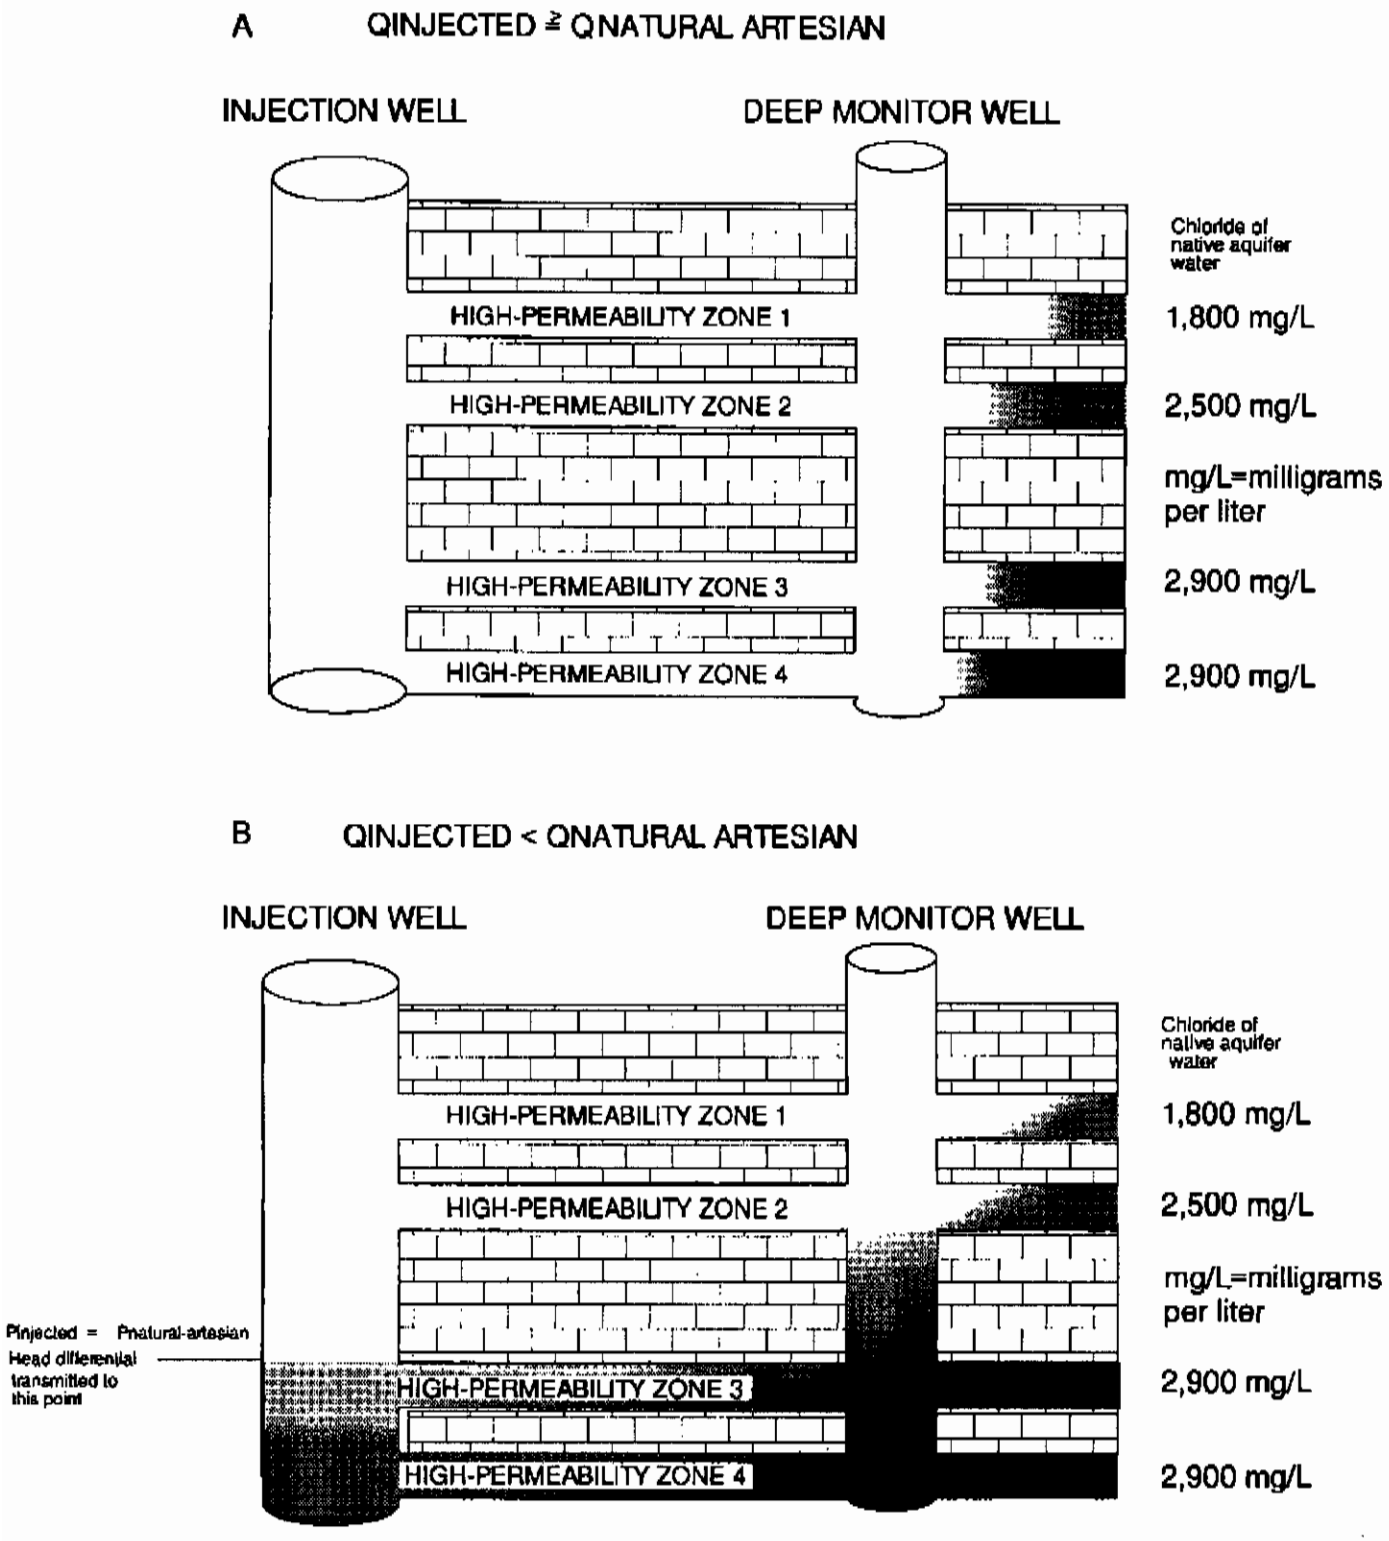

Figure 11. The injection process for two injection/recovery rate ratios: (A) QINJECTION/QNATURAL ARTESIAN is greater than or equal to 1.0, and (B) QINJECTION/QNATURAL ARTESIAN is less than 1.0.

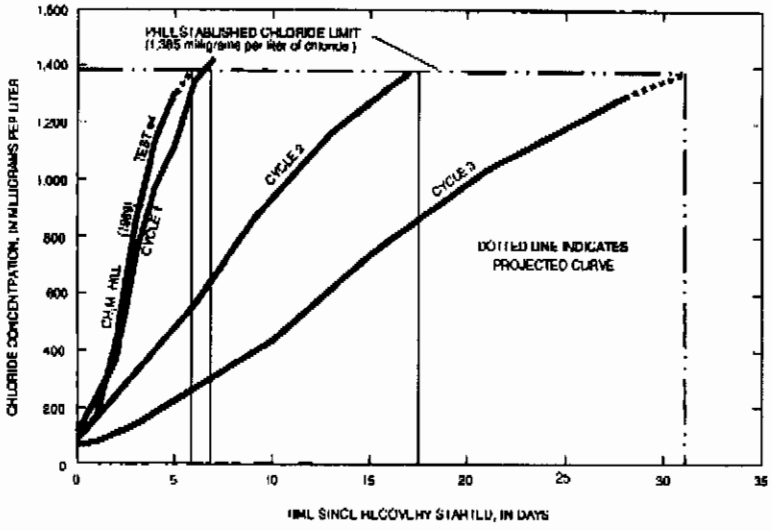

Figure 12. Chloride concentrations in the injection well during the recovery phase of cycles 1, 2, and 3 from the present study and test no. 4 from a previous study.

concentration levels equivalent or close to the injected water concentration, was instead reached at higher concentration levels.

Analysis of chloride concentrations in water at the injection-recovery well and at the deep monitor well (figs. 4, 6, and 8) indicates that flow through the Lower Floridan aquifer is not representative of a simple uniform-isotropic outflow of freshwater in a confined aquifer followed by a similar type of backflow. For the simple freshwater case of uniform-isotropic outflow and backflow within a porous media, changes in chloride concentration in water at the monitor well during recovery would precede changes in chloride concentration at the injection-recovery well. At some time during recovery, conditions at the monitoring well would return to background levels of chloride concentration because the bubble of injected water would clear the monitor well location while some freshwater still remained around the injection-recovery well. However, chloride concentrations returned to background levels at the injection-recovery well prior to achieving background conditions at the deep monitor well (figs. 4, 6, and 8). This suggests that the aquifer system is not characterized by a simple uniform-isotropic type flow, but instead responds as a conduit or cavernous type flow system. This hypothesis is illustrated by figure 11 and supports the corresponding discussion of cases where QINJECTED is less than QNATURAL. Figures 4, 6, and 8 also show that there were no significant changes in chloride concentration in water recovered from the shallow monitor well during the study, indicating that the injected freshwater did not reach this location vertically.

At the beginning of the recovery phase of cycle 1, chloride concentrations in water at the deep and shallow monitor wells were similar (fig. 4B). However, for cycles 2 and 3 (at the beginning of the tests), the chloride concentration in water at the deep monitor well was lower than in water at the shallow monitor well (figs. 6B and 8B). Additionally, the chloride concentration in water at the deep monitor well water at the beginning of cycles 2 and 3 was very similar to concentrations in water at the injection-recovery well (figs. 6B and 8B), indicating that injected water reached the deep monitor well during cycle 1 operations.

SIMULATION ANALYSIS OF SUBSURFACE INJECTION, STORAGE, AND RECOVERY OF FRESHWATER

The movement of solutes through porous media is controlled by both advection and hydrodynamic dispersion. Advective transport describes the movement of solute particles along the average direction of fluid flow at a rate equal to the mean pore-water velocity. Hydrodynamic dispersion describes the spread of solute particles along and transverse to the direction of average fluid flow in response to molecular diffusion and mechanical dispersion.

The following variable-density advective dispersive solute-transport equation was modified by

Quiñones-Aponte and Wexler (1995) for saturated flow and conservative solute species from a more general form presented by Voss (1984):

$$\frac{\partial(n\rho c)}{\partial t} = \nabla\cdot(n\rho v c) + \nabla\cdot[n\rho(D_d I + \underline{D}_m)\cdot\nabla c] + Q' c' \quad (6)$$

where:

n is the apparent porosity of the aquifer [dimensionless],

c is volumetric solute concentration in aquifer fluid [M/L^3],

t is time [T],

∇ is the gradient operator [1/L],

v is the average pore-water velocity [L/T],

D_d is the molecular diffusion coefficient [L^2/T],

I is the identity tensor (ones on diagonal, zero elsewhere),

$\underline{D}_m$ is the dispersion tensor [L^2/T],

Q' is the volumetric injection rate per unit area of aquifer [L/T], and

c is volumetric solute concentration in the injected fluid [M/L^3].

In equation *(6)*, the term $Q' c'$ represents only sources of fluid. Withdrawals of fluid from the aquifer are not considered in equation *(6)* because the concentration of solute in the fluid being withdrawn, c', is identical to the solute concentration c in the aquifer.

The average pore-water velocity (v) needed to solve equation *(6)* can be determined by:

$$v = -\frac{q}{n} \quad (7)$$

where q is specific discharge (flow rate per unit cross-sectional area) [L/T].

The rate of ground-water flow (specific discharge) is represented by Darcy's law:

$$q = -k(\nabla p - \rho g z)/\mu \quad (8)$$

where:

k is the intrinsic permeability of the aquifer materials [L^2],

p is the fluid pressure [M/LT^2], and

z is the altitude above a reference datum [L].

The variable-density flow equation is developed using Darcy's law *(8)* and the principle of conservation of fluid mass:

$$\frac{\partial(n\rho)}{\partial t} = -\nabla\cdot(\rho q) \pm Q_p \quad (9)$$

where:

Q_p is the mass of fluid injected (+) or withdrawn (-) per unit time per unit volume of aquifer [M/L^{3}T].

A generalized digital model was constructed to simulate the subsurface injection, storage, and recovery of freshwater in the Lower Floridan aquifer at the Lake Okeechobee injection-well site. The model was constructed using a modified version of the Saturated-Unsaturated TRAnsport (SUTRA) code (Voss, 1984), which simulates variable-density advective-dispersive solute-transport and variable-density ground-water flow. This modified version of SUTRA for a regular rectangular grid, QSUTRA (Quiñones-Aponte and Wexler, 1995), reduces computer storage and time, allowing for more-detailed discretization. Like the original code (SUTRA), QSUTRA uses the Galerkin finite-element technique (Voss, 1984) to compute the solution of the ground-water flow and solute-transport equations. The ground-water flow equation *(9)* is solved using the Incomplete Cholesky-Conjugate Gradient method (Kuiper, 1987), and the solute-transport equation *(6)* is solved using the Line Successive Overrelaxation method (Young, 1954).

The simulations of freshwater injection, storage, and recovery in the Lower Floridan aquifer were made using the radial flow option of the QSUTRA code. Because of a lack of information on the spatial variability of the hydraulic and transport characteristics, several assumptions had to be made: (1) the effect of the background hydraulic gradient is negligible, (2) the aquifer is divided into vertically adjacent layers characterized in the model as homogeneous with respect to their hydraulic and transport characteristics, (3) the hydraulic and transport characteristics are homogeneous along the radial direction of flow, and (4) the aquifer characteristics are isotropic along the horizontal (radial) direction.

Model Concept and Construction

The conceptual model represents a generalized version of the Lower Floridan aquifer at the Lake Okeechobee injection-well site (fig. 1). It was developed on the basis of data obtained from geophysical logs, straddle packer tests, pumping tests, and injection tests during a previous study (CH_2M Hill, 1989). According to the data by CH_2M Hill (1989) and several

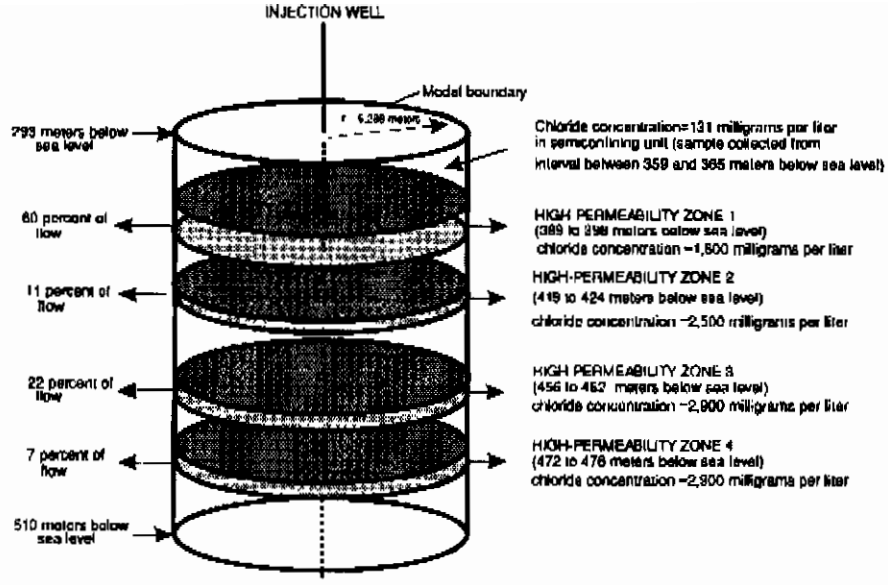

Figure 13. Generalized conceptual model of the Lower Floridan aquifer at the Lake Okeechobee injection-well site.

assumptions described previously, a generalized representation of the aquifer conditions at the site can be produced using a cylindrical coordinate system. This representative system can be justified for the case of injection or pumping from a single well where regional hydraulic gradients are small and aquifer hydraulic and transport characteristics are isotropic.

As previously discussed, the Lower Floridan aquifer can be visualized as containing four relatively independent high-permeability flow zones: high-permeability zone 1 (389 to 398 m below sea level), high-permeability zone 2 (419 to 424 m below sea level), high-permeability zone 3 (456 to 462 m below sea level), and high-permeability zone 4 (472 to 476 m below sea level). The high-permeability zones are characterized by fracture or cavernous type flow and are partly isolated from each other by hydrogeologic units of relatively low hydraulic characteristics. Sixty percent of the flow travels along high-permeability zone 1, 11 percent travels along high-permeability zone 2, 22 percent travels along high-permeability zone 3, and 7 percent travels along high-permeability zone 4 (fig. 13 and table 1). A very small percentage of the flow is transported as diffuse flow throughout the semiconfining units that are present between the high-permeability zones.

Water samples collected using a straddle packer (CH_2M Hill, 1989) indicated large differences in total dissolved solids, chloride concentrations, and water level altitude between the representative high permeability zones (table 2). High-permeability zone 1 had a total dissolved solids concentration of about 4,000 mg/L, a chloride concentration of about 1,800 mg/L, and a water-level altitude of 12.4 m. High-permeability zone 2 had a total dissolved solids concentration of about 5,740 mg/L, a chloride concentration of about 2,500 mg/L, and a water-level altitude of 12.1 m. High-permeability zones 3 and 4 had a total dissolved solids concentration of about 6,710 mg/L, a chloride concentration of about 2,920 mg/L, and a water-level altitude of 11.9 m. Although the high-permeability zones are relatively close to each other, the differences in water-quality data and water-level altitude indicated some degree of confinement between the zones. Additionally, an analysis of a water sample collected from 349 to 365 m, which represents a segment of the middle semiconfining unit (fig. 2), indicated that the total dissolved solids concentration was 656 mg/L and the chloride concentration was 131 mg/L (table 2). This result suggests that the degree of hydraulic connection among the high-permeability zones is relatively small.

Grid Design

A cylindrical coordinate finite-element grid was constructed (fig. 14) to study the subsurface injection, storage, and recovery cycles in the Lower Floridan aquifer at the Lake Okeechobee injection-well site. The model grid represents a radial extension of 6,288 m out

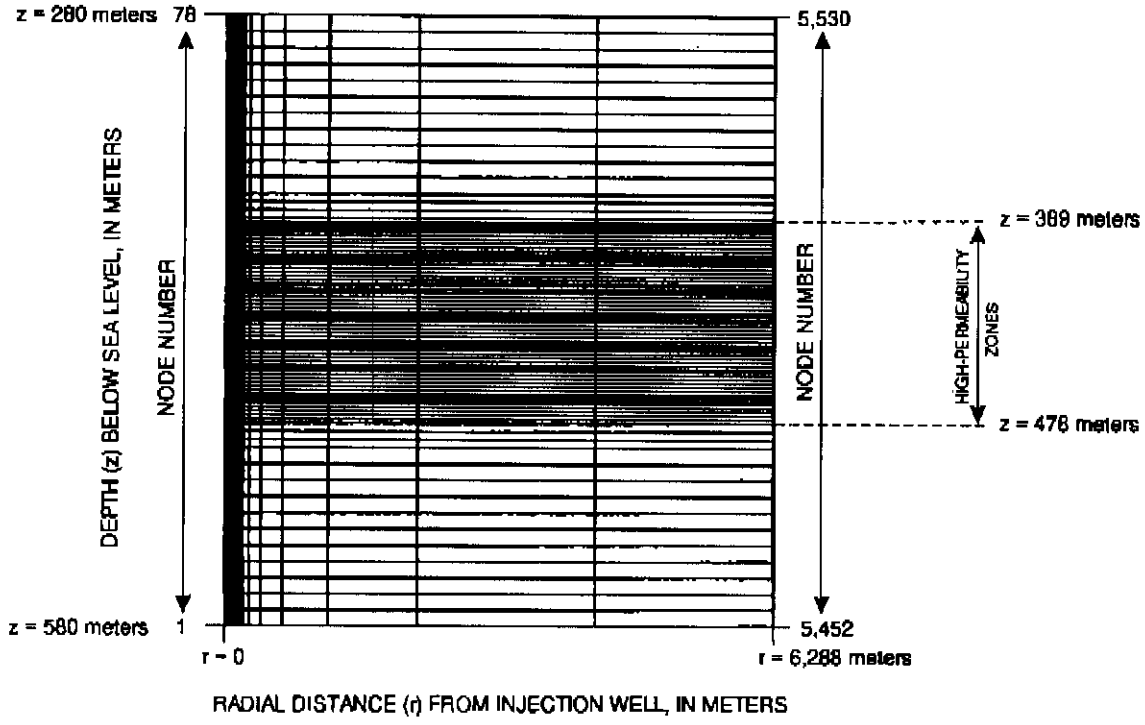

Figure 14. The cylindrical coordinate finite-element grid of the Lower Floridan aquifer at the injection-well site.

from the injection well into the aquifer. The grid is finer in the vicinity of the injection well to avoid errors associated with numerical dispersion (artificial dispersion due to inadequate discretization) and large differences between sides of a model-grid element. Elements represent a 2-m thickness and 2-m length near the well but vary elsewhere. Elements represent 4-m lengths at a distance of 100 m from the well, 8-m lengths at a distance of 120 m from the well, and lengths as much as 2,048 m beyond a distance of 160 m. Element thickness varied from 2 to 8 m, with 4-m thick elements providing a transition. Elements representing 8 m of aquifer thickness are used for the first 11 and last 11 rows of the model grid. Elements representing 2 m of aquifer thickness are used for 50 rows of the grid, corresponding to the aquifer interval that would be affected by injected canal water. Elements representing 4 m of aquifer thickness are used for 6 rows of the grid and correspond to a transition between the element rows representing thicknesses of 2 and 8 m (fig. 14).

Boundary and Initial Conditions

Boundary and initial conditions were determined for the generalized model of the Lower Floridan aquifer at the Lake Okeechobee injection-well site. Boundary conditions were set from $r = 0$ to $r = 6{,}288$ m at $z = 280$ m and $z = 580$ m below sea level, the limits of the finite-element grid (fig. 14). Specified pressure nodes were set at the top and bottom of the Lower Floridan aquifer with specified chloride concentration for any inflow across these boundaries (upper and lower limits of the modeled zone). Specified pressures were set equal to hydrostatic pressure ($P = h\rho g$). The chloride concentration was set equal to the concentration of the native water at these boundaries, which was obtained from in-situ samples. The boundary condition at the well ($r = 0$) was applied by specifying the mass flux equal to the injection rate. The flux was distributed among the boundary nodes along the length of the injection zone using an analysis from packer test data (fig. 13 and tables 1 and 2). The analysis showed that the flow distribution was 60, 11, 22, and 7 percent for high-permeability zones 1, 2, 3, and 4, respectively. The aquifer hydraulic characteristics (K and k) were determined in a similar manner using field determined transmissivity values and procedures described earlier in the report. A chloride concentration corresponding to the injected water during injection was specified at the well boundary ($r = 0$). A flux-average chloride concentration (weighted average concentration using flux as weighting factor) for water withdrawn during recovery was calculated using simulated chloride concentration values at boundary nodes representing the well (fig. 14, $r = 0$). The vertical lateral boundary (external boundary) was represented as a no-flow/

no-transport condition with the assumption that this boundary is sufficiently far away from the area of interest. At the upper and lower model limits, the constant pressure and concentration boundaries can be justified because of the distance from the injection source and the permeability gradients that exist throughout the 300-m thickness.

The initial pressures were assumed to be hydrostatic ($P = h\rho g$) and set equal to the equivalent freshwater head that corresponded to static conditions prior to injection. Initial chloride concentration was set equal to solute concentration in the native aquifer water at the different flow zones and boundaries (table 2). The fluid density ρ was assumed to depend only on solute concentration C and was calculated by the model based on initial solute concentrations and the following functional relation between density and solute concentration at each node:

$$\rho = \rho_i + (\rho_n \quad \rho_i)\,[(C - C_i)/(C_n - C_i)] \qquad (10)$$

where:

ρ_i is density of injected water [M/L^3],

ρ_n is density of native water [M/L^3],

C_i is solute concentration in injected water [M/L^3], and

C_n is solute concentration in native water [M/L^3].

Time Steps

To avoid numerical dispersion associated with a large time-step size, initial time-step sizes were set at or less than 100 seconds. The time-step size was increased during the injection phase so that the injected water front (neglecting dispersion) moved a constant distance with each successive time step. In the simulation of the mixing of two water bodies in a radial flow field, it is important to require that the time step, Δt, satisfies the condition:

$$\frac{v\ \Delta t}{2.0} \ll \alpha_L \qquad (11)$$

where α_L is the longitudinal dispersivity of the aquifer [L] (Kipp, 1987).

The time step must be of such size to permit the simulated movement of the injected water front inside a model element without an abrupt transition from one element to the next. For the radial coordinate system, water velocity increases as the water particles move closer to the well, and therefore, the time-step size must be increased during injection and decreased during recovery to meet the stability criterion established by equation *(11)*.

The final time-step size from the injection phase was used and maintained uniformly for the entire simulation of the storage period. During the recovery phase, the time-step size was gradually reduced from its maximum value as the injected water front moved closer to the well.

Calibration and Testing

The calibration and testing of the model was performed by changing the model variables within realistic limits, until a satisfactory comparison between the observed and simulated solute breakthrough data was obtained. Initial model variables were set according to data presented in tables 1 and 4. Other model constants are listed in table 5. A vertical anisotropy (k_H/k_V) ratio of 100:1 was assumed for the high-permeability zones and the semiconfining units that are present between the zones. For the semiconfining units, a horizontal intrinsic permeability value (k_H) of 1.53×10^{-11} m^2 (square meters) and a vertical intrinsic permeability value (k_V) of 1.53×10^{-13} m^2 were assigned. These values were derived using equation *(5)*, a k_H/k_V ratio of 100:1, and data from a CH_2M Hill (1989) straddle packer test in the middle semiconfining unit (349 to 365 m below sea level). The porosity for the semiconfining units between the high-permeability zones was assumed to be 0.15. The apparent effective porosity value listed in table 4 for the high-permeability zones was the result of calibration trials. Although conceptually this apparent effective porosity value (5 percent) seems to be too low for the high-permeability zones, it was the highest value (combined with the calibrated intrinsic permeabilities) to yield acceptable results in modeling the chloride concentration breakthrough curve at the deep monitor well.

Because the open intervals of the injection and monitor wells include more than one node, composite chloride concentration values representative of the wells were computed using simulated chloride concentrations at nodes representing the well. The computation was determined using a weighted average value (with permeability as a weighting factor) from nodes representing the open interval of the monitor wells and a flux-weighted average concentration value from nodes representing the injection well. Composite

chloride concentration values determined using the flux-weighted method are more accurate than composite concentration values from the permeability-weighted method. However, at the time of this study, the computer model (QSUTRA) does not provide for the computation of flux-weighted average concentrations at nodes representing an observation well.

Satisfactory comparisons of simulated to observed dimensionless chloride concentrations for the deep monitor well were obtained when using the model to simulate the injection and recovery phases of cycle 1 (fig. 15) using the parameters listed in table 4. Several attempts were made, changing the hydraulic and transport parameters by two or three orders of magnitude and changing the boundary conditions. Different combinations of no-flow and specified pressure boundary conditions were tested for the model limits. However, no acceptable comparison of simulated to observed dimensionless chloride concentrations for the injection well during the recovery phase of cycle 1 was obtained (fig. 16). A dimensionless version of chloride data obtained in the field (observed data) compared to dimensionless chloride data obtained from four calibration attempts (simulated data) for the injection well is shown in figure 16. The simulated data in figure 16 represent model results using the parameters in table 4 and represent the simulated values for different longitudinal and transverse dispersivities (α_L = 1.0 m and α_T = 0.1 m, α_L = 2.0 m and α_T = 2.0 m, α_L = 1.0 m and α_T = 1.0 m, and α_L = 1.0 m and α_T = 0.6 m).

Although many other calibration attempts were made, only the results for which the model input

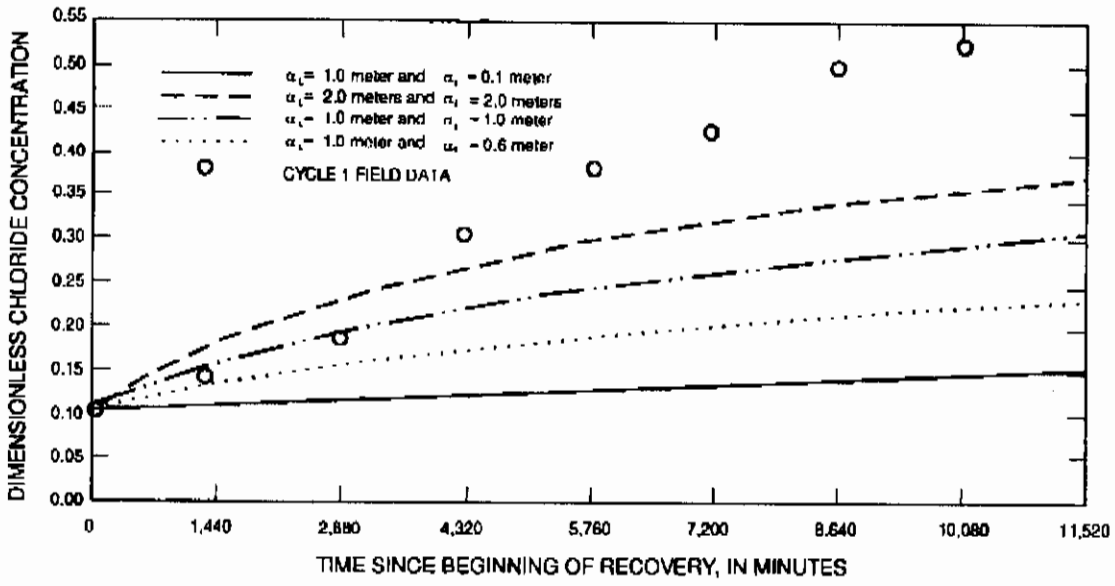

Figure 16. Observed and simulated dimensionless chloride concentrations in the injection well during the recovery phase of cycle 1.

variables were close to the parameters listed in table 4 are presented in this report. It was suspected that the cavernous/conduit nature of the Lower Floridan aquifer would allow for very high velocities (relative to typical ground-water velocities) to develop near the injection well. Such velocities would preclude an appropriate representation of flow and solute transport using the QSUTRA model, which is based on porous media assumptions. Porous media type models are based on Darcy's law which assumes a linear proportionality between specific discharge (discharge per unit measured of aquifer thickness) and hydraulic gradient. This proportionality is characteristic of laminar ground-water flow. The Reynolds number, defined below, is used to determine limits between laminar and turbulent flow regimes. For turbulent flow, the linear proportionality between specific discharge and hydraulic gradient is not valid. Where turbulent flow occurs, a porous media based flow model would compute hydraulic gradient distributions smaller than actual field gradients. Therefore, to test for the occurrence of turbulent flow, Reynolds numbers were estimated for different distances from the injection well using two different conceptual models, porous media and cavernous conceptual models. The Reynolds number (R_e) is defined as the ratio of inertial forces to viscous forces:

$$R_e = \frac{v\ d}{V} \qquad (12)$$

where:

d is a characteristic length (in this case, thickness of flow zone for cavernous conceptual system or $k^{1/2}$ [the square root of the intrinsic permeability] for the porous media conceptual system) [L], and

V is the fluid kinematic viscosity [L^2/T].

Reynolds numbers were only estimated for high-permeability zone 1 (9-m thick), which constituted 60 percent of the flow (fig. 13). The Reynolds numbers were estimated for two different conceptual systems in radial or cylindrical coordinates, a cavernous system and a porous media system (table 6). To estimate Reynolds numbers of actual field conditions at different distances from the injection source, it was necessary to determine or approximate the actual pore-water velocity at the different locations, the effective thickness of the flow zone (cavernous conceptual system) or intrinsic permeability (porous media conceptual system), and the fluid kinematic viscosity.

The actual radial ground-water flow velocity at a location from the injection source (the deep monitor well, located 171 m from the source) was determined from a chloride concentration breakthrough curve. This was accomplished by identifying the inflection point of the chloride concentration breakthrough curve, which usually coincides with the 50 percent concentration change from native to injected water. Data from test no. 4 by CH_2M Hill (1989) was used to estimate the pore-water velocity at the deep monitor well (fig. 17 and

[1]The cavernous conceptual system is $2\pi rb \cdot correction\ factor$ and the porous media conceptual system is $2\pi rbn \cdot correction\ factor$ where r is the radial distance from the injection source, b is the thickness of the flow zone, and n is the apparent porosity of the aquifer (dimensionless). The correction factor was applied to adjust the thickness area of the flow zone in order to approximate actual field velocities. The correction factor was determined using the actual ground-water flow velocity estimated at the deep monitor well located 171 meters from the injection well.

[2]Actual field velocity estimated from a concentration breakthrough curve at the deep monitor well (fig. 17).

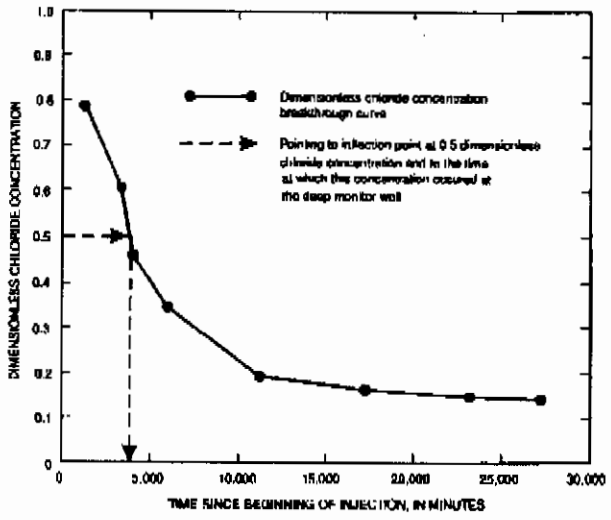

Figure 17. Dimensionless chloride concentration breakthrough curve of data from test no. 4. Test data from CH_2M Hill (1989).

table 3). These test data were selected for velocity determination because the subject test background concentration (native water concentration) was well established. This is important in determining the actual inflection point of the breakthrough curve (50 percent concentration change). The estimated pore-water velocity at the deep monitor well was 0.000760 m/s (meter per second). The area perpendicular to the flow for the case of radial flow is defined as $A = 2\pi rb$ where A is the area, r is the radial distance from the injection source, and b is the thickness of the flow zone. The effective area was first estimated at the location of the deep monitor well for which a velocity value was previously determined. The effective area was estimated by using the relation:

$$Q = v \cdot A_{eff} \cdot correction\ factor \qquad (13)$$

or:

$$A_{eff} = \frac{Q}{v \cdot correction\ factor} \qquad (14)$$

where Q is the flow through the flow zone. The correction factor was applied to the areas determined for different distance r to obtain an effective area (A_{eff}) for each location, and the effective area was used alone with flow rate to determine velocities at the different distances.

For the case of the porous media conceptual system, the square root of the intrinsic permeability of the high-permeability zone 1 (table 1) was used as the characteristic length as recommended by Bear (1979). Fluid kinematic viscosity in this zone was assumed as 8.639×10^{-7} m^2/s (square meters per second) at a water temperature of 26.7 degrees Celsius. For the case of the cavernous conceptual system, an effective thickness was determined using the same correction factors that were applied to the area to determine A_{eff} and used in equation *(12)* as the characteristic length.

For the porous media conceptual system, the Reynolds numbers were greater than 10 at distances less than 1.42 m from the injection well (fig. 18). This number (Reynolds number equal to 10) represents the upper limit of laminar porous media flow, which is the fundamental assumption for the application of Darcy's law to ground-water flow (Bear, 1979). At the deep monitor well located about 171 m from the injection well, the Reynolds number was about 0.08 which indicates laminar ground-water flow (porous media flow) at that location (fig. 18). The Reynolds number was about 100 at a distance of 0.1 m from the injection well (fig. 18). Thus, application of Darcy's law to ground-water flow is not valid at this distance nor is the transport solution, which is affected by the head gradient in the advection terms of the governing solute-transport equation. This may explain why the QSUTRA model produced good results for the deep monitor well, but was not able to produce acceptable results for the injection well. For the cavernous conceptual system, Reynolds numbers less than about 2,000 that are representative of laminar flow in circular tubes (Rouse,

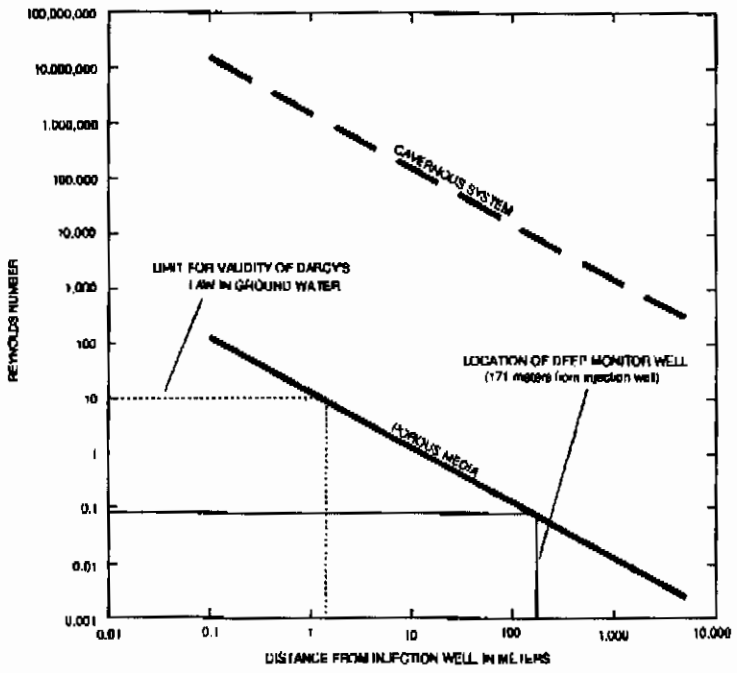

Figure 18. Reynolds number for a cavernous conceptual system and a porous media conceptual system as a function of distance from the injection well

1956, p. 174) were obtained at distances greater than 800 m (fig. 18). The Reynolds number was greater than 2,000 at distances less than 1,000 m from the injection well. This number represents the upper limit of laminar flow.

SUMMARY AND CONCLUSIONS

A series of freshwater subsurface injection, storage, and recovery tests were conducted at an injection-well site near Lake Okeechobee in Okeechobee County, Florida, to assess the recoverability of injected canal water from the Lower Floridan aquifer. Initial testing at the Lake Okeechobee injection-well site was previously conducted by a private consultant, and some of their results have been included as part of the U.S. Geological Survey study. At the study site, the Lower Floridan aquifer is characterized as having four local, relatively independent, high-permeability flow zones (389 to 398 m, 419 to 424 m, 456 to 462 m, and 472 to 476 m below sea level). The transmissivity of the aquifer at the injection well was estimated to be about 71,000 m^2/d from 377 to 509 m below sea level (equivalent to an average hydraulic conductivity of 540 m/d).

Four subsurface injection, storage, and recovery test cycles were conducted at the Lake Okeechobee injection-well site. Cycle 1 included injection and recovery phases; cycles 2 and 3 included injection, storage, and recovery phases; and cycle 4 included only an injection phase. The volumes of water injected ranged from 387,275 to 1,343,675 m^3 and the average injection rates ranged from 14,549 to 21,043 m^3/d for all the cycles. The volumes of water recovered, prior to achieving (or projecting) the preestablished water-quality limit (5,000 µS/cm of specific conductance, which is equivalent to about 1,385 mg/L of chloride concentration), ranged from 106,200 to 484,400 m^3 and the average recovery flow rates ranged from 16,892 to 17,700 m^3/d for cycles 1, 2, and 3. The recovery efficiency for successive cycles 2 and 3 increased from 22 to 36 percent and is expected to continue increasing with additional cycles. Cycle 1 and test no. 4 (from a previous study) were conducted under similar background conditions (background conditions equal to native-aquifer water conditions or no residual injected water from a previous test). The volumes of water injected were 686,324 m^3 for cycle 1 and 344,185 m^3 for test no. 4. The recovery efficiency was 24 percent for test no. 4 and 15 percent for cycle 1, indicating that the value decreases with increasing volumes of injected water. All these results are in agreement with those from previous studies.

Cycle 4 was conducted to define the dynamics of the aquifer system during the injection phase. A comparison of chloride concentration breakthrough curves at the deep monitor well (about 171 m from the injection well) for cycles 1 and 4 and test no. 4 reflects unexpected differences, especially considering that all three tests were conducted under similar background conditions. One major difference was that the concentration asymptote, expected to be reached at concentration levels equivalent or close to the injected water concentration, was instead reached at higher concentration levels. One factor that may explain the unexpected differences suggests that the ratio of injection to recovery rates could affect the chloride concentration breakthrough curves at the deep monitor well. For cases where the injection rate is smaller than the natural artesian flow rate, the head differential might not be transmitted to the deeper high-permeability zones. The injected water would probably reach the deep monitor well only through the upper high-permeability zones, and the chloride concentration values observed at this well would represent a mix of water from the different upper and lower high-permeability zones. Hence, the asymptote would be reached at a higher chloride concentration level in cases where the injection rate is smaller than the natural artesian flow rate.

A generalized digital model was constructed to simulate the subsurface injection, storage, and recovery of freshwater in the Lower Floridan aquifer at the Lake Okeechobee study site. The model was constructed using a modified version of the SUTRA code (QSUTRA). QSUTRA uses the Incomplete Cholesky-Conjugate Gradient method to solve the ground-water flow equation and the Line Successive Overrelaxation method to solve the solute-transport equation. A cylindrical coordinate finite-element grid was constructed to study the subsurface injection, storage, and recovery cycles in the Lower Floridan aquifer, and boundary and initial conditions were determined for the generalized model.

The calibration and testing of the model was performed by changing the model variables within realistic limits, until a satisfactory comparison between the observed and simulated solute breakthrough data was obtained. Satisfactory comparisons of simulated to observed dimensionless chloride concentrations for the deep monitor well were obtained when using the model during the injection and recovery phases of cycle 1, but not for the injection well during the recovery phase of cycle 1 even after several attempts. This precluded the determination of the recovery efficiency values by using the model. The cavernous or conduit nature of the Lower Floridan aquifer at the local scale permits very high velocities (relative to typical ground-water velocities) to develop near the injection well. Such velocities could explain the unsatisfactory comparisons of simulated to observed dimensionless chloride concentrations for the injection well and failure of the model to represent the field data at this well. To test this possibility, Reynolds numbers were estimated at varying distances from the injection well, taking into consideration two aquifer conceptual systems: porous media and cavernous.

For the porous media conceptual system, the square root of the permeability value was used as a characteristic length to estimate Reynolds numbers. The Reynolds numbers were greater than 10 at distances less than 1.42 m from the injection well. Thus, application of Darcy's law to ground-water flow might not be valid at this distance. At the deep monitor well located about 171 m from the injection well, the Reynolds number was about 0.08 which is representative of laminar porous media flow conditions.

For the cavernous conceptual system, the thickness (9 m) of high-permeability zone 1 was used as a characteristic length to estimate Reynolds numbers. The Reynolds numbers were greater than 2,000 at distances less than 1,000 m from the well. This number represents the upper limit of laminar flow, which is the fundamental assumption for the application of Darcy's law to free flow.

In conclusion, the simulation of recovery efficiency for the Lower Floridan aquifer at the Lake Okeechobee injection-well site might require the application of a free-flow type model (conduit flow or fracture flow model). This type of model may produce a more realistic representation of the actual fluid motion in the aquifer and will provide appropriate estimates of the recovery efficiency.

Analytical Model for Estimation of Steady-State Capture Zones of Pumping Wells in Confined and Unconfined Aquifers

by Stuart Grubb[a]

Abstract

The analysis of capture zones of pumping wells is useful for designing pumping systems and wellhead protection programs. Using discharge potentials, equations are derived that can be applied to confined, unconfined, or combined confined and unconfined aquifers. The transient equations are transcendental and cannot be solved explicitly. However, infinite-time (steady-state) equations are presented which can be solved. They define an area in which, theoretically, all the water in the aquifer will eventually reach the pumping well, although the equations do not consider the effects of hydrodynamic dispersion. Equations for calculating the stagnation point, upgradient divide, and dividing streamline within the aquifer and an example problem are presented.

1. Introduction

A capture zone is defined as the area of an aquifer in which all the water will be removed by a pumping well or wells within a certain time period. Capture zone analysis has been recognized as an important consideration in the design of ground-water remediation systems and wellhead protection programs (Javandel and Tsang, 1986; Lee and Wilson, 1988). Bear and Jacobs (1965) investigated the movement of water particles injected into aquifers, and their analytical model is often used for determining capture zones as well. Several standard ground-water texts have simple equations for determining the infinite-time (steady-state) capture zone of a single well in a confined aquifer with uniform regional flow (for example, Bear, 1979; Todd, 1980). Equations can be superimposed to calculate the capture zone of multiple well systems (Javandel and Tsang, 1986), and computer models have been developed for analyzing multiple wells and heterogeneous aquifers (for example, McElwee, 1991). These models include the EPA's wellhead protection area (WHPA) package (EPA, 1990).

This paper presents a model for determining capture zones which is applicable not only to confined aquifers, but to unconfined and combined confined and unconfined aquifers as well. Portions of the model development were presented in Javandel and others (1985) and Bear and Jacobs (1965). These authors used the potential ($K\phi$) and the specific discharge to develop the equations. The primary difference in the model presented here is that the equations are generalized in terms of discharge potential so they can be used for confined aquifers, unconfined aquifers, and combined confined and unconfined aquifers by simply using the appropriate definition of one parameter, the discharge potential. The discharge potential concept was developed over 20 years ago and is fully documented in Strack (1989) and discussed by Marsily (1986), but it is not widely used.

2. Analytical Model

The assumptions for this model are as follows:

- The aquifer is homogeneous, isotropic, and infinite in horizontal extent.
- Uniform flow (steady-state) conditions prevail.
- A confined aquifer has a uniform transmissivity and no leakage through the upper or lower confining layers. An unconfined aquifer has a horizontal lower confining layer with no leakage, rainfall infiltration, or other vertical recharge. The effect of these assumptions is discussed later.
- Because the equations assume steady-state conditions, the storativity of a confined aquifer and the specific yield of an unconfined aquifer have been neglected. Hydrodynamic dispersion is also neglected.
- Dupuit assumption, i.e. vertical gradients are negligible.

[a]Grubb Environmental Services, 2233 15th Avenue, North St. Paul, Minnesota 55109.

Received October 1991, revised February 1992, accepted March 1992.

Discussion open until July 1, 1993.

• The well is fully penetrating, is open over the thickness of the confined or unconfined aquifer at the well, and pumps at a constant rate.

Complex potentials are used to describe the distribution of discharge potentials throughout the aquifer. For background on the mathematics of complex potentials, Strack (1989, p. 269) gives a good, concise overview of the theory of complex functions. The complex potential for uniform regional flow in the (x, y) plane is

$$\Omega = -Q_0 z e^{-i\alpha} + C \tag{1}$$

and the complex potential for a well is (Strack, 1989, p. 279)

$$\Omega = \frac{Q_w}{2\pi} \ln(z - z_w) + C \tag{2}$$

where Q_0 = discharge vector of uniform flow; z = complex potential = $x + iy$; z_w = complex potential at the well; α = angle between the x axis and uniform flow; Q_w = discharge from the well; and C = constant which corresponds to the elevation of the bottom of the aquifer. Assume that $C = 0$. Note that

$$e^{-i\alpha} = \cos\alpha - i\sin\alpha \tag{3}$$

and

$$Q_0 = Q_{x0} + Q_{y0} = \frac{d\Phi}{dx} + \frac{d\Phi}{dy} \tag{4}$$

where Q_{x0} = x component of uniform flow; Q_{y0} = y component of uniform flow; and Φ = discharge potential.

The discharge potential is defined differently for confined, unconfined, and combined confined and unconfined aquifers as follows (Strack, 1989, p. 49):

Confined aquifer:	$\Phi = Kb\phi$
Unconfined aquifer:	$\Phi = \frac{1}{2}K\phi^2$
Combined confined and unconfined aquifer:	$\Phi = Kb\phi - \frac{1}{2}Kb^2$ for confined part
	$\Phi = \frac{1}{2}K\phi^2$ for unconfined part

where K = hydraulic conductivity; b = confined aquifer thickness; and ϕ = hydraulic head (or phreatic head) above the bottom of the aquifer. Writing equations in terms of discharge potentials is useful because the same equations may be used for all three types of aquifers by simply using the appropriate definition for Φ.

Because the complex potentials and the boundary conditions considered are linear and homogeneous, any linear combination of complex potentials can also be solved according to the principle of superposition. Superimposing (adding) the complex potentials for uniform flow and for flow to the pumping well gives

$$\Omega = \Phi + \Psi_i = -Q_0 z e^{-i\alpha} + \frac{Q_w}{2\pi} \ln(z - z_w) \tag{5}$$

where Ψ = stream function.

The real and imaginary parts of (5) are

$$\Phi = -Q_0([x - x_w]\cos\alpha + [y - y_w]\sin\alpha) + \frac{Q_w}{4\pi} \ln([x - x_w]^2 + [y - y_w]^2) \tag{6}$$

$$\Psi = Q_0([x - x_w]\sin\alpha + [y - y_w]\cos\alpha) + \frac{Q_w}{2\pi} \tan^{-1}\left(\frac{y - y_w}{x - x_w}\right) \tag{7}$$

where x_w, y_w = x and y coordinates of the well.

The velocity components v_x and v_y in the x and y directions, respectively, along a particular streamline are

$$v_x = \frac{dx}{dt} = \frac{1}{Bn}\frac{d\Phi}{dx} = \frac{-Q_0\cos\alpha}{Bn} + \frac{Q_w[x - x_w]}{2\pi Bn([x - x_w]^2 + [y - y_w]^2)} \tag{8}$$

$$v_y = \frac{dy}{dt} = \frac{1}{Bn}\frac{d\Phi}{dy} = \frac{-Q_0\sin\alpha}{Bn} + \frac{Q_w[y - y_w]}{2\pi Bn([x - x_w]^2 + [y - y_w]^2)} \tag{9}$$

where n = porosity; t = time since pumping began; and B = aquifer thickness defined for different aquifers as follows

Confined aquifer:	$B = b$	
Unconfined aquifer:	$B = \phi$	
Combined confined and unconfined aquifer:	$B = b$	for confined part
	$B = \phi$	for unconfined part

For this problem assume that the uniform flow is in the direction of the x axis so that $\alpha = 0$. Equation (7) can then be written

$$x - x_w = [y - y_w]\,\text{cotan}\,\frac{2\pi}{Q_w}(\Psi - Q_0[y - y_w]) \tag{10}$$

Substituting (10) into (9) yields

$$dt = \frac{2\pi Bn}{Q_w}[y - y_w]\csc^2\frac{2\pi}{Q_w}(\Psi - Q_0[y - y_w])\,dy \quad \ldots . (11)$$

After integrating,

$$t = \frac{Bn[y - y_w]}{Q_0}\cot\frac{2\pi}{Q_w}(\Psi - Q_0[y - y_w]) + \frac{BnQ_w}{2\pi Q_0^2}\ln\sin\frac{2\pi}{Q_w}(\Psi - Q_0[y - y_w]) + f(\Psi) \tag{12}$$

where $f(\Psi)$ is a constant dependent on the particular streamline considered. Equation (12) describes the time when water particles starting at a specific (x, y) coordinate along the streamline will reach the pumping well. When pumping first begins, the particles closest to the well will be captured

immediately. In other words, $x = x_w, y = y_w, t = 0$ will be a solution to the equation. Therefore

$$f(\Psi) = \frac{-BnQ_w}{2\pi Q_0^2} \ln \sin \frac{2\pi}{Q_w} \Psi \quad (13)$$

Substituting (13) into (12) yields

$$t = \frac{Bn[y - y_w]}{Q_0} \cot \frac{2\pi}{Q_w} (\Psi - Q_0[y - y_w]) + \frac{Bn}{2\pi Q_0^2} \ln \frac{\sin \frac{2\pi}{Q_w} (\Psi - Q_0[y - y_w])}{\sin \frac{2\pi}{Q_w} \Psi} \quad (14)$$

Substituting (7) into (14) yields

$$t = \frac{Bn[x - x_w]}{Q_0} - \frac{BnQ_w}{2Q_0^2} \ln \frac{\sin\left(\frac{2\pi}{Q_w} Q_0[y - y_w] + \theta\right)}{\sin \theta} \quad (15)$$

where $\theta = \tan^{-1}([y - y_w]/[x - x_w])$.

Three dimensionless parameters may be introduced:

$$\bar{x} = \frac{2\pi Q_0}{Q_w}[x - x_w]; \quad \bar{y} = \frac{2\pi Q_0}{Q_w}[y - y_w]; \quad \bar{t} = \frac{2\pi Q_0^2}{BnQ_w} t \quad \ldots . (16)$$

Substituting (16) into (15) yields

$$\bar{t} = \bar{x} + \ln \frac{\sin\theta}{\sin(\bar{y} + \theta)} \quad (17)$$

or

$$e^{\bar{x} - \bar{t}} = \sin\bar{y} \frac{\bar{x}}{\bar{y}} + \cos\bar{y} \quad (18)$$

Bear and Jacobs (1965) provide additional analysis of equation (18) and its implications for ground-water transport in confined aquifers. Unfortunately, equation (18) is transcendental and cannot be solved explicitly for either x or y. Iterative solutions have been developed for solving special cases of the equation (for example, McElwee, 1991). These solutions are valid for unconfined aquifers as well if the dimensionless parameters introduced in equation (16) are used in equation (18).

3. Single Well in Uniform Flow at Infinite Time (Steady State)

A quick and simple analysis which is useful for many hydrogeologic projects is determining the capture zone of a single well in uniform flow at infinite time, or steady state. This will define an area in which all the water in the aquifer will reach the well if the well pumps for a sufficiently long time. At infinite time equation (18) can be simplified considerably and solved for x. The equations below give three critical parameters, the stagnation point, the upgradient divide, and the equation for the dividing streamline.

For simplicity, consider $x_w = 0$, $y_w = 0$, and $\alpha = 0$ as shown in Figure 1. The stagnation point is where $v_x = v_y = 0$. From equation (9) it is clear that $v_y = 0$ when $y = y_w = 0$. Substituting into equation (8) and solving for x yields

$$x_{STAG} = \frac{Q_w}{2\pi Q_0} \quad (19)$$

where x_{STAG} is the distance from the well to the downgradient stagnation point. As $\bar{t} \to \infty$, the equation for a streamline [equation (18)] becomes

$$\bar{x} = \frac{-\bar{y}}{\tan\bar{y}} \quad (20)$$

As $x \to \infty$ then $\tan y \to 0$, and $y \to N\pi$ where N = integer. Therefore, by equation (16), as $x \to \infty$

$$\bar{y} \to \frac{NQ_w}{2Q_0} \quad (21)$$

Substituting equation (21) into equation (7) with $x \to \infty$ yields

$$\Psi = \frac{NQ_w}{2} \quad (22)$$

The dividing streamline will approach the stagnation point. Substituting equation (22) and the coordinates of the stagnation point into equation (7) yields N = 1. Therefore, as $x \to \infty$, the dividing streamline will approach the line

$$y_{DIV} = \pm \frac{Q_w}{2Q_0} \quad (23)$$

which represents half the width of the capture zone far upgradient of the well. Considering that N = 1, substituting equation (16) into equation (20) yields the equation for the dividing streamline

$$x = \frac{y}{\tan\left(\frac{2\pi Q_0}{Q_w} y\right)} \quad (24)$$

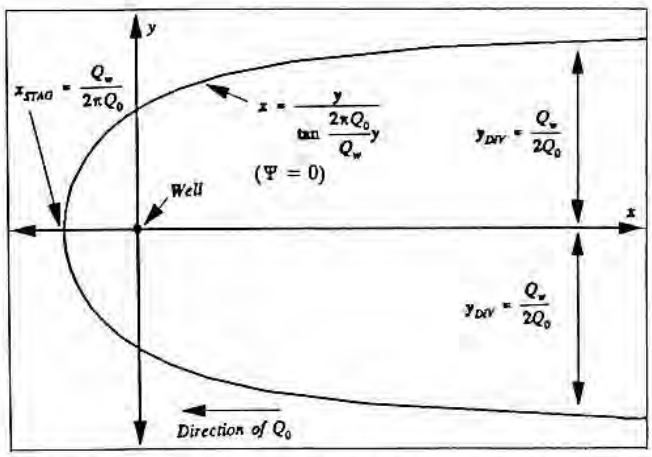

Fig. 1. Stagnation point, upgradient divide, and dividing streamline at infinite time (steady state).

The stagnation point, upgradient divide, and dividing streamline are shown on Figure 1. Because the direction of uniform flow for this problem is aligned with the x axis, $d\Phi/dy = 0$ and

$$Q_0 = \frac{d\Phi}{dx} \cong \frac{\Phi_1 - \Phi_2}{L} \tag{25}$$

where Φ_1 and Φ_2 = downgradient and upgradient discharge potentials, respectively, along a streamline before pumping begins; and L = distance between the locations where Φ_1 and Φ_2 were measured. The equations for the stagnation point, upgradient divide, and dividing streamline can be simplified into more common terms by substituting the above definition for Q_0 and the appropriate definitions for Φ. For a confined aquifer

$$x_{STAG} = \frac{Q_w}{2\pi Ti} \tag{26}$$

where i = natural hydraulic gradient = $d\phi/dx$ and T = aquifer transmissivity = Kb,

$$y_{DIV} = \pm \frac{Q_w}{2Ti} \tag{27}$$

and the dividing streamline is

$$x = \frac{y}{\tan\left(\frac{2\pi Ti}{Q_w}\, y\right)} \tag{28}$$

For an unconfined aquifer

$$x_{STAG} = \frac{Q_w L}{\pi K(\phi_1^2 - \phi_2^2)} \tag{29}$$

$$y_{DIV} = \pm \frac{Q_w L}{K(\phi_1^2 - \phi_2^2)} \tag{30}$$

and the dividing streamline is

$$x = \frac{y}{\tan\left[\frac{\pi K(\phi_1^2 - \phi_2^2)}{Q_w L}\, y\right]} \tag{31}$$

Equations (19), (23), and (24) can also be applied to combined confined and unconfined aquifers. To calculate Q_0 for this scenario, substitute the appropriate definition for Φ into equation (25) based on whether Φ was measured in the confined or unconfined part of the aquifer. For example, if Φ_1 is measured in the unconfined portion of the aquifer and Φ_2 is measured in the confined portion of the aquifer, then $\Phi_1 = \frac{1}{2}K\phi_1^2$ and $\Phi_2 = Kb\phi_2 - \frac{1}{2}Kb^2$. Substituting into equation (25) yields

$$Q_0 = \frac{K(\phi_1^2 - 2b\phi_2 + b^2)}{2L} \tag{32}$$

Note also that equation (6) may be used to obtain values of Φ throughout the aquifer by substituting the appropriate x and y coordinates. The effect of several pumping (or injection) wells on the value of Φ at any point in the aquifer may also be determined by using equation (6) and the principle of superposition. A separate equation for Φ is written for each well being considered based on its x_w, y_w, and Q_w. The separate equations are then added to yield one equation for Φ for any point in the aquifer.

4. Example Problem

The data for this example problem were adapted from a site in Wisconsin which formerly had a leaking underground storage tank. The leak had been detected shortly after it occurred, and a pumping well was to be installed to contain the spread of petroleum hydrocarbon contamination in the aquifer. The project hydrogeologist needed to determine the capture zone of the well as part of the pumping system design and evaluation.

In this example, the problem will be solved assuming the aquifer is confined [using equations (26)-(28)] and unconfined [using equations (29)-(31)], and the results will be compared. A site map is shown on Figure 2. Note that the x-axis has been aligned with the ground-water flow direction.

The aquifer and well characteristics are: Hydraulic conductivity (K) (determined from aquifer tests): 72 ft/day; Elevation of the lower confining layer: 1618.00 ft; Elevation of the upper confining layer (confined aquifer only): 1629.00 ft; Measured ground-water elevations in piezometers: P-1 = 1630.50 ft and P-2 = 1629.50 ft; Distance between P-1 and P-2 (L): 235 ft; Pumping rate (Q_w): 963 ft^3/day (5 gpm); ϕ_1 = 1630.50 ft − 1618.00 ft = 12.50 ft; and ϕ_2 = 1629.50 ft − 1618.00 ft = 11.50 ft. A cross section of the aquifer is shown on Figure 3.

For the confined aquifer:

$$b = 1629.00 \text{ ft} - 1618.00 \text{ ft} = 11.00 \text{ ft}$$

$$T = Kb = 790 \text{ ft}^2/\text{day}$$

$$i = \frac{\Phi_1 - \Phi_2}{L} = 0.00425$$

$$x_{STAG} = \frac{Q_w}{2\pi Ti} = 46 \text{ ft}$$

$$y_{DIV} = \pm \frac{Q_w}{2Ti} = \pm 140 \text{ ft}$$

and the dividing streamline is

$$x = \frac{y}{\tan\left(\frac{2\pi Ti}{Q_w}\, y\right)} = \frac{y}{\tan 0.022y}$$

For the unconfined aquifer:

$$x_{STAG} = \frac{Q_w L}{\pi K(\phi_1^2 - \phi_2^2)} = 42 \text{ ft}$$

$$y_{DIV} = \pm \frac{Q_w L}{K(\phi_1^2 - \phi_2^2)} = \pm 130 \text{ ft}$$

and the dividing streamline is

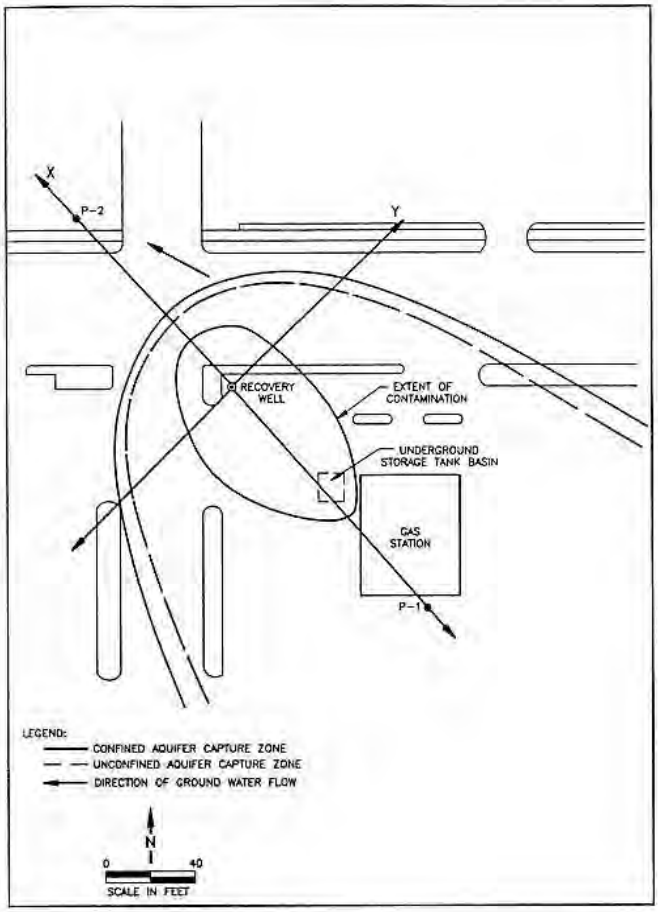

Fig. 2. Site map for the example problem showing the calculated capture zones.

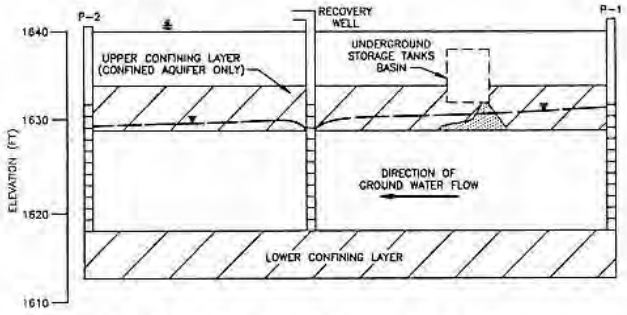

Fig. 3. Cross section of the aquifer along the x-axis.

$$x = \frac{y}{\tan\left[\dfrac{\pi K(\phi_1^2 - \phi_2^2)}{Q_w L}\, y\right]} = \frac{y}{\tan 0.024y}$$

The results of the analyses are shown on Figure 2.

5. Limitations of the Model

The steady-state equations presented in Section 1 neglect the influence of storativity and specific yield. The significance of this assumption decreases as pumping continues, and by definition storativity and specific yield = 0 at infinite time (steady state). Bear and Jacobs (1965) present a discussion of the effect of neglecting storativity for a confined aquifer with an injection well. They state that the actual front of the water injected from the well will lag behind the calculated front due to the storativity of the well and the aquifer. Similarly, in a pumping situation the actual capture zone will be somewhat smaller than the calculated capture zone due to the water being removed from storage.

The influence of water naturally added to or subtracted from the aquifer system other than regional uniform flow (leakage and infiltration) is not included in the equations. For unconfined aquifers, this may be a good assumption in urban areas or other areas where drainage systems prevent rainfall infiltration. If the addition of water to the aquifer through leakage and infiltration were considered in the equations, the result would be a smaller calculated capture zone.

The model is based on the Dupuit assumption, i.e., vertical gradients are negligible. For this reason, the model may not be accurate in areas of aquifer recharge or discharge, including the area near a well.

Hydrodynamic dispersion is commonly neglected from capture zone analyses. If dispersion were included in the analysis, there would not be a sharp capture zone boundary but rather a wide boundary with width proportional to the dispersion coefficient. Within the boundary only some fraction of the water particles would be captured by the well after a given time.

While the capture zone equations are clearly useful for solving problems related to contaminant transport or wellhead protection, it should be noted that the equations consider only advective flow. The solution to a contaminant transport problem must also incorporate the effects of dispersion, diffusion, sorption, degradation, and retardation.

6. Conclusions

Despite the assumptions and simplifications necessary to derive these equations, the equations can provide useful information for designing pumping systems or wellhead protection programs. Although they do not consider hydrodynamic dispersion, equations (26) through (31) are particularly useful for a quick analysis of critical properties of an aquifer and pumping system. While the many assumptions greatly restrict its applicability, users of the model should find many hydrogeologic problems of limited scope which could benefit from this analysis. The model presented in Section 2 is developed in terms of discharge potentials, which makes the equations applicable to confined, unconfined, and combined confined and unconfined aquifers. Previously derived capture zone equations (and computer programs) could also be modified and written in terms of discharge potentials to make them applicable to both confined and unconfined aquifers.

Computer Programs

A computer program is available which will solve and graph the capture zone equations in this paper. Included on the same computer diskette are spreadsheets for Lotus 1-2-3 and Quattro Pro which solve and graph these equations and other equations commonly used for well design and groundwater modeling. To order these programs, send a check or money order for $20 to Grubb Environmental Services, 2233 15th Avenue, North St. Paul, MN 55109. Please indi-

cate whether you prefer 5.25-inch or 3.5-inch IBM formatted diskettes.

Apparent Relative Retardation of Tritium and Bromide in Dolomite

by Darrell I. Leap[a]

Abstract

In order to determine the suitability of bromide as a surrogate for tritium for ground-water tracing in fractured and fissured dolomite, apparent relative retardation coefficients of bromide with respect to tritium were computed by the cumulative relative mass-time method from breakthrough curves of both substances, when used simultaneously as tracers in a two-well recirculating tracer test. Throughout the 33.78-day test, relative retardation differences of only a few hundredths were detected for most of the testing time.

Tritium was less retarded in flow through highly transmissive openings than in more diffuse flow. Bromide was generally retarded relative to tritium except at the pumping well where the concentrations of both were diluted an order of magnitude below those in the monitoring wells, and tritium was retarded slightly more than bromide.

Apparent relative retardation was found to change with transmissivity, concentration, flow-path length and time, but not enough to rule out bromide as a suitable surrogate for, or even better than, tritium in dolomite if the limitations of each tracer are known.

Introduction

The Problem

Tritium has been touted by references below as one of the best substances for tracing ground-water movement because it is a constituent of water and behaves very conservatively. Tritiated water acts very much like normal water in ground-water flow systems. Because of its radioactive nature (a low-level beta emitter) with a half-life of 12.43 years (Mann et al., 1982), regulations usually prohibit its use except under very restrictive conditions, and usually with hard-to-obtain permission from regulatory agencies.

Therefore, suitable surrogate tracers are often needed which behave as closely as possible to tritium, but which are not radioactive or chemically hazardous. In addition, there is a need to quantify, as precisely as possible, the in situ behavior of such surrogates relative to tritium for various geologic media. This information is needed for (1) tracer-testing aquifers in order to gain information about their hydraulics and solute-transport properties in general; and (2) tracer-testing for the same purposes aquifers already contaminated by tritium or other radioactive substances, but into which injection of additional radioactive substances for tracing purposes would be undesirable or prohibited.

In order to quantify such relative tritium-surrogate behavior so that the information can be properly applied in field tests, and the test results understood, the following questions must be answered about the apparent retardation of the bromide surrogate relative to that of tritium:

1. How conservative is bromide with respect to tritium over a range of normalized concentrations?
2. What are the retardation characteristics of tritium and bromide in flow in open fractures and fissures versus flow in lower-transmissivity media?
3. How does retardation of bromide relative to retardation of tritium change over time during flow?
4. How does the relative retardation change with flow-path length? And finally,
5. How does bromide compare to tritium as a surrogate?

This information was of great interest to the U.S. Geological Survey and the U.S. Department of Energy, especially in the Amargosa Desert of southern Nevada, in the fractured and fissured Cambrian dolomite downgradient of the Nevada Test Site.

This study has for the first time precisely quantified the relative retardation differences to be expected between tritium and bromide tracers in fractured and fissured dolomite on the field scale. This information and the newly developed methodology reported herein can help investigators better plan future tests of a similar kind and interpret the results therefrom, using different tracer combinations in different lithologies.

Background and Literature Review

Numerous tracer tests using bromide and tritium have been performed to study movement of surface water, ground water, and soil moisture. Clayton and Smith (1963) reported that the radioactive bromide-82 ion was not adsorbed at all in river-tracing experiments. Payne (1968) found bromide to give results identical to tritium when both were used as tracers in karst conduits. Payne (1988) also

Received July 1991, revised January 1992, accepted January 1992.

Discussion open until January 1, 1993.

states that tritium is the "ideal tracer" in a review of isotope hydrology. Comparison of bromide and nitrate in unsaturated soils showed that both behaved identically (Smith and Davis, 1974). Schmotzer et al. (1973), after tracing water through limestone caverns, reported, "bromide does not appear to be lost by precipitation, adsorption or absorption, and is biologically stable." Similar results in karst studies were reported by Jester and Uhler (1974).

Miettinen (1978) studied the movement of tritium in soils and suggested that slight retardation of tritium might occur due to hydrogen exchange on clay micelles attached to magnesium. This process would only be important in water with low pH, and not in dolomitic aquifers. Tennyson and Settergren (1980) used nonradioactive bromide to trace water through the root zone of two silt loams and found that bromide was not retained on soil particles by ion exchange. Hamill (1980) considered bromide as the next best tracer to tritium after finding no adsorption of bromide as a river tracer.

Murray et al. (1981) used lithium bromide (LiBr) solution as a tracer to verify the hydraulic connection between a sanitary landfill and a downgradient spring in carbonate rocks. Bromide proved very useful because of (1) its low background concentration; (2) existence of a sensitive analytical procedure (neutron activation); (3) its lack of toxicity; and (4) its conservative nature, especially in the presence of organics which rendered rhodamine WT unusable in this case.

Moreno and Neretnieks (1985) considered tritium and bromide both to be nonsorbing tracers when both were used individually in laboratory experiments in fractured granite. They found that (1) dispersion in channels within the fracture wall can be greater than dispersion along the nonchanneled part of the fracture; (2) diffusion and sorption into the rock matrix may be two important processes in retardation; and (3) diffusion increases with increasing contact time of tracer and rock.

Wierenga and Van Genuchten (1989) performed unsaturated-flow tracer experiments with tritium and chloride in columns 30 cm and 6 m long; both were filled with loamy fine sand containing 4.7% clay, and less than 1% organic matter. Their research showed that for both column lengths, (1) dispersivity using tritium breakthrough data averaged 0.88, and 0.87 for chloride; (2) the mean retardation factor or coefficient R_d for tritium was 0.94 ($R_d = 1.0$ indicates no retardation), and that for chloride was 0.87, indicating less retardation for chloride (meaning it traveled faster than both tritium and the advective water velocity; (3) this value in turn was due to the effects of anionic exclusion of the chloride from clay particles which caused chloride to move ahead of the advective front. They concluded that chloride and bromide may not be ideal tracers for unsaturated fine-grained soils because they can move faster than the advective front. Anionic exclusion is also discussed in detail in Bolt et al. (1978).

Research Objectives

Although Payne (1968) studied bromide and tritium together in a karst system, it was decided that a higher degree of quantification was needed of the possible subtle differences in behavior that might not be apparent from inspection of breakthrough curves alone, especially since normalized concentrations are generally plotted on a logarithmic scale which compresses differences between curves. This decision was also motivated by the varying conclusions in the literature about the efficacies of bromide versus tritium.

More detailed behavioral information was felt to be especially necessary in the aquifer of interest—the Cambrian Bonanza King dolomite in the Amargosa Desert of southern Nevada, because of its wide range of fracture apertures (from less than one mm to several cm).

Because of its numerous fractures and fissures, this aquifer would be expected to contain much more rock surface area and discrete pore spaces in which more retardation could take place than in a karst system with only large, open conduits.

This particular study, utilizing data and information from a 33.78-day, two-well recirculating tracer test that was run to determine aquifer dispersivity (Leap and Belmonte, 1992), was initiated with the objectives of answering the five questions asked earlier.

Research Approach

The research approach consisted of running a two-well recirculating test with an injection well, a pumping well, and three sampling or monitoring wells (Figure 1) in an aquifer between 191 and 218 meters from the surface. Ammonium bromide (NH_4Br) and tritiated water (HTO) were simultaneously used as tracers and subsequently compared in behavior.

Each ground-water sample retrieved was split into aliquots—one for tritium analysis and one for bromide. Tritium was analyzed by liquid scintillation at the National Water Quality Laboratory of the U.S. Geological Survey, in Denver, Colorado, and the results corrected for radioactive decay. Bromide was analyzed by neutron-activation analysis at the Breazeale TRIGA nuclear reactor facility of the Pennsylvania State University.

The normalized concentration of each tracer was computed as (C/C_o) where C = concentration at any time, and C_o = initial concentration of the initial injected tracer pulse or spike. The results were plotted as breakthrough curves of normalized concentration vs time to obtain estimates of the apparent longitudinal dispersivity by the method of Grove (1971) (Leap and Belmonte, 1992). Further analyses of the curves were conducted for this study to determine apparent relative retardation of bromide with respect to tritium at each sampling well at each sampling time by the Cumulative Relative Mass-Time Method, developed for this study and described in a subsequent section.

Retardation of bromide relative to tritium was then studied to determine its variation with respect to concentration, transmissivity, time of flow, and flow-path length. A comparison was then made of bromide as a general surrogate for tritium by assessing the range of relative retardation determined during the 33.78-day test.

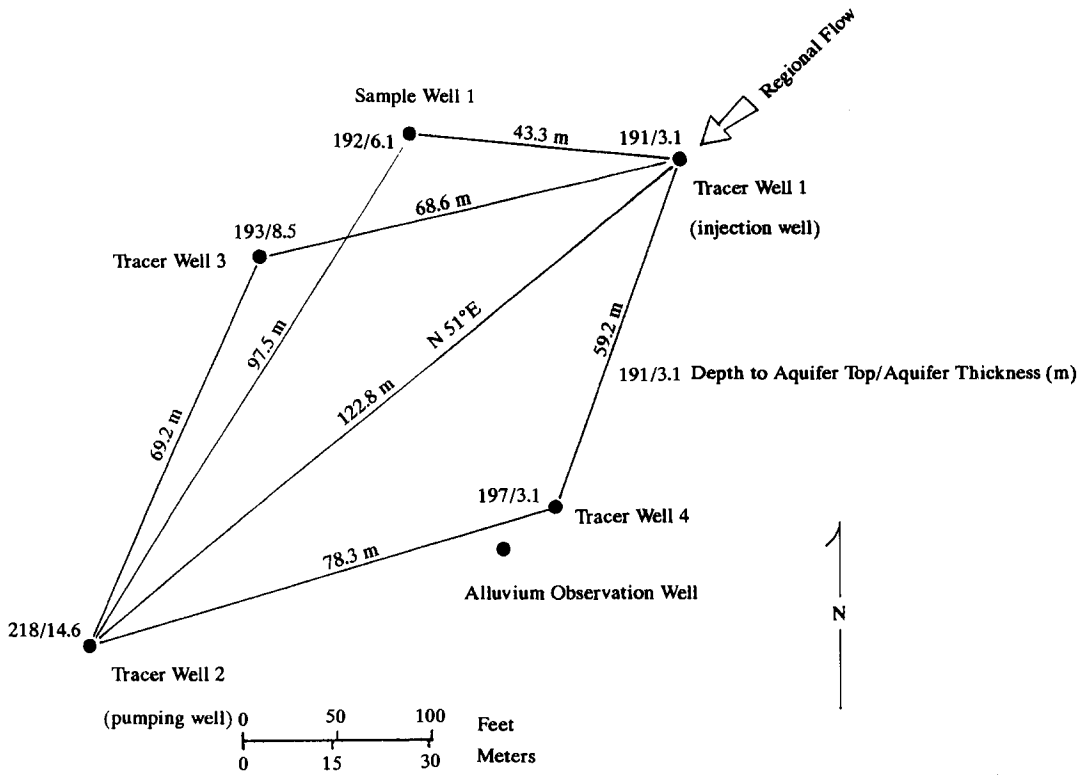

Fig. 1. Map showing locations of wells, aquifer depths, and aquifer thicknesses at the Tracer Site (after Leap and Belmonte, 1992).

Basic Theory

Retardation

Retardation of a dissolved chemical tracer species is due to sorption, chemical reactions with porous media or fracture walls, and movement into dead-end pores by diffusion. As a result, the tracer mass will not move as fast as the average advective velocity of ground water which carries it. The retardation coefficient in porous media is expressed as (Freeze and Cherry, 1979; Prickett et al., 1981)

$$R_d = \frac{v}{v_c} \tag{1}$$

$$R_d = 1 + \frac{\rho_b K_d}{n} \tag{2}$$

and in fractured media (Burkholder, 1976) as

$$R_d = 1 + AK_a \tag{3}$$

where v = average ground-water velocity; v_c = average velocity of the tracer mass; ρ_b = bulk mass density of the porous medium; n = effective porosity; K_d = distribution coefficient of the porous medium; K_a = fractured-rock distribution coefficient; and A = ratio of fracture-wall surface area to void space (volume).

In a normalized breakthrough curve of a tracer with a constant-concentration source, v_c is the velocity of the point where $C/C_o = 0.5$ on the breakthrough-curve front (Figure 2). In a normalized breakthrough curve resulting from a rectangular pulse source (constant concentration over finite injection time), v_c is the velocity of the center of mass of the pulse as shown in Figure 3.

Equations (1)-(3) could not be used to analyze the results of this experiment because (1) it was impossible to accurately assess A, K_d, K_a, or ρ_b; and (2) the recycled pulses of tracers made the curve tails too high and long to obtain a center of mass. The apparent retardation of bromide, relative to that of tritium (Apparent Relative Retardation) had to be estimated by another method developed

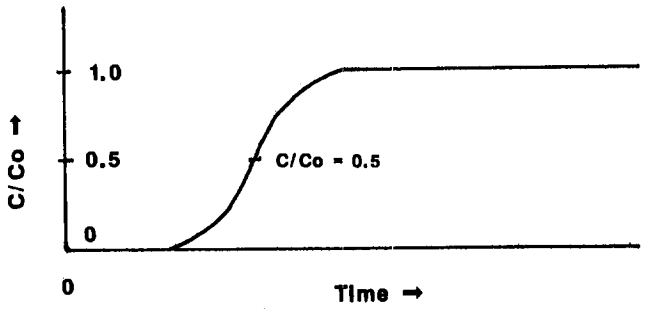

Fig. 2. Normalized breakthrough curve resulting from transport of a tracer from a constant-concentration source.

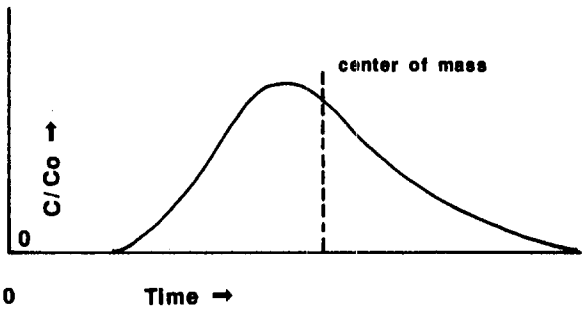

Fig. 3. Normalized breakthrough curve resulting from transport of a tracer from a rectangular-pulse source.

below—the Cumulative Relative Mass-Time (CRMT) method. The modifier, "Apparent," is used because in the absence of absolute retardation coefficients, what may appear to be differences in retardation of two tracers may be partly due to their different anionic exclusion rates as well as actual retardation.

Computing Relative Retardation by the Cumulative Relative Mass-Time Method

The mass-time area under the breakthrough curve between two sampling times (t_{i-1} and t_i) can be computed as

$$a_i = \int_{t_{i-1}}^{t_i} (r_i t + b)dt \tag{4}$$

where $i \geq 2$; r_i = slope of the curve between two consecutive sampling times, i.e.,

$$r_i = \frac{(m_i - m_{i-1})}{(t_i - t_{i-1})} \tag{5}$$

assuming a linear change in mass per unit time between closely spaced sampling points; b = intercept of the curve; N = total number of sampling times; $t_1 = 0$, i.e., the first or zero sampling time; t_N = last sampling time; and m_i = mass detected in one unit volume (i.e., concentration at sampling time, i).

Evaluation of the integral yields

$$a_i = (\frac{r_i}{2})(t_i - t_{i-1})^2 + b(t_i - t_{i-1}) \tag{6}$$

The sum of the mass-time increments, or Cumulative Area of Mass-Time (CAMT) from the beginning of the curve to any subsequent sampling time is given by

$$CAMT_k = \sum_2^k a_i \tag{7}$$

where $k \leq N$.

$CAMT_k$ can be normalized to obtain the dimensionless Cumulative Relative Mass-Time (CRMT), as shown

$$CRMT_k = \frac{CAMT_k}{(C_o \times T_o)} \tag{8}$$

where C_o = original concentration of initial pulse, and T_o = time duration of the initial-pulse injection; or

$$CRMT_k = \frac{\sum_2^k a_i}{(C_o \times T_o)} \tag{9}$$

The difference, $DIFF_i$, between the CRMT curves of tritium and bromide at any sampling time, t_i, is simply

$$DIFF_i = CRMT(T)_i - CRMT(Br)_i \tag{10}$$

This number is used to observe subtle differences between CRMT values of two different tracers which may not be readily apparent visually when plotted on a logarithmic scale due to compression of the vertical axis.

The Apparent Relative Retardation Coefficient, ARR_d, of bromide (relative to tritium) up to a certain sampling-time point, k, is found by

$$ARR_{dk} = \frac{CRMT(T)_k}{CRMT(Br)_k} \tag{11}$$

If $ARR_{dk} > 1.0$, bromide is retarded relative to tritium; if $ARR_{dk} < 1.0$, tritium is retarded relative to bromide; if $ARR_{dk} = 1.0$, neither is retarded relative to the other.

Determining an absolute retardation coefficient of a particular tracer (a unique R_d) is not possible with this method in the case of recirculation, because a unique center of mass of the breakthrough curve is not obtainable. In the absence of recirculation, the center of mass for a discrete pulse would simply be the point on the breakthrough curve corresponding to $CRMT_N/2$, assuming $CRMT_N$ were computed for the entire pulse breakthrough curve.

Factors and Processes Affecting Relative Retardation in Dolomite

(A) Anionic Exclusion

Clays, because of their negatively charged surfaces, tend to anionically exclude negatively charged halide ions (Bolt et al., 1978; Wierenga and Van Genuchten, 1989). This process would be expected to be most significant in low-transmissivity zones and clay-rich pores. Anionic exclusion would cause some bromide to move faster than normal through water, and faster than tritium, to produce a lower apparent relative retardation of bromide with respect to tritium.

(B) Molecular Diffusion

Tritium diffuses through normal water as tritiated water (HTO), with a molecular weight of approximately 20, and a diffusion coefficient at 25°C, variously reported in 10^{-5} cm^2/sec as ranging from 2.25 (Devell, 1962), to 2.44 (Wang et al., 1953).

Ammonium bromide diffuses through water as an ion pair such as (NH_4^+-Br^-) as required to maintain electroneutrality. The molecular weight of NH_4Br is approximately 98, or 4.9 times that of tritiated water. The diffusion coefficient of NH_4Br at 25°C is calculated from Cussler (1984) to be 2.02×10^{-5} cm^2/sec, or 0.90 to 0.83 times that of HTO.

Although the values of the diffusion coefficients of HTO and NH_4Br for a purely aqueous phase do not differ greatly, tritiated water will diffuse into small dead-end pores more readily than the larger and heavier (NH_4^+-Br^-) ion pair, under the same concentration gradient. The expected effect of greater tritium diffusion into dead-end pores would be increased actual tritium retardation and less apparent retardation of bromide relative to tritium in low-transmissivity zones, where more dead-end pores would be expected.

In flow through large conduits with minimal interaction of tritium and bromide with dead-end pores, clays, or conduit walls, tritium would be expected to move faster than bromide because of its lower molecular weight and higher diffusion coefficient, providing the concentration gradients were the same for both tracers. The expected effects would be lower actual retardation of both tracers, but increased

relative retardation of bromide with respect to tritium, as opposed to effects in less transmissive areas.

(C) Concentration Effects

In general, the higher the concentration, the greater will be the rate of anionic exclusion of bromide and diffusion of both species.

(D) Effects of Flow-Path Length

Increasing the flow-path length (which is affected by recirculation) will in general increase the effective surface upon which the above actual processes can take place.

In very long flow paths, within low-transmissivity media, one would expect the effects to include greater actual retardation of tritium by dead-end pore diffusion, with lesser retardation of bromide by dead-end pore diffusion with respect to tritium, but more anionic exclusion of bromide due to an increased ratio of residual clay volume to pore volume. As a result, the apparent relative retardation of bromide with respect to tritium should decrease. In open-conduit flow, long flow paths should allow more tritium diffusion in the direction of flow with greater apparent relative retardation of bromide with respect to tritium.

(E) Effects of Residence Time

In general, the effects of longer residence time of a tracer in the system is similar to those resulting from longer flow paths because it allows a tracer to be in contact with retarding media for longer periods.

Field Research Site and Experimental Setup

The field research was carried out at the U.S. Geological Survey's Amargosa Tracer Calibration Site (hereafter called the "Tracer Site") in the Amargosa Desert of southern Nevada, approximately 121 km northwest of Las Vegas, and 24 km southwest of Mercury (Leap and Belmonte, 1992). A two-well recirculating system was already installed at the site, consisting of an injection well, a pumping well, and four monitoring wells (Figure 1), denoted as follows: Tracer Well 1 (TW1), the injection well; Tracer Well 2 (TW2), the pumping well; and monitoring wells, Tracer Well 3 (TW3), Tracer Well 4 (TW4), Sample Well 1 (SW1); and the Alluvium Observation Well (AOW)—the latter was not used for the test. Samples were taken during the test from all the wells except TW1 and AOW.

The aquifer is a highly fractured and fissured zone confined within the dolomitic Cambrian Bonanza King formation. The thicknesses and the elevations of the top and bottom of the aquifer are shown in Figure 1. Thickness ranges from 3.1 m at TW1 and TW4 to 14.6 m at TW2.

Examination of drilling logs (Johnston, 1968) and cores (in the U.S. Geological Survey's core library at Mercury, Nevada) revealed fractures, vugs, and fissures ranging in width from less than one mm to 45 cm, with no preferred orientation. Borehole flowmeter tests precisely defined the top, bottom, and thicknesses of the permeable fractured and fissured zone constituting the aquifer.

A six-inch (15-cm) diameter PVC pipeline connected TW2 and TW1. A separate injection trailer positioned near TW1 contained a glove box and injection pump for injecting radioactive tracers into TW1. Bromide was injected from a mixing tank and pumped directly into the recirculating pipeline, 1.2 m upstream from TW1 (Leap and Belmonte, 1992).

The monitoring wells, TW3, TW4, and SW1, were each equipped with submersible pumps positioned midway between the top and bottom of the aquifer, which were connected to PVC sample-delivery lines. A delivery line was also connected to the recirculating pipeline near TW1 to retrieve samples of effluent from TW2 (Leap and Belmonte, 1992).

All delivery lines entered a sampling trailer where samples were periodically collected by automatic samplers. All pumps and samplers were activated to take samples automatically at preselected times. Travel times of samples from sampling pumps to samplers were negligible.

Description of Field Tracer Experiments

The recirculating system was started and allowed to run for three days before injection in order to check it for problems. At zero time, $t_1 = 0$, the beginning of tracer injection, tritium and bromide were injected as rectangular pulses (constant concentrations throughout finite injection times), essentially simultaneously with each other. Bromide was injected from a mixing tank containing 414 kg of ammonium bromide (NH_4Br) dissolved in 860 liters of water from the aquifer. The injection rate was such that the injection time period (T_o) lasted 15.6 minutes (0.011 day), to produce a rectangular pulse in the aquifer with an initial bromide concentration (C_o) of 20,425 mg/l.

Tritium injection began 40 seconds later and lasted for a T_o of 14.4 minutes (0.010 day). A total of 12.2 curies (Ci) of tritiated water in a volume of one liter was injected at such a rate as to produce a rectangular pulse entering the aquifer with a C_o of 0.797 μCi/ml. The 40-second time lag between injection start times of the two tracers was considered negligible.

The entire tracer test, running with an average recirculation rate of 15.5 l/s, lasted for 33.78 days, and samples were taken from TW2, TW3, TW4, and SW1 over the entire test period.

Frequency of Sample Analysis

Analyses of bromide and tritium were made of samples taken at the same times. Samples were taken more frequently before peak times, and less frequently afterward.

From TW2, 129 samples each of bromide and tritium were analyzed over a period of 33.78 days to give an average frequency of 3.8 samples per day. From the other three wells, 52 analyses were made each of bromide and tritium over 33.78 days to yield an average of 1.5 samples per day.

Each tritium concentration reported herein represents the average of five separate analyses with an analytical error generally between 1 and 2.5 percent. The analytical error of bromide concentrations from five separate analyses ranged between 1 and 1.75 percent. These errors were not great enough to cause any significant effects upon the calculated DIFF and ARR_d curves below.

Results and Discussion of Data Analysis

Visual Inspection of Breakthrough Curves

Normalized breakthrough curves (C/C_o) of both tritium and bromide were constructed from sample analyses from all four sampled wells. Figures 4 (a, b, c, and d) show the curves from TW2, TW3, TW4, and SW1, respectively. Arrival times of breakthrough-curve peaks are summarized in Table 1. All curves show the effects of recirculation, i.e., the falling limbs or tails of the curves do not drop as fast as one would expect in the case of a dispersed finite tracer pulse without recirculation.

At TW2, both tritium and bromide curves peaked at 8.03 days and the curves show recirculation beginning at approximately 10.44 days, as evidenced by dips in both curves, but later recirculated pulses are impossible to ascertain. The particular curve shapes (long drawn-out tails), and order-of-magnitude dilution when compared to curves from other wells described below, are due to the wider total area of flow of tracer-spiked water to TW2, mass loss, and the introduction of unspiked water by TW2 to the spiked mass (Figure 5).

The tritium and bromide breakthrough curves from TW2 were analyzed by the method of Grove (1971) to estimate values of average aquifer porosity of 10 percent, longitudinal dispersivity of 27.4 m using the tritium curve, and 30.3 m using bromide (Leap and Belmonte, 1992). Only at TW2 was the normalized concentration of bromide consistently higher than that of tritium. Both the higher concentration and higher dispersivity of bromide is due to greater apparent retardation of tritium relative to bromide at TW2, as explained later. The ratio of bromide dispersivity to tritium dispersivity was 1.1, which is very close to the ratio of chloride dispersivity to tritium dispersivity of 1.09 reported by Wierenga and Van Genuchten (1989).

Wells SW1 and TW3 are on the same side of the flow system, in the thicker, more transmissive part of the aquifer, but TW4 is on the opposite side in the thinner, less transmissive part (Figure 1). Bromide and tritium curves from these three wells lie on top of each other.

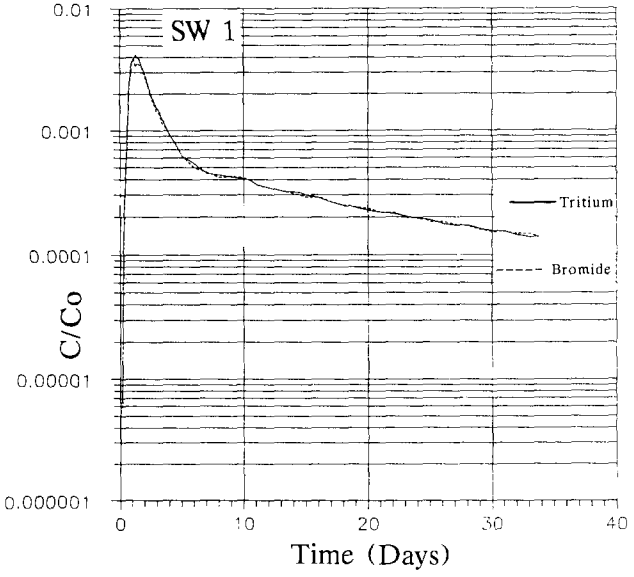

Fig. 4d. Tritium and bromide breakthrough curves from SW1.

Table 1. Summary of CRMT, DIFF, and ARR_d Data at Selected Times from Each Well Sampled

Well	*Sampling times (in days)*		*CRMT(T)*	*CRMT(Br)*	*DIFF*	*ARR_d*	*Distance from TW1 (in m)*

At SW1, tritium peaked at 1.28 days, 0.17 days behind the bromide peak at 1.11 days. Recirculation appears to have begun between 5 and 6 days at SW1, and between 6 and 7 days at TW3, as evidenced by rather sudden changes in curve slopes. Tritium peaked at TW3 at 0.78 days, and bromide at 0.94 days (a difference of 0.16 days).

The TW4 curve shows a tritium peak at 1.28 days, 0.17 days behind the bromide peak at 1.11 days. One pulse began almost immediately, and two recirculated pulses came through afterward—one began at 3.2 and the other at 18.1 days, respectively.

TW3 is 25.3 m further from TW1 than is SW1 (Figure 1 and Table 1). Yet, peaks of tritium and bromide arrived at TW3 at 0.5 and 0.17 days, respectively, earlier than at SW1 because of a more permeable pathway between TW1 and TW3 than between TW1 and SW1. Peak arrival times at TW4 were the same as those at SW1 which is 15.9 m closer to the injection well (TW1).

It is important to note that only at TW3 did tritium peak before bromide. This phenomenon, as explained later, is believed to suggest that the more open pathway to TW3 caused increased relative retardation of bromide with respect to tritium because of less actual retardation of and perhaps more diffusion of tritium along the path to TW3. Such is not the case in other wells located in less transmissive flow paths.

Cumulative Relative Mass-Time and Relative Retardation Data

Computed values of CRMT and DIFF are shown graphically in Figures 6 (a, b, c, and d) for TW2, TW3, TW4, and SW1, respectively. Figure 7 shows ARR_d curves from all four wells. Table 1 summarizes the data at selected sampling times.

As in the case of the breakthrough curves, tritium and bromide CRMT curves are nearly parallel in all cases. This closeness belies small and subtle differences between the CRMT's of both tracers plotted on a logarithmic scale, which compresses deviations between the curves. Therefore, one must examine the DIFF curve for each tritium-bromide pair to notice the true differences between the CRMT curves

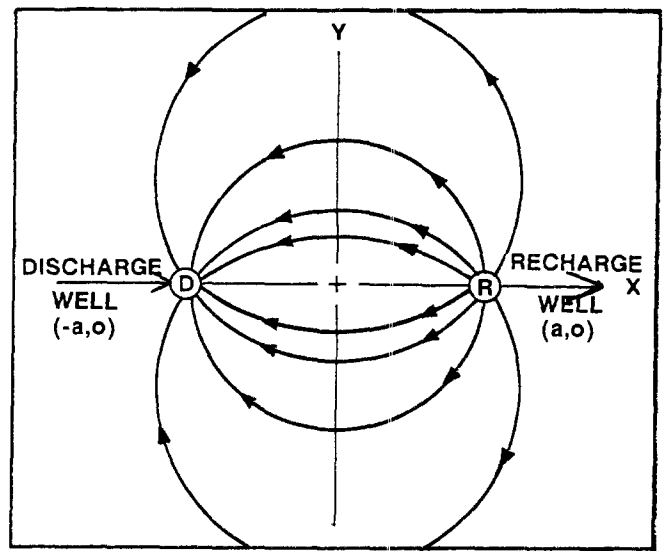

Fig. 5. Generalized ground-water flow system of a homogeneous, isotropic aquifer during a two-well recirculating tracer test (after Grove and Beetem, 1971).

of each. In all curves except those from TW2, CRMT(T) > CRMT(Br).

A DIFF curve is not shown for TW2 because CRMT(Br) is greater than CRMT(T) after the peak time, due to higher normalized concentrations of bromide than of tritium over time, resulting from slight retardation of tritium with respect to bromide and ionic exclusion of bromide during transport through generally less transmissive pathways to that well. Thus, equation (10) yields negative values for DIFF, which cannot be shown on a logarithmic scale. Table 1 lists negative DIFF values from TW2 for selected times.

In all cases, the CRMT and DIFF curves from TW3 and SW1 are generally smooth and gradually increase after peak arrival times. Both CRMT and DIFF curves for TW4 show distinct perturbations beginning at the same time as the trough between the breakthrough-curve peaks and the first recirculated pulse. CRMT curves from TW2 also increase smoothly, but the DIFF values (Table 1) show very small differences between them (not exceeding −0.00722). The absolute value of this number is less than those from the other wells.

Table 1 shows that except for TW4, the CRMT values of both tracers decreased with increasing distance from TW1 (the injection well). The distance from TW1 to TW4 is between that from TW1 to SW1, and TW1 to TW3, and the CRMT values of TW4 are lower than those of either of the other two wells.

This was due to the fact that longer flow distances allowed concentrations to be lowered by more retardation and dilution. This was also pronounced in TW4 because of low transmissivity. Recirculation also added the factors of irretrievable mass loss and dilution, decreasing the concentration.

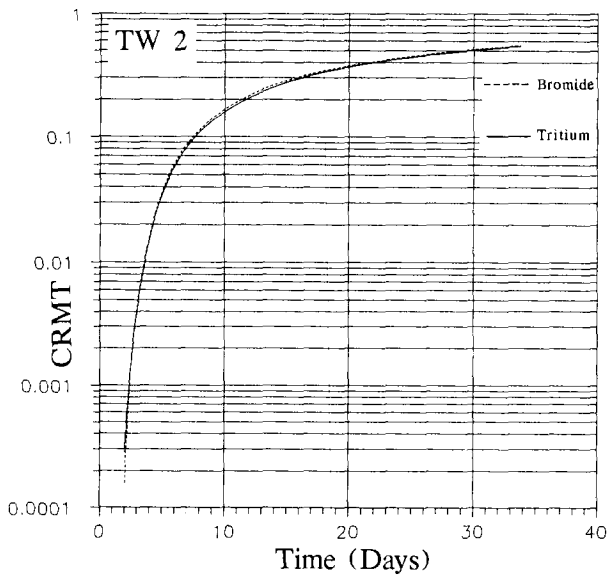

Fig. 6a. CRMT curve from TW2.

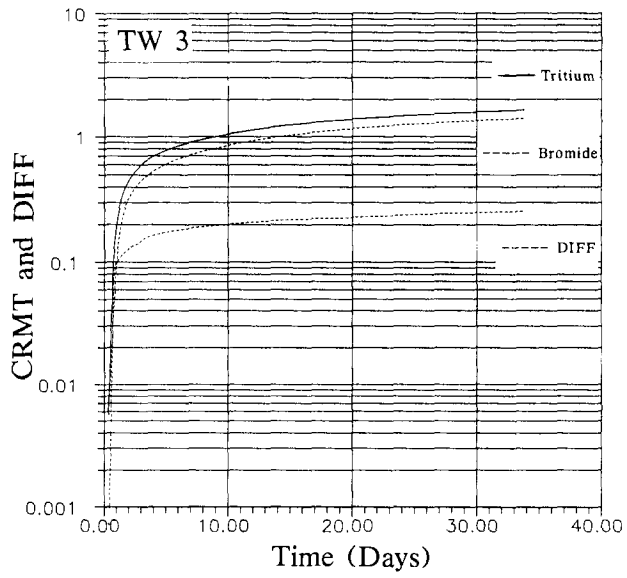

Fig. 6b. CRMT and DIFF curves from TW3.

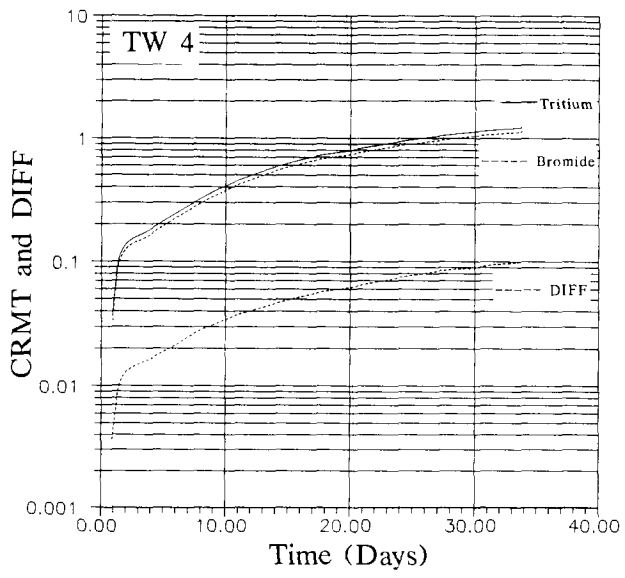

Fig. 6c. CRMT and DIFF curves from TW4.

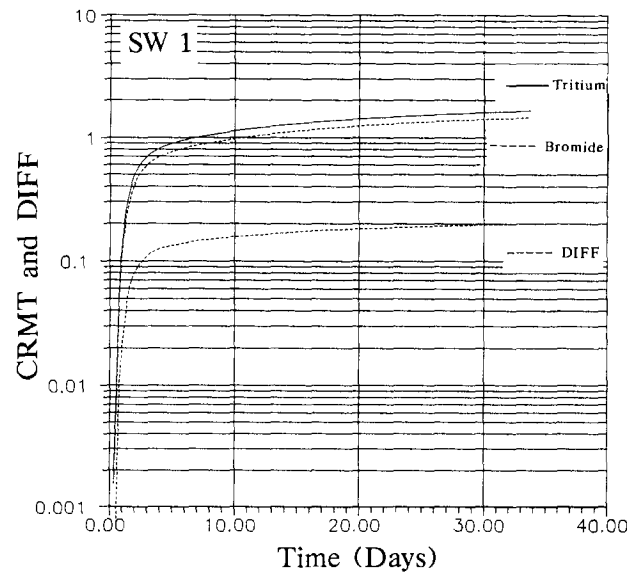

Fig. 6d. CRMT and DIFF curves from SW1.

ARR_d values after peak times, from highest to lowest, are found in the following order: TW3, SW1, TW4, and TW2 (Figure 7 and Table 1). ARR_d values from the first three wells are always greater than 1.0, and decrease in value after peak times, but the ARR_d curve of TW2 increases after the peak time and remains less than 1.0. From Figure 7 and Table 1, it is apparent that with the exception of TW3, ARR_d values decrease in general with increasing distance from the injection well (TW1).

After peak times, in flow to TW3, TW4, and SW1, bromide was apparently relatively retarded over time more than tritium, but at a decreasing rate, because at first, tritium was more mobile than bromide, but over time, tritium retardation and anionic exclusion of bromide decreased the rate. On the other hand, in flow to TW2, tritium was relatively retarded by an amount slightly greater than that of bromide, but bromide continued to be retarded at a slightly greater rate relative to that of tritium because the tritium concentration had become low enough that its retardation rate slowed to slighly less than the rate of bromide. These explanations are evidenced by the decreasing ARR_d curves over time from TW3, SW1, and TW4; and increase with time in the curve from TW2.

This argument is strengthened by study of Figures 6 (a, b, c, and d) and equation (11), from which it can be deduced that decreasing values of ARR_d from TW3, TW4, and SW1 over time could only be due to a decreasing **rate** of increase of CRMT(T) with respect to the **rate** of increase of CRMT(Br), i.e.,

$$\frac{\partial^2 CRMT(T)}{\partial t^2} < \frac{\partial^2 CRMT(Br)}{\partial t^2} \qquad (12)$$

This is because neither the rate of increase of CRMT(T) nor that of CRMT(Br) could have increased over time unless one appeals to some hitherto unknown and unobserved process of desorption and/or deretardation which would not have been likely to occur because of fairly constant values of pH and temperature during the test.

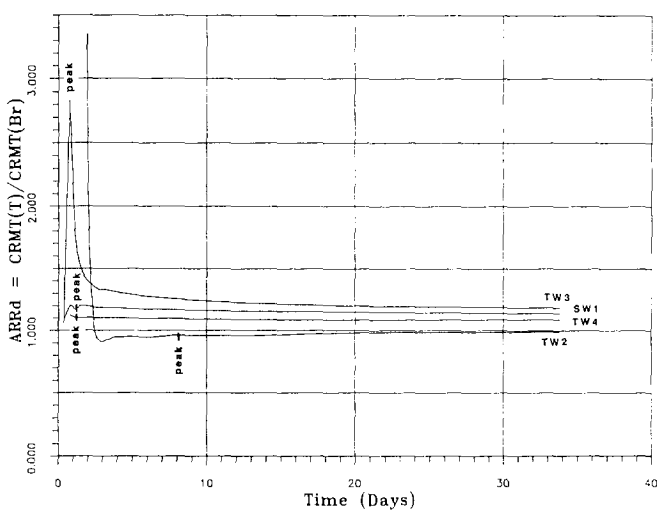

Fig. 7. ARR_d curves from TW2, TW3, TW4, and SW1.

Bromide concentration was also an order of magnitude less at TW2 than at other wells; yet, the increase in the ARR_d curve at TW2 toward a value of unity indicates that the rate of tritium retardation was continuing to decrease relative to the rate of bromide retardation, even though tritium was still more retarded than bromide.

This behavior at TW2, very different than at the other wells, was due to an order-of-magnitude dilution below that at the other wells. This in turn was caused by pumping unspiked water at TW2, a wider area of flow to TW2 through less transmissive media, and injection of mass out of the system at TW1. As a result, there was greater opportunity for greater relative apparent retardation of tritium with respect to bromide than at the other wells.

Suitability of Bromide as a Tritium Surrogate

From the previous discussions, it is apparent that bromide is a better surrogate for tritium (i.e., bromide behaves more like tritium) in lower transmissivity diffuse flow (as at TW2 and TW4) than in flow in more transmissive media in dolomite. This is because tritium is actually retarded more in diffuse flow and therefore, relative retardation of bromide is less than in more transmissive flow (as at TW3 and SW1). Flow-path length and residence time do not appear to be as important in higher transmissivity flow as they are in lower transmissivity flow.

The ARR_d values do not appear large enough to rule out bromide as a general tritium surrogate in either flow environment because of (1) the generally low relative retardation of bromide, and (2) the small change in ARR_d values from all wells over the last 30 days of the test. In fact, this argument suggests that bromide may be a more suitable tracer than tritium in dolomite of widely varying transmissivity over a long time because bromide appears to be less sensitive to variations in concentration, residence time, flow-path length and transmissivity. This recommendation may seem contrary to the suggestion of Wierenga and Van Genuchten (1989), that chloride and bromide may not be the best tracers in sandy soil, but this research has shown that in low-transmissivity dolomite, bromide behaves essentially like tritium.

Conclusions

Using two tracers simultaneously revealed properties of apparent relative retardation not discernible with only one. From the results of this research, the following conclusions are evident as answers to the five original questions in the "Introduction."

1. Neither tritium nor bromide are completely conservative tracers in fissured and fractured dolomite, but tritium can be relatively retarded very slightly with respect to bromide at very low normalized concentrations (at or less than 3×10^{-4}). At higher normalized concentrations (from 3×10^{-4} to 3×10^{-3}), tritium was relatively less retarded than bromide, but the rate of apparent relative bromide retardation decreased over time.

2. Tritium is retarded more readily than bromide when flowing through low-transmissivity dolomitic media with large total surface area, such as sets of microfractures, vugs,

and other pores which produce diffuse flow and dead-end porosity, but it was apparently relatively less retarded than bromide in more transmissive open fractures and fissures, perhaps due in part to greater tritium mobility in these zones than in the less transmissive zones. Bromide retardation did not appear to vary as much as tritium retardation with changes in transmissivity.

3. The apparent relative retardation coefficient of bromide with respect to tritium changed no more than a few hundredths over 30 days after peak arrival at any well.

4. Retardation was also exacerbated by increasing flow-path length because the longer the path, the greater was the rock-fracture surface area in contact with the water to provide surface for retardation. Therefore, similar tests performed on longer scale systems would be likely to yield greater retardation values.

5. In general, differences in apparent relative retardation were so slight that bromide can indeed be considered a suitable surrogate for tritium in tracing ground-water flow in fractured and fissured dolomite, in diffuse and/or open-conduit flow. Bromide may actually be a better tracer than tritium in a widely varying flow environment.

Aquifer Analysis and Modeling in a Fractured, Heterogeneous Medium

by R. R. Lee[a], R. H. Ketelle[a], J. M. Bownds[a], and T. A. Rizk[b]

Abstract

A ground-water flow and contaminant transport modeling study was performed at a proposed low-level radioactive waste disposal site on the Department of Energy's Oak Ridge Reservation to assess the accuracy of a computer simulation of the flow field in the shallow water-table aquifer. The migration of a ground-water tracer, under controlled field conditions, was used as a comparative benchmark of solute transport simulations assuming different aquifer characteristics. A conventional approach to aquifer analysis and modeling, which assumed the domain to be homogeneous with low anisotropy, resulted in an inaccurate simulation of tracer migration. Alternative conceptual models were formulated which considered the effects of geologic heterogeneities on tracer migration which could be verified by additional data acquisition and analysis. Application of the alternative concepts in numerical modeling resulted in more accurate simulations of tracer migration. These results suggested that local geology created discrete flow pathways oriented oblique to the maximum gradient which were unresolved in conventional aquifer analysis. Results of the study showed that standard approaches to aquifer analysis and computer modeling are crudely representative of the flow field and provide nonconservative estimates of contaminant transport at the scale of a waste disposal unit. By adopting an iterative approach to site characterization, conceptual model formulation, and numerical modeling, the level of resolution provided by a ground-water tracer was accurately simulated.

Introduction

In general, there is a need to calibrate/validate the results of ground-water flow and contaminant transport models with field data. In some relatively simple flow systems, this process may be straightforward; however, the reliability of simplistic flow and transport estimates decreases in relation to system complexities and spatial and temporal extrapolation beyond available site data for model calibration. To determine the level of data collection and analysis effort required to achieve a reasonably accurate computer simulation at a moderately complex site, a field and modeling study was performed. This paper describes the process used to calibrate a numerical ground-water flow and contaminant transport model. Through iterative conceptual model formulation and testing, model application, and field testing, numerical simulation results were obtained which accurately approximated the migration of a ground-water tracer.

Site Description

The study site is located in the Valley and Ridge Province of the southern Appalachians on the Department of Energy's Oak Ridge Reservation (Figure 1). The site encompasses about an acre of hillside terrain bordered on the southwest by a small perennial stream. Interbedded (about 1 m scale) limestone, siltstone, and shale lithologies of the Cambrian age Conasauga Group, Maryville Limestone underlie the site. The orientation of bedrock strike is N 55° E, and the rocks dip 45° SE, consistent with the regional structural setting. Fractures are ubiquitous, and soil is thin to essentially absent. Weathered bedrock (regolith) extends from just beneath the ground surface to depths ranging from about 3 to 10 m. The piezometric surface fluctuates approx-

imately 0.3 to 1 m in response to normal seasonal precipitation, and is generally coincident with the bedrock weathering interface.

Site Characterization Methods and Interpretations

Geologic and hydrogeologic characterization studies included rock core drilling, lithologic and geophysical logging, construction of individual and cluster piezometers, discrete zone straddle packer testing, falling head testing, performance of two pumping tests drawing water from different aquifer zones, and continuous and periodic water-table monitoring. Aquifer tests were performed to depths of about 55 m. Drilling was performed by coring, augering, or rotary methods using low pressure water as the drilling fluid to reduce artificial fracture dilation.

Geologic Investigations

Rock coring was performed at four locations in the immediate site periphery from depths of 10 to 60 m to establish stratigraphic control and to perform straddle packer tests. Core hole locations are illustrated in Figure 1. Bedrock consisted of three irregularly interbedded lithologic units of about 1 m thickness each. Two units consisted of relatively homogeneous limestone and shale, and the third unit consisted of calcareous siltstone with planar to wavy laminated, coalesced lenses of silty limestone or 2 to 5 cm thick limestone beds. Lithologic correlations, in some cases to the bedding plane level of resolution, indicated overall lateral continuity, particularly of the shale units, with minor lateral character change in the limestone units. With the exception of a limited zone of intense deformation, on-site bedrock attitude was uniformly 45° SE. While bedding plane fractures were presumed to be laterally extensive, joints and fractures which crossed lithologies generally did not penetrate adjacent lithologies. Such joints and fractures were generally separable into two strike and two dip sets. Occasional vertically extensive fractures (as much as about 15 cm long) were filled with calcite. Fracture density ranged from about 15 to 30 fractures/m, occurring more frequently in heterogeneous, thin-bedded lithologies.

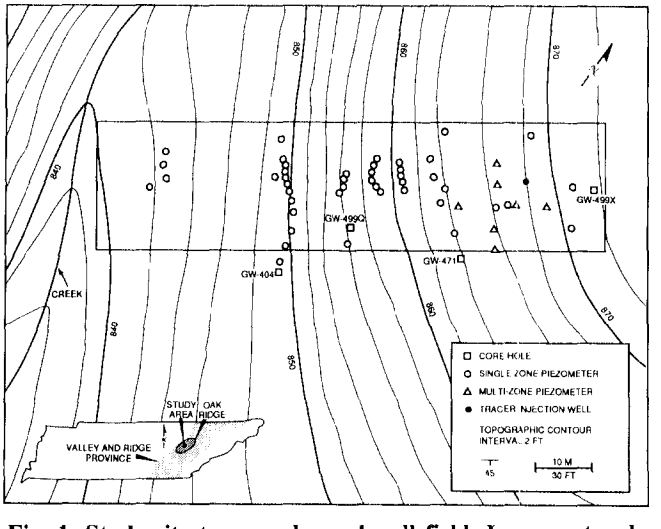

Fig. 1. Study site topography and well field. Large rectangle represents computational domain boundary.

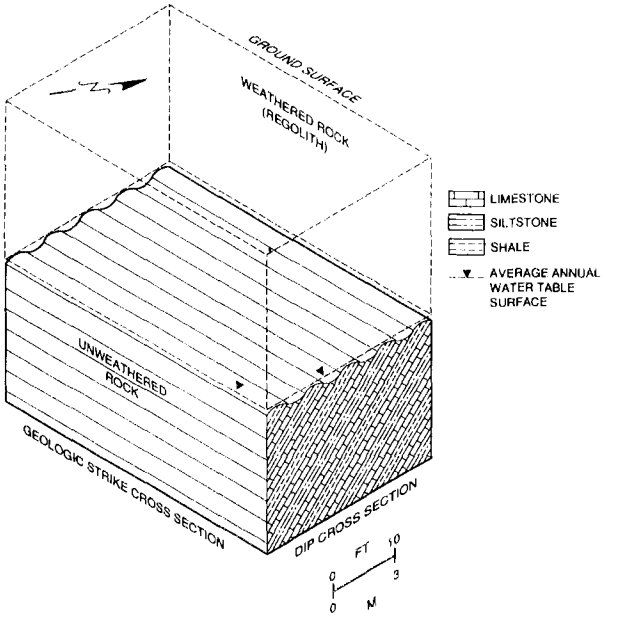

Fig. 2. Simplified block diagram of subsurface geology and piezometric surface.

Geophysical logs were obtained from each core hole to document stratigraphic control and for correlation with rock core. Such logs included natural gamma, neutron, neutron porosity, compensated density, density porosity, single point resistivity, long and short normal resistivity, and temperature. Logs were also used for comparison with results from straddle packer testing (discussion to follow) to investigate potential geophysical evidence of lithologic and/or fracture-related flow.

Depth to the bedrock weathering interface, based on the depth to machine auger refusal, was used for comparison with the rock core and geophysical log data to achieve more precise stratigraphic control. Auger refusal data indicated strike-normal relief on the bedrock weathering interface which was interpreted to be related to differential weathering of the approximately 1 m thick limestone and shale-dominated lithologic units. Figure 2 is a simplified block diagram depicting subsurface geologic conditions and the interpreted strike-normal corrugated aspect to the bedrock weathering interface. The average annual water-table surface is included for reference.

Hydrogeologic Investigations

Site hydrogeologic studies were performed to obtain both overall and discrete zone aquifer properties. Aquifer testing included pumping tests, straddle packer tests performed above and below the water table, slug tests, and the performance of a ground-water tracer test.

Pumping Tests

Two 24 hr pumping tests were performed in the shallow and deep portions of the aquifer (from nominal 6 to 33 m depths). Because previous pumping tests at Oak Ridge sug-

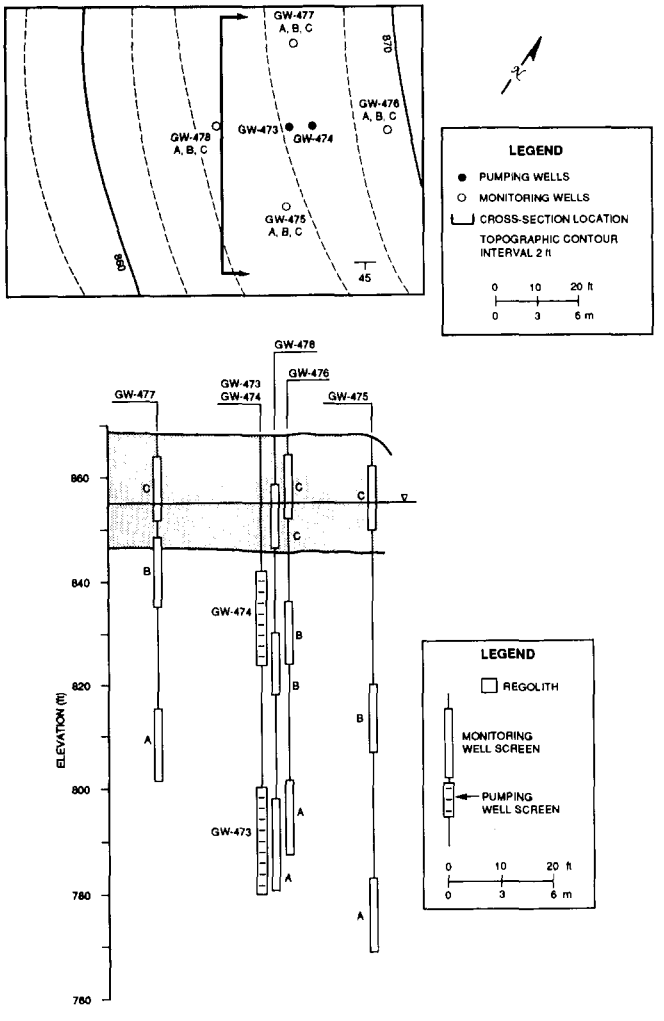

Fig. 3. Pumping test plan layout and stike-normal cross section.

gested aquifer anisotropy parallel to geologic strike (Davis et al., 1984; and Lozier et al., 1986), the plan view pumping test well field was oriented parallel and perpendicular to geologic strike. The plan and cross-sectional pumping test layout are shown in Figure 3. Each monitoring well cluster consisted of three wells. Shallow wells were located within the water table above the bedrock weathering interface. Intermediate and deep monitoring wells were located at different depths but in the same strata to investigate lithologic or structural influences on aquifer response to pumping. Shallow and deep pumping wells were located in the same strata as the intermediate and deep monitoring wells, respectively. Figure 4 illustrates the 24 hr drawdown isopleths for the shallow wells during the shallow pumping test as representative of both tests.

Pumping test data were analyzed for transmissivity and storage coefficient using the methods described by Chow (1952), Neuman (1975), and Theis (1935). Estimates of bulk hydraulic conductivity were obtained from the geometric mean of the transmissivity data assuming a 6 m aquifer thickness based on the pumping test setup. In general, the Theis and Neuman analytical methods provided slightly higher values of hydraulic conductivity (factor of 2 to 3). The geometric mean hydraulic conductivity value for the deep and shallow pumping tests was 1×10^{-5} and 7×10^{-5} cm/s, respectively, with both tests exhibiting a one order-of-magnitude range of values. These data suggested a weak relationship between hydraulic conductivity and depth.

The data were analyzed for aquifer anisotropy using the Gringarten and Witherspoon (1972) fractured aquifer solution and the Papadopulos (1965) infinite aquifer solution. In both analyses, the major and minor hydraulic conductivity axes were parallel and normal to bedding, respectively. Using iterative methods, the Gringarten and Witherspoon solution suggested an hydraulic conductivity anisotropy ratio of about 2:1 parallel to geologic strike. Parameters obtained from the Papadopulos solution using a nonlinear optimization technique (Crane et al., 1980) indicated an anisotropy ratio of 38:1 parallel to strike (Rizk, 1990). In similar settings at Oak Ridge, Davis et al. (1984) report an anisotropy value of about 4:1 parallel to strike, Smith and Vaughn (1985) obtained values of 5:1, and Geraghty and Miller (1990a) report an optimum value of 3:1 in model calibration. Use of the Papadopulos solution in the analysis of an NaCl tracer pumping test in the same stratigraphic unit but in another location at Oak Ridge yielded an average value of about 30:1 parallel to strike (Lozier et al., 1986).

Straddle Packer and Slug Tests

Slug tests were performed in 19 piezometers in the pumping test area at depths ranging from 5 to 26 m to obtain values of bulk hydraulic conductivity. Piezometer screen lengths ranged from 1.2 m in wells located near the water table to 4 m in deeper wells. Data were analyzed by the procedure described by Hvorslev (1951). Hydraulic conductivity values ranged from 2×10^{-4} to 8×10^{-7} cm/s with a geometric mean value of 1×10^{-5} cm/s. Values of hydraulic conductivity were not found to be related to screen length or well depth.

Two stages of straddle packer tests were performed, one before and one after the tracer test. In both stages of testing, correlative stratigraphic intervals in two core holes were tested. The first stage consisted of 19 tests performed to depths of 55 m using a 4 m interpacker spacing. These tests were performed to investigate relationships between values of hydraulic conductivity and depth, fracture density, and

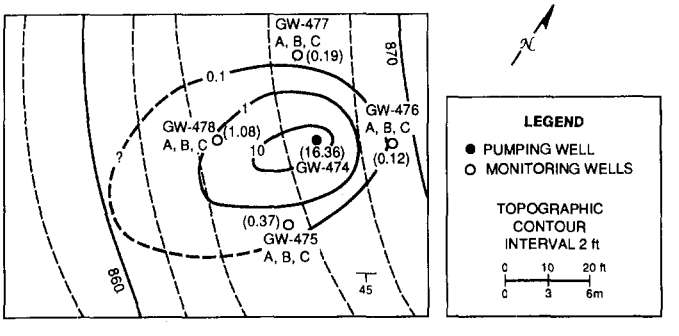

Fig. 4. Drawdown isopleths at completion of the 24 hr shallow pumping test.

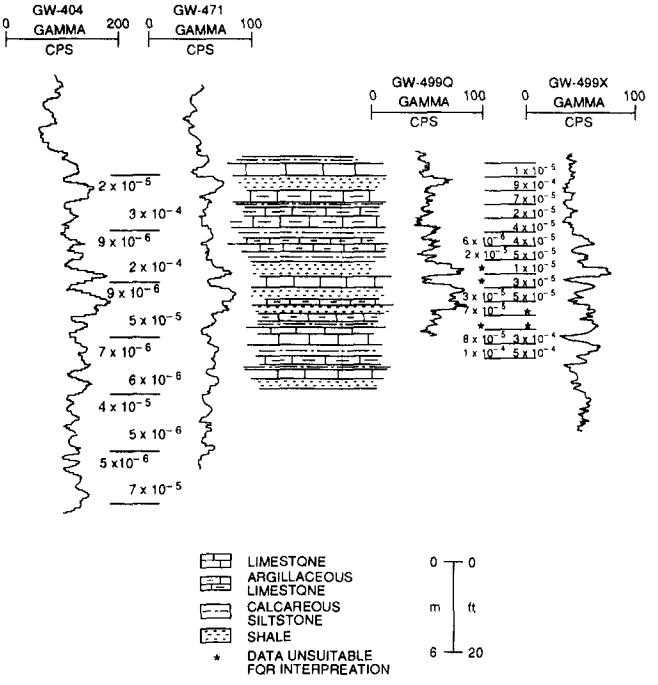

Fig. 5. 1 and 4 m straddle packer and falling head test results in correlative stratigraphic intervals.

geophysical evidence of flow and for comparison with test results from the pumping and slug tests. In the second stage, another 23 packer tests were performed in two additional core holes to depths of 14 m using a 1 m interpacker spacing. These tests, which included 10 falling head tests in the vadose zone (in regolith), were performed to investigate hypotheses relating values of hydraulic conductivity with lithology, test scale, test method, and weathered vs. unweathered bedrock.

The straddle packer test setup consisted of two inflatable packers with pressure transducers located between packers and above and below the straddle packer string. A predetermined interpacker spacing was set above ground. After positioning the packer string and inflating the packers at the designated core hole depth, water was removed from the interpacker space by swabbing. For the falling head tests, water was pumped through the drilling rods to a level close to ground surface. For all tests, care was taken to remove or introduce water to minimize alterations to natural formation properties.

Preliminary data analyses were performed on-site with portable computers, and reanalyses were performed in the office. Tests performed below the water table were analyzed by methods described by Horner (1951), Hvorslev (1951), and Gringarten et al. (1979). Falling head tests performed above the water table were analyzed by the methods described by Stephens and Neuman (1982a and 1982b) and Hvorslev (1951). Figure 5 shows lithologically correlated core hole natural gamma logs and straddle packer and falling head test hydraulic conductivity values from correlative test intervals for both the 4 and 1 m tests to depths of about 30 m.

Analysis of the test results revealed a weak relationship between values of hydraulic conductivity and test scale, fracture density, and/or depth, and no systematic relationship with lithology or test method. Hydraulic conductivity values from vadose zone falling head tests were indistinguishable from straddle packer tests performed below the water table. Qualitative predictions of the outcome of test results based on rock core and geophysical log data were reasonably accurate in about 25% of the tests. The geometric mean hydraulic conductivity value of the 4 m tests was 3×10^{-5} cm/s ranging from 3×10^{-4} to 3×10^{-6} cm/s. The geometric mean hydraulic conductivity value of the 1 m tests was 4×10^{-5} cm/s ranging from 9×10^{-4} to 6×10^{-6} cm/s. With the exception of one vadose zone test, values of hydraulic conductivity obtained from all test methods were within the range of values reported by Connell and Bailey (1989) for the Maryville Formation in Bear Creek Valley elsewhere at Oak Ridge.

Tracer Test

The tracer test was performed under ambient conditions (natural site gradient). Based on water elevation data from the pumping test cluster wells, additional tracer detection well clusters and single piezometers were constructed in the immediate vicinity, downgradient from the selected tracer injection well location. Well clusters were constructed similar to those for the pumping test, and single piezometers were constructed similar to the shallow wells in the pumping test clusters. Background wells were constructed to more accurately describe the piezometric surface and to define the tracer plume boundaries.

Following the removal of 10 l of water from the injection well, 10 l of 40% Rhodamine-WT dye solution was introduced to the upper 0.3 m of the water-table surface. As tracer migration progressed, 39 additional shallow detection wells were constructed in the shallow portion of the aquifer in front of the tracer plume to obtain tracer arrival data and to describe detailed plume evolution. To avoid disturbances to plume migration, drilling for the additional detection wells was performed by augering to the bedrock weathering interface, and the wells were not developed. Depending on sampling location and migration behavior, samples were obtained from between 8 hr and biweekly intervals and immediately following precipitation events. Biweekly water elevation data were obtained from all detection wells. Daily precipitation data were obtained from a nearby meteorological station. Tracer analysis at 1 ppb resolution was performed on-site using fluorimetric techniques.

Figure 6 illustrates the 10 ppb tracer concentration contour at three months superimposed on the piezometric surface described by shallow wells at locations shown. Because the piezometric surface in the immediate vicinity of the injection well on the day of injection was essentially the same as shown in Figure 6, tracer was anticipated to migrate along the maximum gradient. Instead, observed tracer migration was parallel to geologic strike in a narrow, slightly meandering, and fingering plume. This indicated the presence of flow field heterogeneities which were unresolved in the initial aquifer analysis. Local irregularities in the piezo-

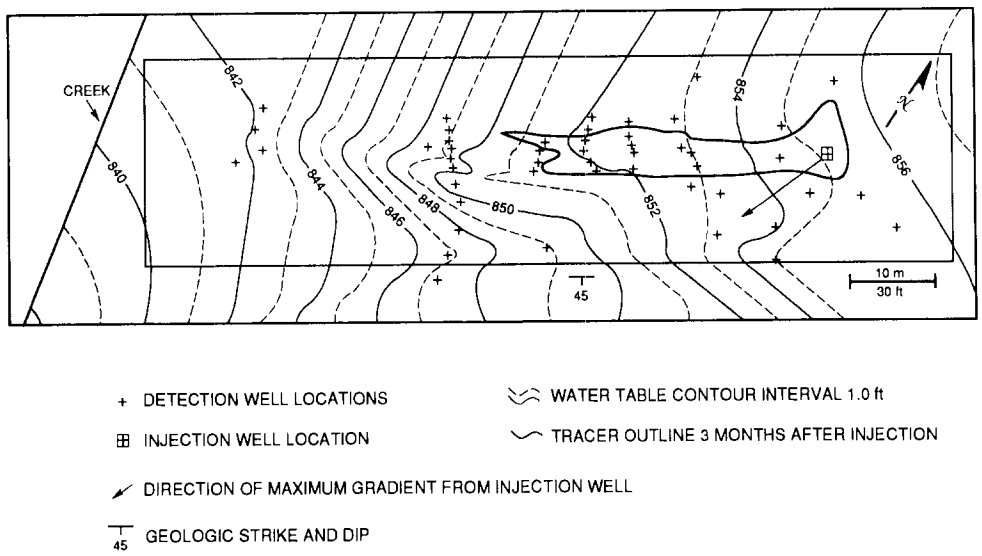

Fig. 6. 10 ppb tracer concentration contour three months after injection superimposed on water-table surface.

metric surface, which were considered artifacts prior to the tracer test and discounted, were found to strongly influence migration. These irregularities in the piezometric surface, strike-parallel ridges of elevated head, flanked the southern boundary of the tracer plume. Despite minor variations in the elevation of the piezometric surface throughout the year, its shape and the position of the plume with respect to the surface remained essentially unchanged.

Early time (one month) tracer migrated in a plume less than 2.5 m wide which reached a maximum width of 6 m after 12 months and a length:width aspect ratio of 7.5:1. Monitoring wells positioned across the plume axis, and sometimes less than 1 m apart, often showed two order-of-magnitude differences in tracer concentration. The tracer boundary was clearly defined; at peripheral locations, repeated concentrations of 10 ppb and less were outside the plume boundary.

In the first two weeks, a high concentration plume migrated as rapidly as 1.0 m/day for about 14 m in the near-field, but another 9 m of migration in the mid-field required an additional 230 days (0.04 m/day). Total migration distance of 33 m (the far-field) for the 100 ppb front required 370 days (0.09 m/day average). Data analysis could not attribute the erratic rate of migration to the presence of a concentration gradient induced by the slug dye injection, and no consistent correlation could be found with changes in the water-table gradient profile or with precipitation. Rather, the migration rate, narrow overall plume shape, and slightly meandering and fingering plume all suggested the presence of lithologic and/or fracture-related pathways of preferred flow.

Average vertical head gradients to depths of 20 to 30 m below ground surface in a hydrogeologic cross section oriented perpendicular to local geologic strike at the site are shown in Figure 7. As shown, the average vertical gradient at the site indicates upward leakage of ground water from deeper zones of elevated head toward the water-table surface. A similar cross section (not shown) oriented parallel to strike, and parallel to the tracer path, shows similar upward leakage conditions from the tracer injection point toward the local stream. The general upward vertical gradient observed at the site explains the observation of tracer only in

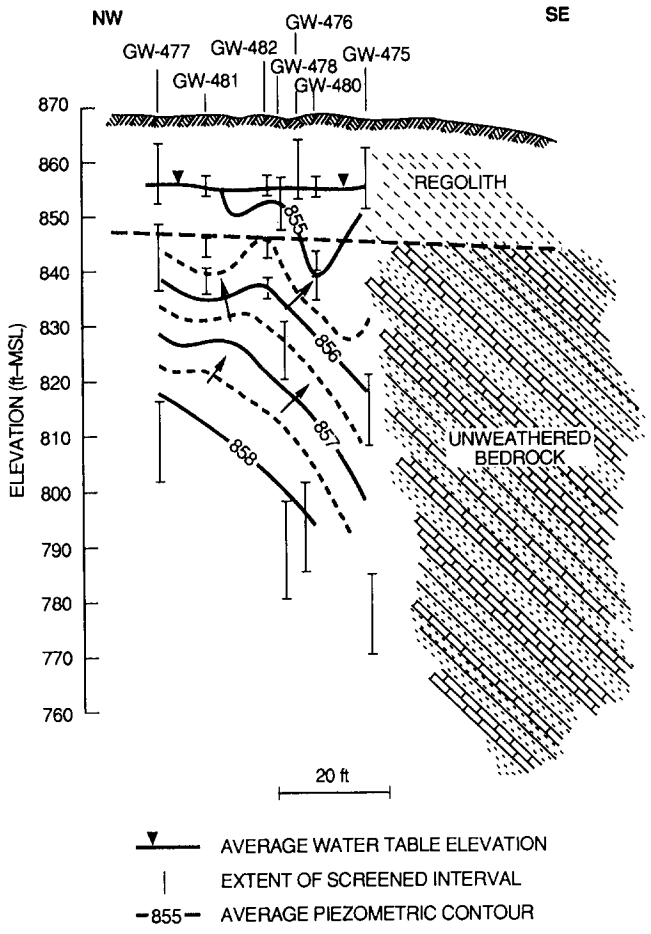

Fig. 7. Strike-normal cross section of the vertical head profile in the vicinity of the pumping test.

the water-table zone of the aquifer. Tracer was never detected at depth despite long-term monitoring at various depths in bedrock within the tracer pathway and in stratigraphically correlative core holes downdip and downslope of the tracer injection zone. Tracer detection and observed vertical gradients at the site demonstrate that neutral density solutes introduced at the water table mix in a thin zone below the water table and migrate through the bedding plane dominated fracture system. This thin mixing zone which is recharged by local precipitation infiltration from above and by upward leakage from below approximates a two-dimensional solute mixing domain.

Numerical Modeling

Because of the vertical head profile and tracer migration confined to the uppermost portions of the aquifer, the aquifer was assumed to be two-dimensional and of uniform thickness throughout. Because of low precipitation during the period of the test and negligible water-table variation, annual average values of hydraulic head data, including creek data, were applied to a continuously differentiable quintic spline for irregularly spaced data (Renka, 1982) to establish constant head boundaries and to generate interpolated head values at all nodes for comparison with computed values. This method, which was used throughout modeling, allowed for calibration throughout the entire spline-generated head surface which provided a more global calibration than simple comparison at selected data locations. Areal recharge of 2.5 cm was applied uniformly over the domain which accommodated the three-dimensional nature of the problem by allowing leakance from any direction. Because of little change in the piezometric surface during the test, the velocity field was assumed to be steady state. Hydraulic conductivity, porosity, and dispersivity parameters (characteristic length) were assumed to remain constant. The code was run in weekly time steps for a period of 12 months.

Because of the overall regular shape of the domain and the flexibility to allow spatially variable hydraulic parameter coefficients in the hydraulic head equation, the USGS Method of Characteristics (MOC) code (Konikow and Bredehoeft, 1988) was used. The computational domain represented a strike-parallel rectangle encompassing the area of tracer migration at the bedrock weathering interface (the water-table surface) with 1×4 m finite difference grid cells (long dimension parallel to strike) to resolve details of tracer plume evolution.

To the extent possible, input parameter values were constrained by analysis of site data. Aquifer studies at Oak Ridge (Geraghty and Miller, 1990b; Lozier et al., 1986; and Davis et al., 1984) have estimated effective porosity values ranging from 1 to 10%. Selection of a relatively low value (3%) seemed plausible for geologic conditions and provided a reasonable scaling factor to simulate tracer migration velocity. While a 6 m aquifer thickness was assumed based on the pumping test setup, tracer migration essentially at the water-table surface suggested that aquifer thickness could be used as a velocity tuning parameter within a 1 to 6 m range, and a 3 m thickness was used. Because flow was assumed to be advective, dispersivity parameters and their anisotropy were varied among cases but kept low within the scale of the problem. Descriptions of the concepts of the flow field which evolved during the study, corresponding differences in model input, and results are described below.

Conceptual Model Descriptions and Modeling Results

For purposes of describing the flow field and providing input parameter values for numerical modeling, the data were equivocal and could be interpreted in several ways. Based on reinterpretations of the data, three conceptual models of the flow field were formulated. As additional field data analysis and/or numerical modeling results dictated, conceptual models were modified or abandoned. A description of each conceptual model and the result of its application in numerical modeling are presented below. Table 1 provides the input parameter values used for each concept. Table 2 compares calibration and results of each concept with tracer data using the evaluation criteria migration direction, migration distance, plume length:width aspect ratio, and average annual velocity. Figure 8 compares the tracer plume configuration at 12 months [Figure 8(a)] with simulations at the same time for the homogeneous, low anisotropic [Figure 8(b)], geologic-based [Figure 8(c)] and hydrogeologic-based [Figure 8(d)] cases described below.

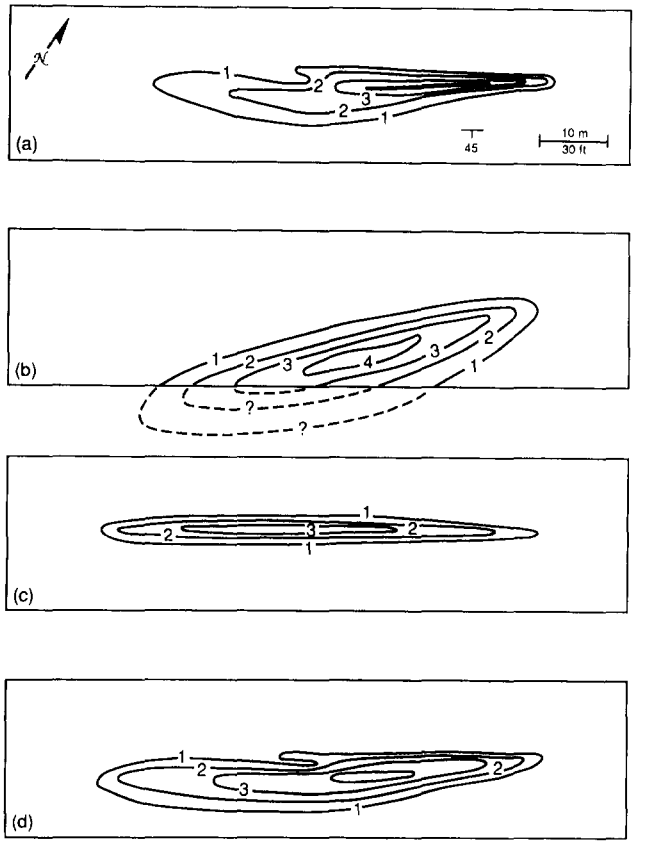

Fig. 8. Log tracer concentration at 12 months (a); and simulation results for the homogeneous, low anisotropy case (b); the geologic-based case (c); and the hydrogeologic-based case (d). Rectangular border represents computational domain boundary in all cases.

Table 1. Input Parameter Values for All Cases

Simulation parameters	Value (by case) Homogeneous	Geologic	Hydrogeologic
Grid parameters			
Number of nodes (x)	20	20	20
Number of nodes (y)	20	20	20
Cell length (x) (m)	4	4	4
Cell width (y) (m)	1	1	1
Hydrologic parameters			
Storage coefficient (steady state)	0	0	0
Hydraulic conductivity (x) (cm/s)	6×10^{-5}	6×10^{-5} (limestone) 6×10^{-7} (shale)	CDF[1]
Hydraulic conductivity (y) (cm/s)	3×10^{-5}	6×10^{-6} (limestone) 6×10^{-8} (shale)	CDF[1] × .03
Medium parameters			
Effective porosity (%)	3	3	3
Saturated thickness (m)	3	3	3
Dispersivity (x) (characteristic length)	1	10^{-3}	1
Dispersivity (y) (characteristic length)	0.1	10^{-3}	0.1
Tracer source parameters			
Number of injection wells	1	1	1
Injection rate (m^3/s)	3×10^{-10}	3×10^{-10}	3×10^{-10}
Concentration (ppb)	10^4	10^4	10^4

[1]Random sampling of the cumulative distribution function (CDF) of field measured values.

Homogeneous, Low Anisotropy Case

The initial conceptual model was developed prior to the tracer test and was based on results of larger scale (4 m) straddle packer tests, slug tests, and pumping tests. These aquifer tests suggested the aquifer could be modeled as a homogeneous, equivalent porous medium with low anisotropy. The concept was supported by the slightly elliptical but generally uniform drawdown observed during both pumping tests which suggested an absence of significant fracture influence and the general agreement in hydraulic conductivity values obtained from all aquifer test methods. A hydraulic conductivity value of 6×10^{-5} cm/s was assigned to all cells, and a hydraulic conductivity anisotropy ratio of 2:1 parallel to strike was used based on the results of the shallow pumping test. Dispersivity parameters were established at the smallest dimension of the problem (1 m) with a longitudinal:transverse dispersivity ratio of 10:1. Calibration was obtained with a root mean square (rms) error slightly greater than 0.1 m and an average difference between computed and spline-generated head values of 0.04 m.

Contrary to subsequent tracer migration, application of the homogeneous, low anisotropy concept in numerical modeling predicted tracer migration 14 degrees from strike, a plume length:width aspect ratio of 2.6:1, and distance of 69 m. Increases in the anisotropy of hydraulic conductivity to 10:1 and 30:1 improved the direction of migration to within 3 degrees of strike and the plume length:width aspect ratio to 5.4 but resulted in increasing migration distance and loss of calibration. Incremental increases in porosity (to 4%) improved the migration distance but provided no improvements in length:width aspect ratio or migration direction. Tuning of dispersivity parameters and their anisotropy to the limits of the problem scale provided little improvement to previous plume configurations. When no reasonable combination of parameter values could approximate the tracer plume and maintain head calibration, modeling efforts were terminated, and the concept was reevaluated.

Geologic-Based Case

An alternative geologic-based concept was developed while the tracer test was ongoing. The concept considered

Table 2. Calibration and Comparison of Tracer Plume at One Year with Modeling Results for Each Concept

Concept	Calibration: Drawdown (m)	Calibration: RMS error (m)	Evaluation criteria: Migration direction (degrees from strike)	Migration distance (m)	Aspect ratio (length/width)	Velocity (m/d)
Tracer	—	—	1	46	7.5	0.13
Homogeneous	0.04	0.1	14	69	2.6	0.19
Geologic	0.06	0.2	0	51	18.7	0.14
Hydrogeologic	0.02	0.2	3	52	7.4	0.14

that tracer migration was related to a systematic hydraulic conductivity contrast between limestone and shale-dominated lithologies which was unresolved by larger scale aquifer testing and/or by physical restriction of tracer caused by the corrugated shape of the bedrock weathering interface. The concept was supported by geologic, auger drilling, hydraulic head, and tracer data. For model input, strike-parallel cells representing limestone lithologies were assigned two order-of-magnitude higher hydraulic conductivity values than cells representing shale lithologies (6×10^{-5} vs. 6×10^{-7} cm/s). Because of the results of the homogeneous, low anisotropy case, a hydraulic conductivity anisotropy ratio of 10:1 was selected for use based on a compromise between high and low values obtained from previous pumping test results. Because of strong directional influences inherent in the conceptual model, dispersivity parameters were kept very low (10^{-3} m). Calibration was achieved with a 0.2 m rms error and an average difference between computed and spline-generated head values of 0.06 m.

Application of the geologic-based concept to modeling resulted in reasonably accurate transport simulations in terms of migration distance, direction, and velocity but a length:width aspect ratio of 18.7:1. As parameter tuning (hydraulic conductivity and dispersivity) to improve the aspect ratio was ongoing, results of the 1 m straddle packer and falling head tests, which were designed to verify the concept, became available. The results indicated an absence of hydraulic conductivity contrast between limestone and shale-dominated lithologies. Despite the intuitively satisfying nature of the concept and the promising modeling results, the inability to verify the concept with field data resulted in its abandonment.

Hydrogeologic-Based Case

A third hydrogeologic-based conceptual model was formulated as the tracer test continued. The concept assumed that the widely varying hydraulic conductivity data were a valid representation of a randomly heterogeneous flow field. Irregularities in the piezometric surface (preferred tracer migration pathways) which flanked the plume on the south, were assumed to represent discrete zones of enhanced discharge flux, possibly fractures. These zones effectively functioned, and could be realistically represented, as conduits of elevated hydraulic conductivity. For model input, hydraulic conductivity values were assigned to each cell by randomly sampling the cumulative distribution function of field measured values. In contrast to a Monte Carlo study, one set (one value/node) of randomly selected hydraulic conductivity values was used. A value at the upper end of measured values (1×10^{-4} cm/s) was assigned to conduits. A hydraulic conductivity anisotropy value at the upper bound of those measured at Oak Ridge (30:1) was used. Despite this seemingly high value of anisotropy, it was thought that in combination with the random values of hydraulic conductivity a more satisfactory result could be obtained. Dispersivity coefficients and their anisotropy were established as in the homogeneous case. Calibration was achieved with a 0.2 m rms error and 0.02 m average difference between computed and spline-generated head values.

Application of the hydrogeologic-based concept in modeling resulted in an accurate simulation of the tracer with highly favorable comparisons in all evaluation criteria. While a robust tracer data set was available for calibration when the simulations were performed, the favorable comparison with the plume shape and evolution using only head data for calibration adds further validity to the concept. Although the 1 m straddle packer tests did not identify conduits of elevated hydraulic conductivity, tracer migration rate data, plume fingering, and hydraulic head data suggest their presence. Their inclusion is required at the 1 to 10 m scale for accurate simulations of the rate of tracer migration in early time steps (two weeks) and to simulate plume fingering, but they have little effect on the accuracy of the position of the 100 and 1000 ppb isopleths at longer times.

Concept Comparison

The aquifer analysis conducted prior to the tracer test was designed to be comprehensive to obtain both overall and detailed aquifer characteristics data using a conventional approach to data collection and analysis. Results of that analysis indicated the flow field could be represented as a homogeneous equivalent porous medium with low anisotropy. Application of that interpretation in numerical modeling, however, resulted in inaccurate simulations of tracer migration. Tracer data clearly indicated that simplifying assumptions in the homogeneous, low anisotropy concept failed to account for system heterogeneities and were not applicable to the shallow aquifer at Oak Ridge.

The alternative geologic and hydrogeologic-based concepts were formulated when tracer data demonstrated the heterogeneous and strongly anisotropic nature of the flow field. While neither concept is wholly supported by interpretations of all site data, both are supported by the bulk of the empirical data. While modeling results indicate the hydrogeologic-based concept most accurately describes the flow field, both alternative concepts provided superior results over the initial homogeneous, low anisotropy concept when applied in numerical modeling. This suggests that modeling at the scale of this test should reflect the strongly heterogeneous character of the flow field by possibly including selected regions resembling fractured porous flow.

Conclusions

Results of this study demonstrate that application of conventional methods of hydrogeologic data collection, data analysis, and numerical modeling to the complex natural setting at Oak Ridge results in only crude estimates of the flow field. In contrast, the level of resolution provided by a ground-water tracer can be accurately simulated while constraining input parameter values to those obtained from interpretations of field data and by adopting an iterative approach to site characterization, conceptual model formulation, and numerical modeling.

Reliance upon the analyses and interpretations of initial site data and modeling results, which assumed homogeneous, slightly anisotropic conditions and domi-

nantly gradient driven flow, would also result in nonconservative estimates of contaminant transport. Tests documented in this study show that a ground-water contaminant will likely not be detected in locations down maximum gradient from a waste disposal unit at this site. In complex hydrogeologic settings, the use of ground-water tracer tests to verify solute transport model results provides an effective means of deterministically evaluating those system characteristics which most influence flow.

ground water

Calculation of Ground Water Ages—A Comparative Analysis

by Maria Clara Castro[1] and Patrick Goblet[2]

Abstract

Ground water age is a fundamental, yet complex, concept in ground water hydrology. Discrepancies between results obtained through different modeling approaches for ground water age calculation have been reported, in particular, between ground water ages modeled by advection and direct simulation of ground water ages (e.g., age-mass approach), which includes effects of advection and dispersion. Here, through a series of two-dimensional (2D) simulations, the impact of water mixing through advection and dispersion on modeled ^{14}C and directly simulated ground water ages is assessed. Impact of dispersion on modeled ages is systematically stronger in areas where water velocities are smaller and far more pronounced on ^{14}C ages. This effect is also observed in one-dimensional models. 2D simulations show that longitudinal dispersion generally acts as a "source" of ^{14}C, while vertical dispersion acts as a "sink," leading to apparent younger or older modeled ^{14}C ages as compared to advective and directly simulated ground water ages. The presence of permeable and impermeable faults provides an equally important source for discrepancies, leading to major differences in modeled ages among the three methods considered. Overall, our results show that a ^{14}C modeling approach using a solute transport model for calculating ground water age appears to be more reliable in ground water systems without faults and where water velocities are relatively high than in systems that are relatively more heterogeneous and those where faults are present. Among the three modeling approaches considered here, direct simulation of ground water age seems to yield the most consistent results in complex, heterogeneous ground water flow systems, giving a vertical age structure consistent with ages expected from consideration of the flow system.

Introduction

The concept of "ground water age" is one of the most fundamental in ground water hydrology. Fundamental because it is critical to effective management of ground water resources, prediction of the rate at which a contaminant migrates, or yet, reconstruction of the past climate through the use of noble gases dissolved in ground water. Knowing the age of ground water implies knowing precisely how a particular ground water system functions, i.e., its hydrodynamic parameters (e.g., hydraulic head distribution, hydraulic conductivity field, and porosity), recharge rates, and cross-formational rates of flow and mass within the system of interest.

Traditionally, two approaches have been used to estimate the age of ground water: estimation of ground water ages through application of the piston flow model concept and through the use of radioisotope tracers (e.g., ^{3}H, ^{14}C, ^{36}Cl; see Phillips and Castro 2003). The first approach considers the age of ground water as corresponding simply to the time elapsed along a streamline since recharge took place. The basic assumption is the presence of a closed system and absence of water mixing of different ages both across formations and within the aquifer itself. The second method, as traditionally employed assuming that all necessary geochemical corrections have been applied (e.g., Plummer et al. 1991), is used under the assumption that radioactive decay is the dominant process causing a reduction/change in the tracer concentration. Although concentrations of these tracers are also affected by ground water mixing through advection, dispersion, and/or diffusion, the impact of such

Received July 9, 2004; accepted December 18, 2004.

processes on the tracer's concentration is often neglected and is not taken into account in the age calculation (e.g., Stute et al. 1992; Castro et al. 2000). Thus, when such processes are not considered, radioisotope ages will correspond to the "true" water ages only in the presence of a closed system and total absence of water mixing. This is, however, not the case for most ground water systems (Pint et al. 2003). Movement of water in porous media is, in addition to advection and like any other tracer, also affected by kinematic dispersion, molecular diffusion, and cross-formational flow, which leads to mixing of water molecules with different ages. Independent of the chosen approach, more accurate ground water ages should be obtained by considering transport by advection, dispersion, and diffusion.

The concept of ground water age has been recently reexamined by hydrogeologists in order to derive model ages that can be compared to field measurements (Goode 1996; Varni and Carrera 1998; Bethke and Johnson 2002a, 2002b). In this approach, a parallel is made between water age and solute concentration. Ground water age is directly simulated by taking into account not only advection but also dispersion and diffusion, and the quantity conserved is the product of water age and its mass. Thus, if ground water mixing processes are non-negligible, direct simulation of ground water age (e.g., age-mass approach), which incorporates mixing of water molecules in the age calculation, should provide more realistic ages than the more traditional methods in which mixing is typically neglected. This is expected to be particularly true in complex ground water systems.

With respect to ^{14}C, which is the tracer of choice for late Pleistocene and Holocene paleoclimatic reconstructions through the use of noble gases dissolved in ground water (e.g., Stute et al. 1992; Weyhenmeyer et al. 2000), issues dealing with loss of ^{14}C by diffusion toward neighboring aquitards leading to apparent older ^{14}C ages have been addressed (e.g., Sudicky and Frind 1981; Walker and Cook 1991; Sanford and Buapeng 1996; Sanford 1997). On the contrary, with the exception of a theoretical analysis on the impact of longitudinal dispersion (Johnson and DePaolo 1996), influence of mixing of water of different ages through advection alone and that of longitudinal and transverse dispersion in particular on ^{14}C ages has received more limited attention.

Here, through a series of two-dimensional (2D) simulations carried out for a complex real ground water flow system, the impact of water mixing through advection as well as that of dispersion is assessed by comparing ground water ages calculated using an advective model, ages based on ^{14}C simulated using a solute transport model, and directly simulated ages. It will be shown how these different modeling approaches respond to changes in hydraulic conductivity and the presence of permeable and impermeable faults in the system. The combined influence of horizontal and vertical dispersion on modeled ages and the resulting vertical and horizontal age distribution are discussed. Through a one-dimensional (1D) analysis, impact of horizontal dispersion on ^{14}C ages as well as its dependency on ground water velocities is illustrated.

For comparative purposes, our starting point will be a 2D ground water flow model of flow in the Carrizo Aquifer and surrounding formations in southwest Texas that has been calibrated with ^{4}He and ^{3}He concentrations (Castro and Goblet 2003a; Castro 2004) and for which advective and directly simulated ground water ages (Castro and Goblet 2003a, 2003b) have been calculated. In this system, based on C isotope measurements available in a number of water samples, ^{14}C ages were previously estimated following the traditional approach in which mixing processes are not considered (Castro et al. 2000). Only radioactive decay and chemical interactions were taken into account in this ^{14}C age calculation, and no attempt to simulate ^{14}C transport in the system with incorporation of mixing processes was made. Subsequent comparison of these calculated ^{14}C ages with modeled advective ages (Castro and Goblet, 2003a) and those obtained through direct simulation of ground water age (Castro and Goblet 2003b) shows lack of agreement at several locations. Here, we attempt to shed some light on possible physical processes that can lead to such discrepancies when different model approaches are considered for the age calculation.

Regional and Hydrogeological Setting

The Eocene Carrizo Aquifer is a major ground water flow system exposed on the northwestern margin of the Gulf Coast Basin in South Texas (Figure 1a). In Atascosa, McMullen, and portions of surrounding counties (Figure 1b), the Carrizo Aquifer lies unconformably on the Lower-Wilcox Formation, a confining layer composed of mudstones and clay (Figure 1c; Hamlin 1988). The confining Recklaw Formation conformably overlies the Carrizo Aquifer and is in turn overlain by the Queen City Aquifer. These formations crop out subparallel to the present-day coastline and dip to the southeast (Figures 1b and 1c). The Carrizo Aquifer terminates at a major growth-fault system, the Wilcox Geothermal Corridor (Figures 1a and 1b). The presence of minor faults is also known in these formations.

Carrizo and Recklaw hydraulic conductivities decrease exponentially over 4 orders of magnitude with increased distance from the recharge area and depth, a decrease that reflects the combined influences of differential compaction of the media as well as down-dip lithological change (Patriarche et al. 2004) giving origin to a complex velocity field (Figure 1c). Calibrated hydraulic conductivities in the recharge area for the Carrizo and Recklaw are 5×10^{-4} and 3×10^{-8} m/s, respectively (Castro and Goblet 2003a). Calibration was obtained by applying exponentially decreasing factors $F_c = \exp -((x_c - 6633)/12{,}000)$ and $F_r = \exp -((x_r - 19{,}133)/12{,}000)$ to the Carrizo and Recklaw, respectively, where x_c and x_r represent any point at a distance x from the origin of the Carrizo and Recklaw outcrop areas, respectively. Hydraulic conductivity values for the Carrizo and Recklaw in the discharge area are 3×10^{-8} and 6.4×10^{-12} m/s, respectively. For the Queen City and Lower-Wilcox formations, we have adopted uniform hydraulic

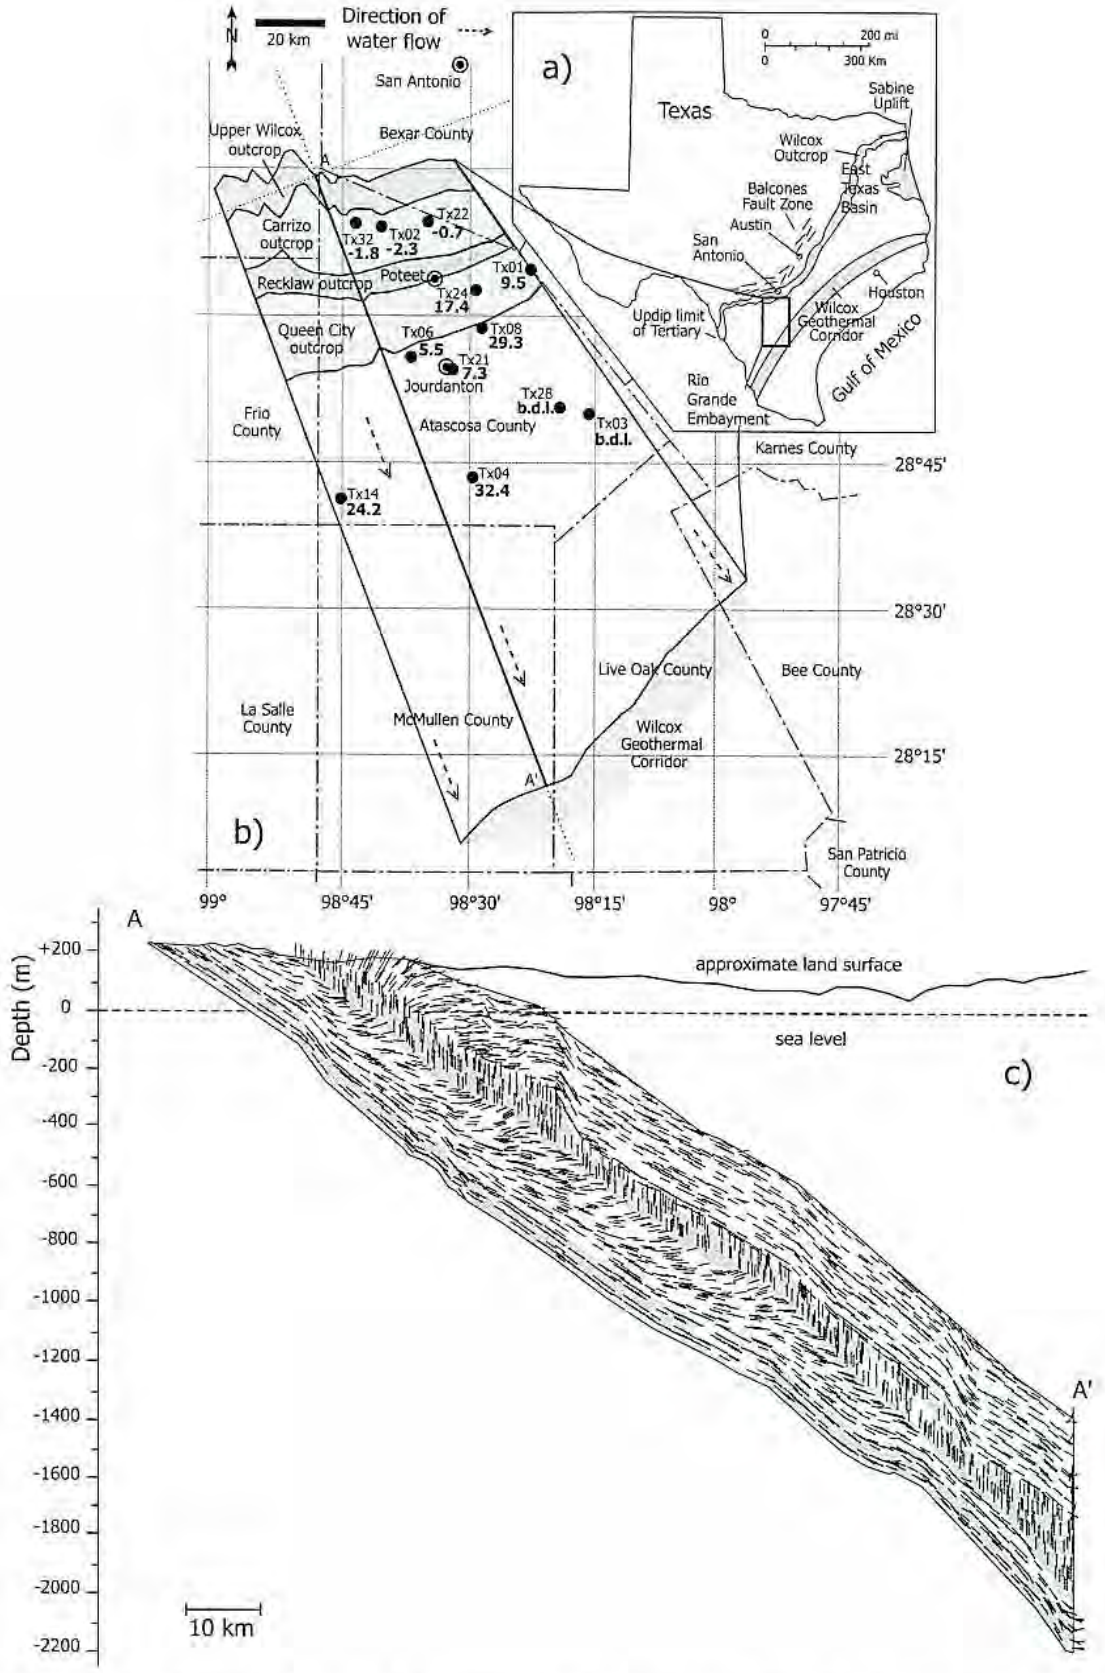

Figure 1. Study area and formation outcrops in southwestern Texas. (a) Geographical and tectonic setting (after Hamlin, 1988). (b) Detailed setting of the area with location of cross section AA′ along which simulations of ground water flow, transport, and age were carried out; sample locations for which ^{14}C ages based on C isotope measurements are available (Castro et al. 2000) indicated as closed circles; ^{14}C ages (kyr) in bold; ^{14}C is below detection limit (b.d.l.) at samples TX28 and TX03. (c) Normalized Darcy velocity vectors in place for the ground water flow model calibrated with ^{4}He (Castro and Goblet 2003a).

conductivities of 5×10^{-5} and 1×10^{-11} m/s, respectively. Average porosity values used in the simulations presented here are 20%, 12.5%, 35%, and 26% for the Queen City, Recklaw, Carrizo, and Wilcox formations, respectively (Castro and Goblet 2003a). Water infiltrates in the Carrizo outcrop area and flows toward the southeast. Discharge occurs by cross-formational upward leakage through the Recklaw. Ground water flow simulations

(Castro and Goblet 2003a) clearly show the presence of semivertical directions of water velocities toward the Recklaw Formation at the top of the Carrizo Aquifer, illustrating the effectiveness of indirect recharge for this confining layer. Near the outcrop, water movement in the Queen City is semivertical due to the strong upward leakage into the Recklaw. Elsewhere, direct influence of upward leakage in the Queen City is not detected and flow in this aquifer becomes essentially horizontal in response to the rapid decrease in hydraulic conductivities of the Recklaw.

Calculation of Ground Water Ages

All steady-state ground water flow simulations presented here were conducted as described by Castro and Goblet (2003a) along cross section AA′ (Figure 1c). The finite-element model is represented by a triangular mesh corresponding to a 120.6-km-long stratigraphic cross section between 220 and −2210 m of elevation, and it comprises 58,968 elements and 31,949 nodes. The mesh is composed of triangles uniformly distributed over the entire length of the cross section with maximum element length of 50 m. The mesh size was chosen to meet three objectives: (1) proper discretization of the different formations and, particularly, of the Carrizo Aquifer; (2) the possibility to introduce sufficiently small values of dispersivity (Table 1); and (3) the ability to extend the 2D mesh into a three-dimensional one (Patriarche et al. 2004). For most of the calculations, the element size conforms to the classical stability criterion for the numerical approximation of the advection-dispersion equation such that longitudinal dispersivity is more than twice the element size. Sensitivity tests with much smaller dispersivity values (α_L = 12.5 m, α_T = 1.25 m) yield results that are not significantly different from the results presented here. In addition, sensitivity tests conducted using a much finer mesh (2.5 m) show that no important bias was introduced by not strictly conforming to the criterion. It is important to note, however, that in the following discussion, emphasis is not on absolute ages; rather, it is on differences in behavior displayed by three different modeling approaches under the same geological and hydrogeological conditions and physical parameters.

Table 1
Diffusion and Dispersivity Parameters Used in ^{14}C and Ground Water Age Simulations

Parameter	Value	Reference
Diffusion coefficients		
$H^1H^3O^{16}$	3.83×10^{-9} m²/s	Wang et al. (1953)
HCO_3^-	1.18×10^{-9} m²/s	Li and Gregory (1974)
Tortuosity coefficients		
Aquifers	0.1	
Confining layers	0.05	
Dispersivity coefficients		
Longitudinal	125 m	
Transverse	12.5 m	

Boundary conditions for the 2D ground water flow model include hydraulic head values prescribed on the outcrop areas of all formations as well as on top of the Queen City Aquifer. At the base of the Wilcox, a no-flow boundary condition was imposed. In addition, a high hydraulic conductivity value of 10^{-5} m/s was imposed at the top of the Queen City in the Wilcox Geothermal Corridor area allowing water to be evacuated upward, representing the situation occurring at the major growth-fault system.

Subsequently, we describe the procedure used for age calculations with the three different modeling approaches: (1) application of the piston flow model principle referred to here as "advective ages"; (2) direct simulation of ground water ages; and (3) simulation of ^{14}C transport and corresponding modeled ages referred to here as "^{14}C Ages."

Advective Ages

For all ground water flow simulations, advective ages were calculated taking into account the established hydraulic gradients, hydraulic conductivity values, porosities, and Darcy velocities. Water travel times were calculated along streamlines as follows:

$$t = \int_{x_0}^{x} \frac{dx}{v} \tag{1}$$

where x_0 represents the origin of a particular streamline; x, a point at any distance x from the origin of the streamline; and v, the modeled pore water velocity. Only advection is taken into account in this age estimation. Thus, mixing of ground water both cross-formational and within the different formations is not considered.

Direct Simulation of Ground Water Age

For all ground water flow simulations presented here, all ground water age simulations were carried out in steady state and calculated as follows:

$$\mathrm{div}[(\omega d + \alpha |U|)\mathrm{grad}\vec{\tau} - \vec{U}\tau] = \omega \tag{2}$$

where ω is the porosity, d is the tritiated water diffusion coefficient in porous media multiplied by the tortuosity coefficient (Table 1), α is the dispersivity tensor (m) expressed in the two main directions of anisotropy by α_L and α_T, respectively, in the longitudinal and the transverse directions of flow (Table 1), τ is the age, and U is the Darcy velocity (m/s).

To account for ground water mixing, we treat water age as one would treat a solute concentration; water age (in seconds) is simulated by considering the product of water mass (ρV) and age (τ) (Goode 1996), where ρ is the water density (kg/m³) and V is the water volume (m³). This quantity, referred to as "age-mass" (kg s), is conserved and is equivalent to moles of a solute tracer. Boundary conditions included zero–age-mass flux across all no-flow and inflow boundaries of the domain (AA′;

Figures 1b and 1c) and no age-mass dispersive flux across outflow boundaries.

Directly simulated water age can be compared to the concentration of a conservative tracer that is not affected by chemical reactions and that accumulates in ground water due to in situ production as well as an external deeper source. Helium is probably the closest example of such a tracer (Castro and Goblet 2003a).

^{14}C Ages

For all ground water flow simulations presented, transport of ^{14}C was simulated in the entire system (cross section AA', Figure 1c) in steady state by taking into account advection, dispersion, diffusion, and radioactive decay following:

$$\mathrm{div}[(\omega d + \bar{\alpha}\,|U|)\mathrm{grad}\vec{\ } \ C - \vec{U}\ \ C] = \omega\lambda C \qquad (3)$$

where d is the diffusion coefficient for HCO_3^- multiplied by the tortuosity coefficient (Table 1), and λ (T^{-1}) is the radioactive decay constant for ^{14}C of 3.84×10^{-12}/s taking into account its half-life of 5730 years (Mann et al. 1961). In a similar approach to that of Sudicky and Frind (1981) and for the sake of simplicity, concentrations of the stable carbonate species are assumed to be uniform throughout the system, with variations of ^{14}C due only to radioactive decay and transport processes. In this situation, the ^{14}C concentration C is expressed as percent modern carbon (pmc). Boundary conditions include a prescribed pmc of 90 (C_0) in all outcrop areas, which corresponds to the measured percent modern ^{14}C value in the Carrizo recharge area (Castro et al. 2000). For all other external boundaries, in particular the top of the Queen City, an outlet condition was prescribed that allows ^{14}C to exit the system by advection. At the bottom of the Wilcox, however, water is devoid of ^{14}C content due to the very low hydraulic conductivities in place. Here, diffusion is the dominant transport mechanism and ^{14}C exits the Carrizo toward the Wilcox in an attempt to reach isotopic equilibrium. Migration of ^{14}C into the Wilcox is, however, very limited in distal extent due to its relatively short half-life. In all formations, waters are also devoid of ^{14}C at the southernmost limit of the system.

After simulation of ^{14}C transport in the system, ^{14}C ages were then calculated following the traditional approach in which ^{14}C is assumed to be transported only by advection, and where dispersion, diffusion, and ground water mixing (cross-formational and within each formation) is neglected. In this case, the water age A (T) that results from simulated ^{14}C concentrations is given by:

$$A = -\frac{1}{\lambda}\ln\frac{C}{C_0} \qquad (4)$$

If ^{14}C concentrations changed (were reduced) as a result of radioactive decay alone and ^{14}C transport was only by advection in total absence of ground water mixing, then the obtained ^{14}C ages should correspond to the calculated advective ages in the entire system. In the examples given and analysis that follows, we will see that this is not the case. More importantly, it will be shown that, for a diversity of natural settings, ^{14}C ages calculated following this approach do not respond to changes in the hydrogeological system in a similar manner to modeled advective ages, nor to ages obtained through direct simulation of ground water age, which portrays the behavior of the water molecule. The most important distinction between simulated water ages and a tracer such as ^{14}C lies in the conservative vs. nonconservative nature of these two tracers.

Although in our ^{14}C transport simulations all mixing processes due to advection, dispersion, and diffusion were accounted for, which is what happens in a real system, it is important to note that our calculated ^{14}C ages, following the most common approach taken for ^{14}C ground water dating, are unadjusted to account for both "losses" and/or "additions" of ^{14}C that have occurred in the system due to mixing processes (e.g., dispersion). As a result, ^{14}C ages determined using this procedure will yield, in certain cases, apparent older or younger ages than one would expect the real age of ground water to be, further reinforcing the argument that such modeled ^{14}C ages do not always accurately portray the dynamics of the ground water system itself.

Simulation Results and Discussion

We proceed to illustrate how the three different modeling approaches lead to differences in calculated ages under distinct hydrogeological conditions. We also illustrate how ground water mixing through advection and dispersion impacts differently the calculation of ages obtained through direct simulation of ground water age and those obtained through transport of ^{14}C. Results of simulations presented here are meant to compare how each modeling approach behaves under different scenarios in one complex aquifer system that represents the Carrizo Aquifer and surrounding formations. When employing these modeling approaches in other complex systems where fluvial, deltaic, and marine depositional environments are present, relative behavior similar to the results presented here is expected. However, these results and, in particular, the observed differences in absolute modeled age values should not be generalized and directly applied to other systems.

Impact of Horizontal Dispersion

Although our goal is not to discuss results in terms of absolute modeled ages, we start by showing the horizontal distribution of these ages in the Carrizo Aquifer (Figure 2a) as calculated from Equations 1 and 2 and by combining Equations 3 and 4 for our original ground water flow model calibrated with ^4He concentrations (Castro and Goblet 2003a). All calculated ages are shown down to 60 km from the recharge area where ^{14}C content reaches ~1 pmc. Further away, the ^{14}C content becomes negligible.

It is clear that these ages differ in absolute values and evolve differently with respect to each other along the ground water flowpath. ^{14}C ages are the youngest along the entire flowpath, while ages obtained through direct simulation of ground water age are younger than advective ages down to 20 km, to become progressively older than

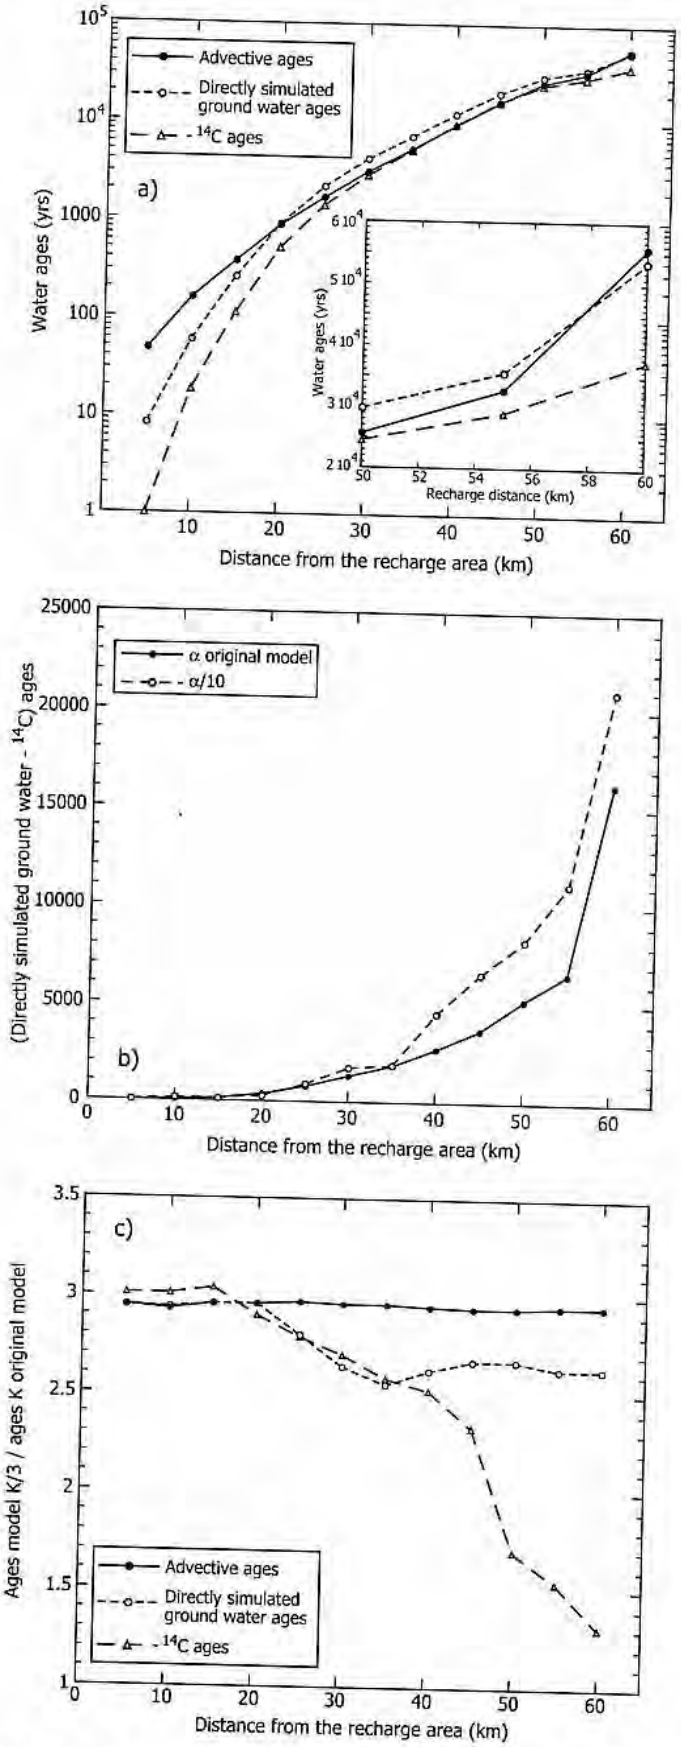

Figure 2. (a) Calculated advective, ^{14}C, and directly simulated ground water ages in the Carrizo Aquifer for a regional 2D ground water flow model calibrated with ^{4}He (Castro and Goblet 2003a) as a function of distance from the recharge area; detail between 50 and 60 km from the recharge area is also shown in a linear scale. (b) Absolute age difference between ^{14}C and directly simulated ground water ages as a function of recharge distance corresponding to the original model for both the original dispersivity tensor value and one which is 1 order of magnitude smaller. (c) Calculated advective, ^{14}C, and directly simulated ground water ages ratios in the Carrizo Aquifer between the original ground water flow model for which hydraulic conductivities in the Carrizo and Recklaw outcrop were reduced threefold ($K/3$), while maintaining all other parameters unchanged, and that one of the original model (K), as a function of distance from the recharge area.

the latter up to 50 km from the recharge area. This trend is then reversed, with directly simulated ages becoming progressively younger than advective ages at ~60 km from the recharge area (Figure 2a). Although not shown, it should be noted that as distance from the recharge area increases, this trend is accentuated, with directly simulated ages becoming younger than advective ages up to tens of thousand years. For example, ~80 km from the recharge area, directly simulated ages are about 22,000 years younger than the latter. Similarly, with increased recharge distance, ^{14}C ages become progressively younger than both advective and directly simulated ages (~18.5 and ~16.2 kyr younger at 60 km, respectively). This increasing age gap with increased recharge distance among all ages is the major feature observed.

The major hydrogeological change taking place along the ground water flowpath in this system is a strong and progressive reduction of the horizontal velocity component, and therefore of the horizontal dispersive flux, up to 2 orders of magnitude 60 km from the recharge area (from 8.5×10^{-7} to 1.7×10^{-9} m/s). Tests carried out in total absence of diffusion show that, with the exception of the Wilcox, diffusion plays a negligible role in this portion of the system, due to the relatively high hydraulic conductivities in all formations. Diffusion impacts directly simulated ground water ages at farther distances, where ^{14}C is no longer detected and where hydraulic conductivities in the Recklaw are $\leq 10^{-10}$ m/s. Thus, diffusion will not be part of our discussion.

To assess the impact of horizontal dispersion on calculated ^{14}C and directly simulated ages, a number of tests were carried out. For example, by reducing the dispersivity tensor 1 order of magnitude while maintaining all other parameters unchanged, the gap between ages increased (Figure 2b), with ^{14}C ages ~22 kyr younger than directly simulated ages, as opposed to ~16 kyr in the original ground water flow system, at 60 km from the recharge area.

On a separate set of simulations, hydraulic conductivities in the Carrizo and Recklaw outcrop areas were reduced threefold as compared to our original ground water flow model. All other parameters remained unchanged. By creating the same decrease of hydraulic conductivities in these two formations, we have roughly maintained the original hydraulic head gradient in the system (see discussion by Patriarche et al. 2004), and the observed increase in advective ages should be proportional to this reduction in hydraulic conductivity and, therefore, velocity. This is what is observed when looking at the ratios between ages obtained in this particular ground water flow system and those in the original one (Figure 2c). The observed increase in advective ages is roughly constant and threefold along the entire domain. The same, however, is not true with respect to ^{14}C and directly simulated ages. Specifically, all three modeling approaches display a similar behavior in areas where the water velocity is greater than $\sim 3 \times 10^{-8}$ m/s, i.e., up to ~20 km from the recharge area (Figure 2c), where advection is dominant. For larger distances from the recharge area (~20 to 35 km) and lower velocity values ($\sim 3 \times 10^{-8}$ to 7×10^{-9} m/s), the observed increase in ^{14}C and directly simulated ages is similar and smaller than the one observed on advective ages. The most remarkable effect, however, is observed on ^{14}C ages. Although in the first portion of the flowpath ^{14}C ages, like advective and directly simulated ages, display a threefold increase, as distance from the recharge area increases and velocities decrease, ^{14}C ages display a smaller and smaller age increase compared to the original flow system, to almost entirely "recover" and display ages that are very close to the original ones (~1.3 times higher) 60 km from the recharge area. Furthermore, the gap that was initially almost nonexistent between ^{14}C and directly simulated ages up to 35 km from the recharge area became far more pronounced with increased recharge distance and decreasing velocities (less than $\sim 7 \times 10^{-9}$ m/s).

From this set of simulations, a few important observations can be made: (1) kinematic dispersion impacts both ^{14}C and directly simulated ground water ages for velocities less than $\sim 3 \times 10^{-8}$ m/s; (2) the influence of dispersion on both ages increases with decreasing velocities; and (3) the influence of longitudinal dispersion is far greater on ^{14}C ages as compared to directly simulated ages for velocities less than $\sim 7 \times 10^{-9}$ m/s. Observations 1 and 2 are in agreement with conclusions reached by Goode (1996) based on a set of simulations carried out in a hypothetical and simpler system. Dispersive and diffusive mixing of water (as verified here on directly simulated ages farther from the recharge area) tends to limit the maximum water ages. With respect to directly simulated ground water ages, this is because, by analogy to Fick's law applied to solutes, dispersive flux of age-mass occurs in the direction of decreasing ages, thus inducing a reduction in the water ages. As pointed out in Observation 3, however, this effect is more visible on ^{14}C ages due to the presence of significant concentration gradients along the flowpath. Such gradients induce more ^{14}C to move from higher to lower concentration areas, resulting in ^{14}C ages that are much younger than the real water age. In this situation, where there is a very strong reduction of the horizontal velocity field, horizontal dispersion acts as a "source" of ^{14}C. This "source effect" is particularly important in low–water velocity areas where the role of dispersion becomes more prominent. Figure 2c shows that in this particular case, horizontal dispersion becomes an important source of ^{14}C at distances $\geq$40 km where the horizontal velocity is less than or equal to $\sim 7 \times 10^{-9}$ m/s. For higher velocity values, i.e., areas closer to the recharge area, the use of our modeling approach to determine ground water ages based on ^{14}C could be, in this situation, reliable.

This example shows that care must be taken when using ^{14}C as a ground water age indicator while neglecting the impact of dispersion. It also shows evidence for the higher reliability of this particular ^{14}C ground water dating method in ground water systems where water velocities are relatively high, thus diminishing the role horizontal dispersion plays, in this particular case, as a source of ^{14}C. Results presented here also seem to indicate that the modeling approach followed to determine ^{14}C ages is likely to be less reliable in highly heterogeneous ground water systems where hydraulic conductivities and

thus water velocities vary over several orders of magnitude, and reach low values, compared to more homogenous ones where velocities are high with only small variations (e.g., 1 order of magnitude or less). A similar conclusion concerning the use of chlorofluorocarbon-based ages for very young water (tens of years) was reached by Weissmann et al. (2002).

This degree of reliability of ^{14}C ages in high— vs. low—water velocity areas due to the impact of horizontal dispersion can also be observed in 1D models as illustrated subsequently.

Impact of Horizontal Dispersion on ^{14}C Ages—High vs. Low Horizontal Velocities

The general steady-state, 1D differential equation incorporating advection, dispersion, and radioactive decay along the flowpath with boundary conditions $C(0) = C_0$ and $C(\infty) = 0$ is as follows:

$$U\frac{dC}{dx} - D^*\frac{d^2C}{dx^2} + \omega\lambda C = 0 \quad 0 \le x \le \infty \tag{5}$$

where D^* is the coefficient of hydrodynamic dispersion, which includes molecular diffusion.

The analytical solution to Equation 5 is given by:

$$C(x) = C_0 \exp\left(\frac{\left(U - \sqrt{U^2 + 4\omega\lambda D}\right)x}{2D}\right) \tag{6}$$

where

$$D = \alpha U \tag{7}$$

and, therefore, molecular diffusion is not taken into account.

Equation 6 can be rewritten as:

$$C(x) = C_0 \exp\left(\frac{x}{2\alpha}\left(1 - \sqrt{1 + \frac{4\omega\alpha\lambda}{U}}\right)\right) \tag{8}$$

Depending on the value of the dimensionless number

$$N = \frac{4\omega\alpha\lambda}{U} \tag{9}$$

which incorporates the combined effects of advection, dispersion, and radioactive decay, a different approximation to Equation 8 can be obtained, thus emphasizing the driving mechanism:

1. For $N << 1$, the approximate solution is:

$$C = C_0 \exp\left(-\frac{x\omega\lambda}{U}\right) \tag{10}$$

This solution is valid for high water velocity values and is not dependent on the dispersivity. Here, radioactive decay is not significant, which leads to a quasi-linear concentration profile and thus absence of dispersion.

2. For $N >> 1$, the approximate solution is:

$$C = C_0 \exp\left(-x\sqrt{\frac{\omega\lambda}{\alpha U}}\right) \tag{11}$$

This solution is valid for low water velocity values and depends directly on the dispersivity. Radioactive decay plays a dominant role here leading to an exponential concentration profile and hence the presence of a dispersive flux.

Using $\lambda = 3.84 \times 10^{-12}$/s and $\omega = 0.35$, ^{14}C concentrations were calculated through Equation 6 for high (8.5×10^{-7} m/s) and low (1×10^{-10} m/s) water Darcy velocities, respectively. For both cases, three different dispersivity values (12.5, 125, and 1250 m) were tested. ^{14}C ages were subsequently calculated using Equation 4.

1D simulation results clearly show (Figure 3a) that, for the high water velocity value, ^{14}C age profiles obtained using Equation 6 for the three different dispersivities are undistinguishable, and thus that dispersion does not impact ^{14}C concentrations and resulting ^{14}C ages as previously shown in the 2D simulations. In contrast, and as previously shown through the 2D model, 1D simulations conducted for lower velocity values clearly illustrate the impact of dispersion on ^{14}C concentrations and resulting ^{14}C ages (Figure 3b).

This 1D analysis further supports the idea that the modeling approach used here to determine ^{14}C ages yields more reliable results in high water velocity areas where ^{14}C ages are not affected by dispersion.

It can also be shown that impact of dispersion on ^{14}C concentration profiles and resulting ^{14}C ages is directly related to the ratio of advective to dispersive flux, not on the absolute dispersive flux value alone. Specifically, this impact is negligible for high values of this ratio. Impact of dispersion on ^{14}C ages increases progressively as the advective/dispersive flux ratio decreases and becomes significant for low values of the latter. This dependency can be directly illustrated in a 1D analysis by using our derived solutions for high (Equation 10) and low (Equation 11) water velocity values and the corresponding parameter values used in both examples. We illustrate this subsequently.

From Equation 10, the advective and dispersive fluxes are given by

$$UC = UC_0 \exp\left(-\frac{x\omega\lambda}{U}\right) \tag{12}$$

and

$$\alpha U\frac{\partial C}{\partial x} = \alpha C_0\omega\lambda\exp\left(-\frac{x\omega\lambda}{U}\right) \tag{13}$$

respectively. Thus, for high water velocities the advective/dispersive flux ratio is:

$$\frac{U}{\alpha\omega\lambda} \tag{14}$$

Similarly, from Equation 11, advective and dispersive fluxes are given by:

$$UC = UC_0 \exp\left(-x\sqrt{\frac{\omega\lambda}{\alpha U}}\right) \tag{15}$$

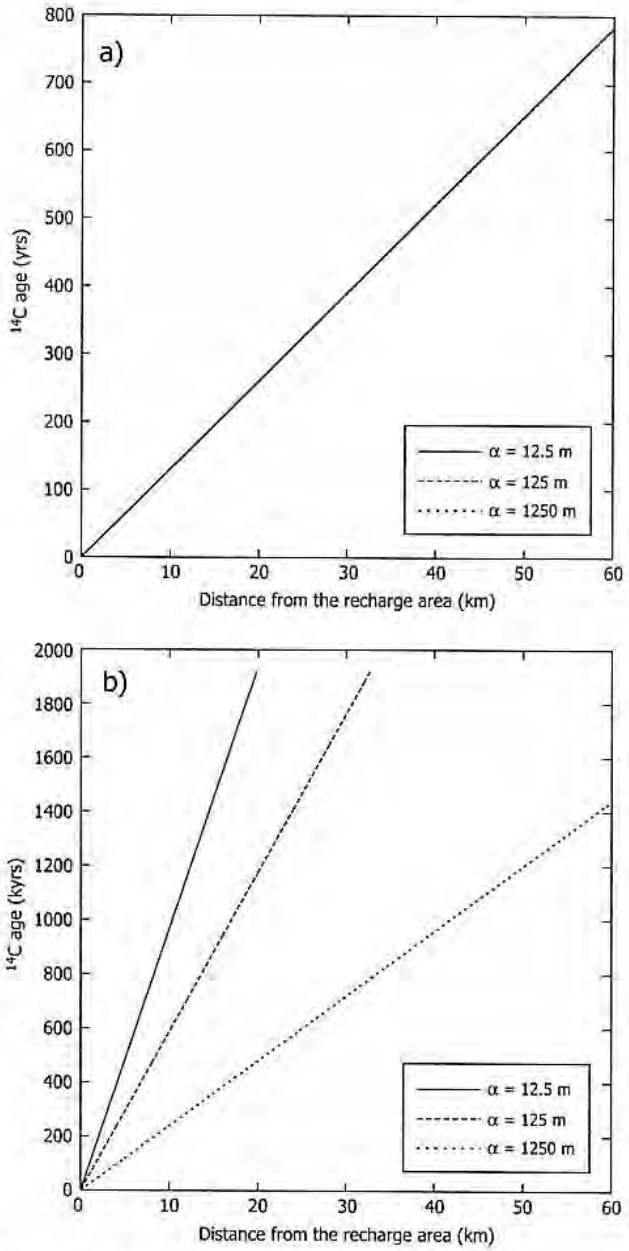

Figure 3. ^{14}C ages calculated using 1D simulations for three different dispersivity values (12.5, 125, and 1250 m): (a) for a high water velocity value ($U = 8.5 \times 10^{-7}$ m/s); (b) for a low water velocity value ($U = 1 \times 10^{-10}$ m/s).

and

$$\alpha U \frac{\partial C}{\partial x} = C_0 \sqrt{\alpha U \omega \lambda} \exp\left(-x\sqrt{\frac{\omega\lambda}{\alpha U}}\right) \qquad (16)$$

respectively. Thus, for low water velocities the advective/dispersive flux ratio is:

$$\sqrt{\frac{U}{\alpha\omega\lambda}} \qquad (17)$$

For α = 125 m, the advective/dispersive flux ratios calculated using Equations 14 ($U = 8.5 \times 10^{-7}$ m/s) and 17 ($U = 1 \times 10^{-10}$ m/s) yield 5000 and 0.8, respectively. This shows that impact of dispersion on ^{14}C ages is indeed dependent on the advective/dispersive flux ratio and is only significant when this ratio is small.

The 1D analysis presented here is simply meant to illustrate theoretically how the impact of horizontal dispersion on ^{14}C ages is dependent on the horizontal velocity value. It is also meant to illustrate how this impact, through its dependency on the coupled advective-dispersive fluxes, becomes more prominent with decreasing velocities and thus with decreasing dispersive fluxes. However, through a 1D analysis it is not possible to evaluate simultaneously the role of horizontal and transverse dispersion as well as the impact of mixing due to cross-formational flow, mixing mechanisms that impact concentration profiles and ground water ages. We thus proceed to analyze the impact of all mixing processes on our three modeling approaches through a 2D analysis.

Vertical Age Structure

A detailed analysis of the age structure along a vertical plane of all calculated ages in our original ground water flow system (Figure 2a) 50 km from the recharge area reveals some interesting results (Figure 4). This includes the Carrizo Aquifer, the overlying confining layer (Recklaw), and the Queen City Aquifer. This complex vertical age structure is essentially the result of the combined effects of mixing due to advection and horizontal and vertical dispersion.

As expected, vertical advective ages in the Carrizo Aquifer display an almost total absence of age gradient. This is because horizontal velocities are similar throughout the entire thickness of the aquifer along a same vertical, with water moving as "packets" along streamlines downgradient (see discussion by Bethke and Johnson 2002b) without exchanging water with neighboring formations (closed system). By contrast, ^{14}C and directly simulated ground water ages show a strong vertical age gradient. Ground water becomes progressively younger from bottom to top (Figure 4). At the bottom of the Carrizo, mixing with older water from the neighboring confining layer is occurring through vertical dispersion, in addition to some ^{14}C exiting the system toward the Wilcox through diffusion. Toward the top of the Carrizo, the vertical dispersion component carrying older water from the bottom becomes smaller, allowing horizontal dispersion to dominate over the vertical component rendering younger ^{14}C and directly simulated ground water ages. Comparison between ages shows once again the influence of horizontal dispersion on ^{14}C ages, the latter being younger than directly simulated ages throughout the entire thickness of the Carrizo due to this artificial source of ^{14}C.

At the interface of the confining layer, cross-formational flow is greatly facilitated through vertical dispersion as opposed to advection (Figure 4). Advective ages in the Recklaw Formation are higher than those in the Carrizo, which is opposite to ^{14}C and directly simulated ground water ages. At the interface with the Queen City, however, the situation is reversed compared to that observed in the Carrizo. In the Queen City, ^{14}C ages are now the oldest throughout most of the thickness and a vertical age gradient is absent (Figure 4). The dominant age

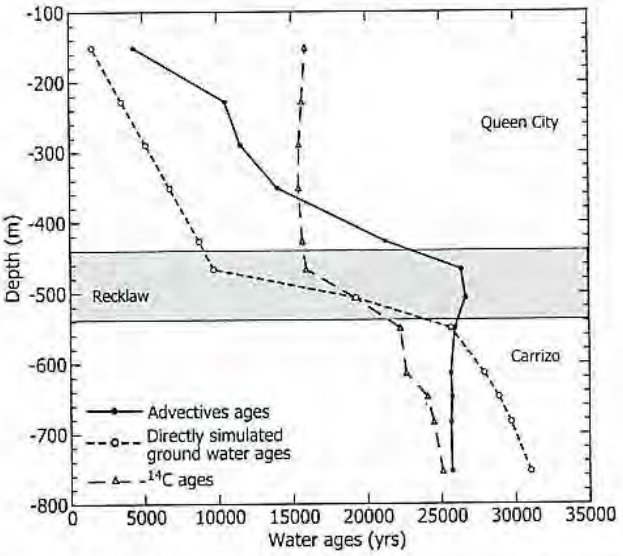

Figure 4. Vertical age structure of calculated advective, ^{14}C, and directly simulated ground water ages corresponding to the original ground water flow model calibrated with ^{4}He concentrations (Castro et al. 2003a) within the Carrizo, Recklaw, and Queen City, 50 km away from the Carrizo recharge area.

factor on ^{14}C ages in the Queen City is now the combined effect of vertical dispersion and advection through vertical upward leakage in the Recklaw, which brings a constant flux of older water with lower ^{14}C content originating in the Carrizo. Here, vertical dispersion acts as a "sink" of ^{14}C. By contrast, and as streamlines in the Queen City (which originate in the Carrizo recharge area) become shorter and shorter toward the top of the aquifer, advective ages display a vertical age gradient here, becoming progressively younger toward the surface. In addition to younger advective water arriving into the Queen City, horizontal dispersion also renders directly simulated ground water ages younger upward. This results in directly simulated ages younger than advective ages, which is the reverse of what is observed in the Carrizo.

Analysis of the vertical age structure in this complex system is important as it illustrates how the combined effect of mixing processes (e.g., advection, horizontal and vertical dispersion, as well as cross-formational flow) might cause very different vertical age structures in different areas/formations of one particular system while using the same dating method. It also illustrates, depending on the formation of interest, how these ages might evolve with respect to each other in unexpected ways.

One last important observation to note is that unlike modeled advective and ^{14}C ages, directly simulated ground water ages display a consistent behavior in the Carrizo and Queen City aquifers, with older ages at the bottom, younger toward the top. Such consistency likely indicates that, when mixing processes are relevant in a particular ground water flow system, direct simulation of ground water age will yield more realistic results than the advective and ^{14}C modeling approaches as described here.

Impact of Faults on Calculated Ages

We also investigated the potential impact of both high- and low-permeability faults that might be present not only within one particular aquifer but also in surrounding confining layers. The presence of faults in sedimentary systems is not uncommon, and a number of local faults are well documented in the Carrizo Aquifer and surrounding formations in our study area (Figure 1b). We carried out a series of simulations in which a fault with a length of ~12.5 m (the smallest element length in our original mesh) was placed ~27 km from the Carrizo recharge area in different formations. Through this set of simulations, variable hydraulic conductivity values were attributed to this fault. With the exception of this newly introduced fault, all other parameters and boundary conditions remained unchanged (Figure 1c; Castro and Goblet 2003a). Here, we present results of two different sets of simulations, the first representing a low-permeability fault placed in the Carrizo, and the second representing a high-permeability fault located in the overlying confining layer, the Recklaw Formation. Low- and high-permeability faults with hydraulic conductivities several orders of magnitude different from the values used in the simulations presented here all reveal similar trends.

Low-Permeability Fault in the Carrizo Aquifer

A hydraulic conductivity of 5×10^{-9} m/s was assigned to a fault introduced in the Carrizo Aquifer. The presence of this low-permeability fault gave origin to a ground water flow system far more complex than the original one (Figure 1c), complexity that is directly translated to calculated ground water ages (Figure 5a). Changes in the ground water flow system induced by the presence of this fault, from the recharge area down to its location, include a relatively small reduction of the horizontal velocity component simultaneously with an increase of the vertical velocity. The most remarkable changes, however, are observed on the opposite side of the fault. Here, a strong reduction of the hydraulic gradient, and therefore of the velocity field, is observed. In addition, in the vicinity of the fault, the direction of vertical leakage in the Recklaw Formation was reversed and is now downward and much smaller (~2 orders of magnitude) than that of the original ground water flow system. The new modeled water ages show these changes in a clear fashion. Between the recharge area and up to the fault location, all ages follow a similar aging trend, and no important differences between advective, ^{14}C, and directly simulated ground water ages behavior can be observed. This is because between the recharge area and the fault location, horizontal advection is by far the dominant transport process affecting all calculated ages. This behavior is consistent with previous results (e.g., Figure 2c). On the opposite side of the fault, however, and due to the strong reduction of the velocity field, all ages are now much older than the original ones, and important discrepancies between their aging behavior are observed (Figure 5a): (1) advective ages display the highest aging rate along the entire trajectory, down to 60 km from the recharge area and (2) near the fault, between ~27 and 35 km, aging of ^{14}C ages is more pronounced than that of directly simulated ground water ages. Simulated ^{14}C concentration distribution shows that a local concentric area with unusually low ^{14}C concentrations has now

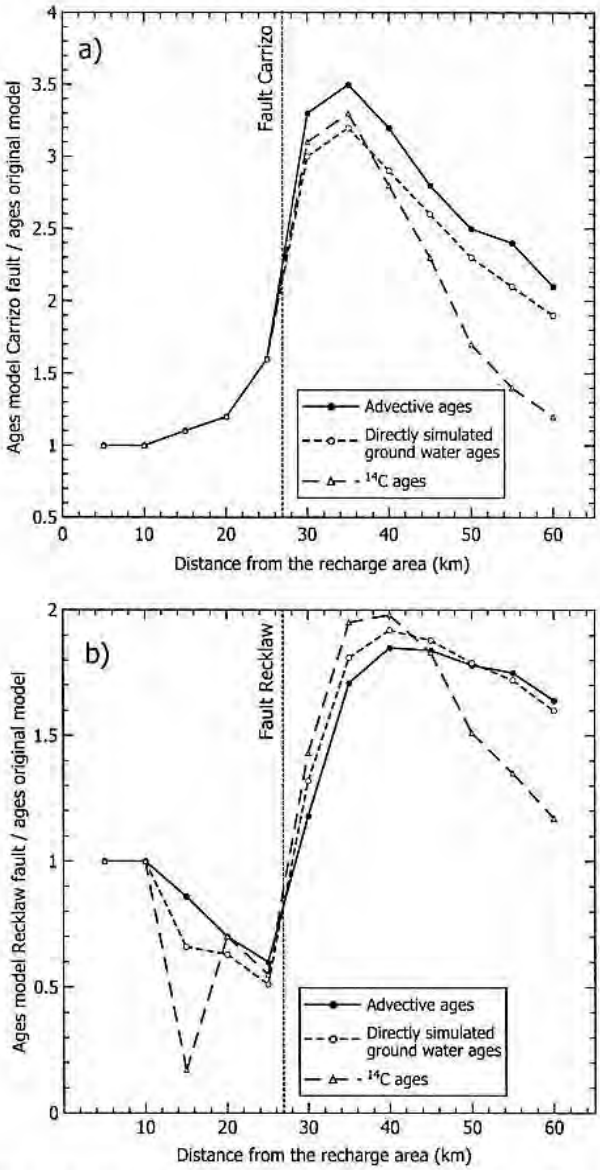

Figure 5. Calculated advective, ^{14}C, and directly simulated ground water age ratios in the Carrizo Aquifer: (a) between the original ground water flow model in which a low-permeability fault was placed in the Carrizo Aquifer (K_{fault} = 5×10^{-9} m/s) and that one of the original model (Figure 2a), as a function of distance from the recharge area. The location of the fault is indicated; (b) between the original ground water flow model in which a high-permeability fault was placed in the Recklaw Formation ($K_{fault} = 1 \times 10^{-2}$ m/s) and that one of the original model (Figure 2a), as a function of distance from the recharge area.

developed in the Recklaw Formation, near the fault. These unusually low ^{14}C concentrations are due to the very slow water movement in this confining layer. As leakage is now downward, almost stagnant water with very low ^{14}C content mix with Carrizo water, resulting in a higher aging rate than directly simulated ground water ages. Further away, at ~40 km and as previously verified, horizontal dispersion plays once again an important role on ^{14}C and directly simulated ground water ages, and the expected behavior is observed, with ^{14}C ages becoming progressively younger than directly simulated ages with increased distance from the recharge area and decreasing velocities.

High-Permeability Fault in the Recklaw Formation

To assess the potential impact on calculated water ages of a permeable fault located in a neighboring confining layer, a hydraulic conductivity value of 10^{-2} m/s was assigned to a fault placed in the Recklaw Formation. Once again, the presence of such a fault gave rise to major changes in the ground water flow system, which, in turn, resulted in important changes and distinct behavior on calculated water ages (Figure 5b). Here, horizontal flow between the recharge area and the fault is greatly enhanced, resulting in advective, ^{14}C, and directly simulated ground water ages that are now younger compared to those of the original ground water flow system. As upward leakage flux in the Recklaw Formation is smaller, less water exits the Carrizo vertically, rendering directly simulated ages and, particularly, ^{14}C ages younger compared to advective ones. On the opposite side of the fault, at ~30 km, the situation is reversed. The presence of the fault has now induced a very strong upward water movement through the Recklaw, in addition to an important reduction of water velocities in the Carrizo. As a result, ^{14}C now exits the Carrizo Aquifer upwards at a much higher rate in the fault area, leading to a much lower ^{14}C content in this aquifer on the opposite side of the fault as compared to the original ground water flow system. Consequently, between the fault location and ~40 km from the recharge area, ^{14}C ages now at a higher rate than advective and directly simulated ground water ages (Figure 5b). This upward water movement affects also the directly simulated ground water ages, although not to the same extent, as previously discussed. In this particular case, and for a relatively short distance, between ~27 and 40 km from the recharge area, advective ages are less affected by aging, while directly simulated ground water ages occupy an intermediate position. Note that despite the fact that advective ages are considerably older here compared to the original ground water flow system due to a reduction of the velocity field, the observed increase of ^{14}C and directly simulated ages is well in excess relative to advective ages due simply to mixing processes. As observed in previous situations, at further distances from the recharge area and with decreasing velocities, ^{14}C ages become younger than directly simulated ground water ages.

Calculated ^{14}C Ages Based on C Isotope Measurements

Simulations presented here were carried out in a complex ground water flow system, the Carrizo Aquifer and surrounding formations, in which the presence of local faults is well known. As pointed out earlier, in this system, based on C isotope measurements available in a number of water samples (Figure 1b; Castro et al. 2000), ^{14}C ages were previously estimated following the traditional approach in which mixing processes are not considered (Castro et al. 2000). Only radioactive decay and chemical interactions were taken into account, and no attempt was made to simulate ^{14}C transport in the system with incorporation of mixing processes (Castro et al.

2000). Subsequent comparison of these calculated ^{14}C ages with modeled advective ages (Castro and Goblet 2003a), and those obtained through direct simulation of ground water age (Castro and Goblet 2003b), shows strong discrepancies at several locations (Figure 6). Such discrepancies are particularly strong between calculated ^{14}C ages based on C isotope measurements (Castro et al. 2000) and modeled advective and directly simulated ground water ages. It is clear that at certain locations (samples TX01, TX24, and TX08, Figure 6), ^{14}C yields apparent ages that are far older than advective and directly simulated ages. In addition, at two locations (TX28 and TX03) where the presence of ^{14}C was expected based on modeling results, ^{14}C was below detection limit (Figure 6). Importantly, farther from the recharge area (samples TX04 and TX14; Figure 1b), where velocities are smaller and the impact of dispersion is more prominent, ^{14}C ages are younger than modeled advective and directly simulated ground water ages (Figure 6). Here, our simulations suggest that mixing with younger water takes place as directly simulated ground water ages become younger than advective ages (sample TX14; Figure 6). Although we cannot be fully confident that these observed discrepancies in the Carrizo Aquifer are the combined result of ground water mixing due to the presence of faults, cross-formational flow through advection, and the impact of both longitudinal and transverse dispersion, the situation observed in the field appears to be consistent with some of the simulation results presented here.

Concluding Remarks

With the set of 2D simulations presented here, we have shown how, due to mixing processes and particularly due to advection and dispersion, modeled advective, ^{14}C, and directly simulated ground water ages evolve differently with respect to each other. The impact of dispersion is particularly strong on ages obtained through simulation of ^{14}C as this mixing process may act as an important source or sink for ^{14}C in the presence of significant concentration gradients. Mixing processes due to advection and dispersion may also give rise to unexpected modeled vertical age profiles. Impact of dispersion on modeled ^{14}C and directly simulated ground water ages is systematically stronger in areas where velocities are smaller, as dispersive flux will occur in the direction of either decreasing ages (direct simulation of ground water age) or decreasing concentrations (modeled ^{14}C ages). Specifically, in the system considered here, impact of dispersion on these calculated ages becomes nonnegligible for water velocities less than $\sim 3 \times 10^{-8}$ m/s, and is particularly pronounced on modeled ^{14}C ages for velocities less than $\sim 7 \times 10^{-9}$ m/s. We also illustrate through a 1D analysis the effect of horizontal dispersion on ^{14}C ages, which depends directly on the ratio of advective to dispersive flux, not on the dispersive flux value alone. Impact of dispersion becomes more prominent with decreasing velocities and thus with decreasing dispersive fluxes. Specifically, this impact is significant for low ratios of advective to dispersive flux and decreases as the ratio increases. Longitudinal dispersion acts generally as a source of ^{14}C within a particular aquifer, while vertical dispersion acts as a sink for ^{14}C both within a single aquifer by enhancing mixing with older water located at greater depths or when crossing confining layers. Thus, depending on how dispersion contributes to additions or losses of ^{14}C, older or younger apparent modeled ^{14}C ages relative to the actual age of ground water might be observed.

The impact of faults on modeled water ages was also assessed. Depending on fault locations (aquifers vs. aquitards) and on its degree of permeability, advective, ^{14}C, and directly simulated ground water ages will evolve in very different ways, leading potentially to local differences in modeled ages up to many thousands of years. Our modeling approach for ^{14}C dating (i.e., ^{14}C ages) has a particularly distinct behavior in complex ground water flow systems where extremely strong variations of the velocity field are present, in addition to the presence of local faults. Here, mixing due to cross-formational flow as well as dispersion may impact significantly the modeled ^{14}C concentrations.

Simulations presented here were carried out in a complex ground water flow system, the Carrizo Aquifer and surrounding formations, in which the presence of local faults is well known. Here, previous calculations of advective (Castro and Goblet 2003a), ^{14}C (Castro et al. 2000), and directly simulated ground water ages (Castro and Goblet 2003b) show the presence of strong discrepancies at several locations. Specifically, discrepancies are particularly strong between ^{14}C calculated based on C isotope measurements neglecting mixing processes (Castro et al. 2000) and modeled advective and directly simulated ground water ages. Although we cannot be fully confident that these observed discrepancies in the Carrizo Aquifer are the combined result of mixing processes due to advection and dispersion enhanced locally by the

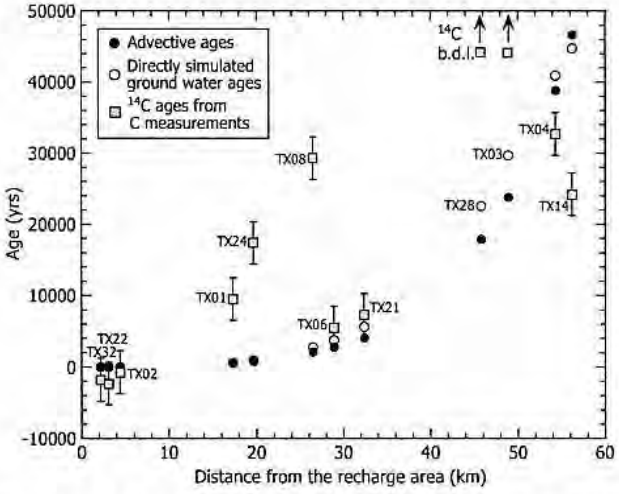

Figure 6. Calculated advective and directly simulated ground water ages (Castro and Goblet 2003a, 2003b, respectively), as well as geochemically corrected ^{14}C ages determined directly from measured ^{14}C concentrations (closed squares) (Castro et al. 2000) in the Carrizo Aquifer at sampling locations in the study area (Figure 1b), as a function of distance from the recharge area. ^{14}C is below detection limit (b.d.l.) at samples TX28 and TX03.

presence of faults, the situation observed in the field is certainly consistent with some of the simulation results presented here. Ideally, ^{14}C ages should be estimated by taking into account all physical and chemical processes affecting its concentration in order to systematically obtain ^{14}C ages that are close to the real age of ground water.

Overall, direct simulation of ground water ages seems to yield more consistent results than the modeling approaches employed here for calculation of advective and ^{14}C ages when mixing processes in a particular ground water flow system are nonnegligible and water velocities vary over several orders of magnitude within one single aquifer. Specifically, and unlike the two other modeling approaches, directly simulated ages display a consistent (or expected) vertical age structure in all formations, with older ages at the bottom, younger toward the top. The modeling approach employed here for calculation of ^{14}C ages will yield more consistent results in systems where ground water velocities are high and exhibit small variation, in addition to systems where faults are absent. Modeled advective ages will yield water ages that are representative of the real system only when mixing processes can be neglected. The latter are thus the most restrictive.

Calculation of Low-Range Flow Velocities in Fractured Carbonate Media from Borehole Hydrochemical Logging Data Comparison with Thermometric Results

by Pascal Bidaux and Claude Drogue[a]

Abstract

Flow rates and concentrations from fractures intersected by a borehole can be estimated by matching simulated concentration profiles to the observed variations in water chemistry along the borehole. Experiments in karstic rocks prove that hydraulic short circuits between fractures yield a very complex flow pattern, and that flow velocities in the borehole may be higher than the velocity at which the piezometric level varies. Combined temperature and concentration studies characterize flow in both high permeability channels and slightly fissured blocks, as chemical profiles detect low velocity flows that cannot be identified on temperature profiles. Such studies are therefore advisable to characterize natural flow in fractured carbonate rocks, but also in other fractured media.

Introduction

As the "equivalent porous medium" concept (Bear, 1972) is generally not applicable at the local scale in fractured media (Long, 1983; Long and Witherspoon, 1985), large scale hydraulic measurements (Witherspoon et al., 1980) only provide a basis for more detailed flow analysis. Specific borehole techniques have been developed to characterize, localize, and quantify ground-water flow precisely. For example, hydrothermal properties of fractures in granite have been determined by injecting water between packers (Hosanski and Ledoux, 1982), but no information on natural flow is obtained because the high pressure modifies the system. Radioisotope methods provide information on natural flow (Moser and Drost, 1986), but these methods are expensive and highly regulated to avoid any negative impact on the environment. Fracture inflow parameters into a borehole produced at a low flow rate also have been characterized by fluid conductivity logging (Tsang, 1987; Tsang and Hale, 1989).

Hydrochemical logging, introduced by Bidaux et al. (1986) to identify microcirculations in granites, consists of determining the variations in water chemistry along an open borehole. It is somewhat similar to fluid conductivity logging, but provides more precise information, as conductivity only gives an indication on the overall mineralization of water. For example, hydrochemical logs along boreholes in a karstic aquifer in Southern China (Yuan et al., 1990), unveiled a simultaneous increase in magnesium concentration and decrease in calcium concentration with no significant conductivity change.

The present paper analyzes hydrochemical logs under their transient aspect. Successive logs are used to estimate fracture inflow parameters (flow rates and concentrations into and out of a borehole). The transient behavior of a concentration profile, resulting from hydraulic short circuits between fractures and from differences in the chemical composition of water inflows, is simulated for a given set of fracture inflow parameters. A field application is given for a 51 m deep borehole at an experimental site in a karstic aquifer in Southern France. Field data processing involves an inverse problem, as the inputs of the model (fracture inflow parameters) are unknown and the outputs (simulated logs) must be adjusted to experimental data. Successive bicarbonate concentration logs are obtained by analyzing water samples taken along the borehole at various depths; then simulations are performed to find the set of fracture inflow parameters which gives the best fit. Finally, the obtained values of fracture inflow parameters are discussed along with the structural context, other hydraulic observations, and thermometric data.

Formulation

A succession of hydrochemical logs is described by a function C(z,t) (concentration in a given element at depth z and time t). Prior to solving the inverse problem (determining fracture inflow parameters from experimental data which are discrete values of C), let us consider the direct problem (generating logs for a given set of fracture inflow parameters). Concentration (in the borehole profile) is

Discussion open until July 1, 1993.

assumed to obey the following equation:

$$D \frac{\partial^2 z}{\partial z^2} - \frac{\partial}{\partial z}(VC) + \phi_f = \frac{\partial C}{\partial t} \quad (1)$$

where D is the apparent longitudinal dispersion coefficient, V is the "through flow" velocity as defined by Moser and Drost (1986), and ϕ_f is the source term related to fracture inflow or outflow. Dissolution/precipitation, adsorption/desorption at the well walls, and chemical reactions within the aqueous phase, depend on the considered element. In the present work, they are neglected as justified previously (Bidaux et al., 1986).

V and ϕ_f directly derive from fracture inflow parameters. Inflows and outflows are assumed to occur only at discrete locations z_{fj} (fractures), and the "through flow" velocity is given by the continuity equation:

$$V(z,t) = \frac{1}{S} \sum_{j,\, z_{fj} < z} Q_{fj}(t) \quad (2)$$

in which $Q_{fj}(t)$ represents the algebraic value of the flow into the borehole at fracture j (positive for an inflow). The horizontal cross section S of the borehole is assumed to be constant. Hence, at each time t, $V_t(z) = V(z,t)$ is a step function of z with a discontinuity $\Delta V = Q_{fj}/S$ at each fracture j. Positive values of V correspond to flow toward the top of the borehole. The source term ϕ_f has a distinct formulation whether it concerns an inflow or an outflow, as concentration in water flowing out from the borehole into a fracture is given by its value in the borehole in front of the fracture, while inflow concentration is set by conditions inside the fracture and not in the borehole. For an inflow, we have:

$$\phi_f(t) = \frac{Q_{fj}(t)}{S} C_{fj}(t)\, \delta(z_{fj}) \quad (3a)$$

in which $C_{fj}(t)$ represents the inflow concentration, and δ is the Dirac function. The expression for an outflow does not involve C_{fj}:

$$\phi_f(t) = \frac{Q_{fj}(t)}{S} C(z_{fj}, t)\, \delta(z_{fj}) \quad (3b)$$

In order to avoid numerical dispersion and oscillations, advection and dispersion are solved separately at each time step. Karasaki (1988) used a similar technique to simulate transport in fracture networks. Instead of calculating the profile $C_t(z)$ at time t from $C_{t-\Delta t}(z)$ directly, using (1), an intermediate fictive profile $C^{(a)}{}_t(z)$ is first calculated, that is obtained from $C_{t-\Delta t}(z)$ by pure advection. Then $C_t(z)$ is obtained from $C^{(a)}{}_t(z)$ by pure dispersion during the time interval Δt. Using a Lagrangian description, advection can be solved exactly for any depth z and within any time interval Δt, by backtracking the fluid particle located at depth z without time or space discretization. The advected concentration $C^{(a)}{}_t(z)$ can be simply calculated from the initial profile and fracture inflow parameters by distinguishing four cases, whether water comes from the borehole, from a fracture, or is a mixture of both borehole and fracture water (Figure 1). Using an Eulerian description,

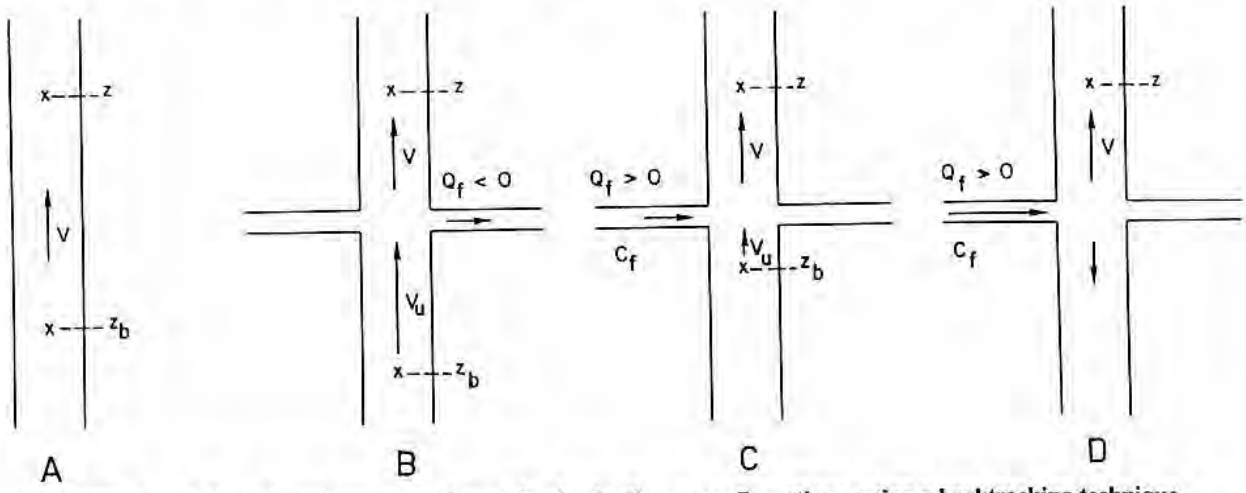

Fig. 1. Determination of the advected concentration at depth z in diverse configurations, using a backtracking technique.

A. No fracture exists between z and z-VΔt. Water at z is unmixed borehole water:

$$C^{(a)}{}_t(z) = C_{t-\Delta t}(z_b), \text{ with } z_b = z - V\Delta t$$

B. An outflow exists at z_f between z and $z - V\Delta t$, and the throughflow velocity upstream is V_u ($|Vu| > |V|$). Water at z is still unmixed borehole water, but the expression of z_b has changed:

$$C^{(a)}{}_t(z) = C_{t-\Delta t}(z_b), \text{ with } z_b = z_f - V_u(\Delta t - (z - z_f)/V)$$

C. An inflow exists at z_f between z and $z - V\Delta t$, and the throughflow velocity has the same direction on both sides of z_f. Water at z is a mixture of fracture water and borehole water from upstream:

$$C^{(a)}{}_t(z) = [Q_f C_f + V_u S C_{t-\Delta t}(z_b)]/VS, \text{ with } z_b = z_f - V_u(\Delta t - (z - z_f)/V)$$

D. An inflow exists at z_f between z and $z - V\Delta t$, and the flow diverges from the fracture. Water at z is unmixed fracture water:

$$C^{(A)}{}_t(z) = C_f$$

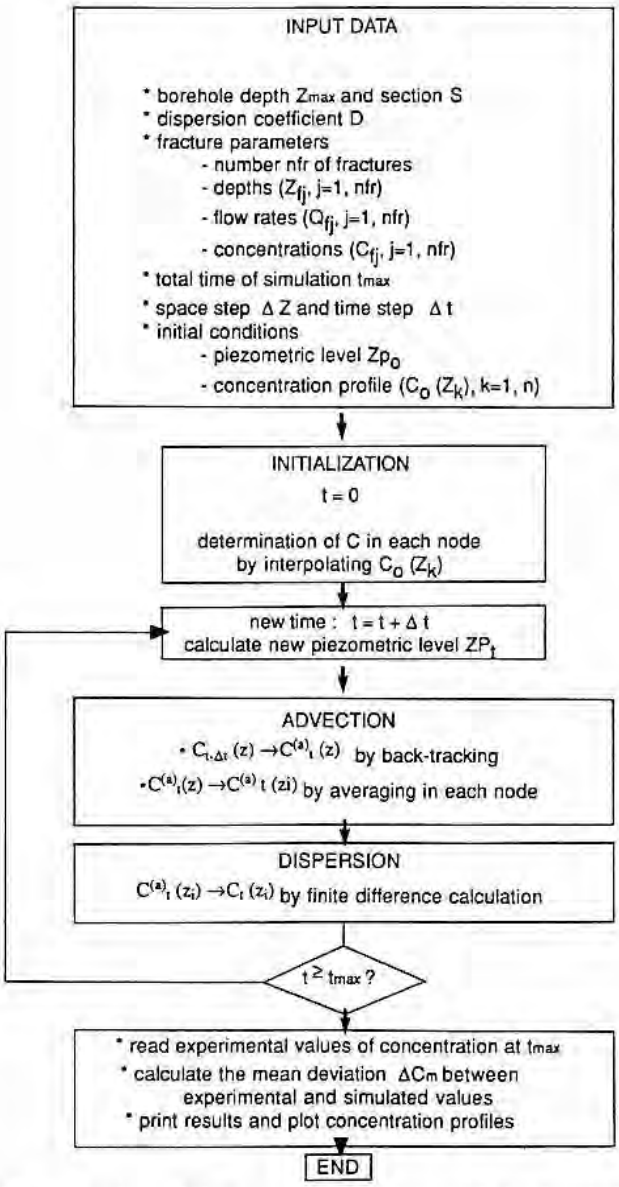

Fig. 2. Structure of the computer code for simulating borehole hydrochemical logging. At each time step, the advective and dispersive problem are solved separately.

dispersion is solved by an implicit finite-difference technique. Because of the discretization, the advected concentration profile is averaged in each node before the calculation of dispersion (Figure 2).

Procedure and Field Results

The Experimental Site

The field measurements concern an experimental site located in the lower Cretaceous limestones and marly limestones at Terrieu, Southern France. The site has been developed since 1975 to study the saturated zone of a karstic aquifer at the scale of the interfractural distance (Drogue and Grillot, 1976). On the site, 20 open boreholes have been drilled on a 5 m × 5 m square grid (Figure 3), whose axes are oriented parallel to the directions for which the intensity of fracturing is maximum (N020 and N110), based on both outcrop mapping and aerial photographs. The boreholes are 60 m deep and reach the saturated zone of the karst. The water table is about 30 m below the ground surface in the dry season. During the rainy season, it is typically 15 to 20 m below the ground surface. Sporadically, some boreholes may become artesian or the whole site may be flooded, as a result of the most violent rains.

Previous measurements on the site have already emphasized a strong correlation between structure and hydraulic behavior. Among them, pumping tests disclose anisotropy. The flow is preferentially oriented parallel to the directions of maximum intensity of fracturing (Pitard,

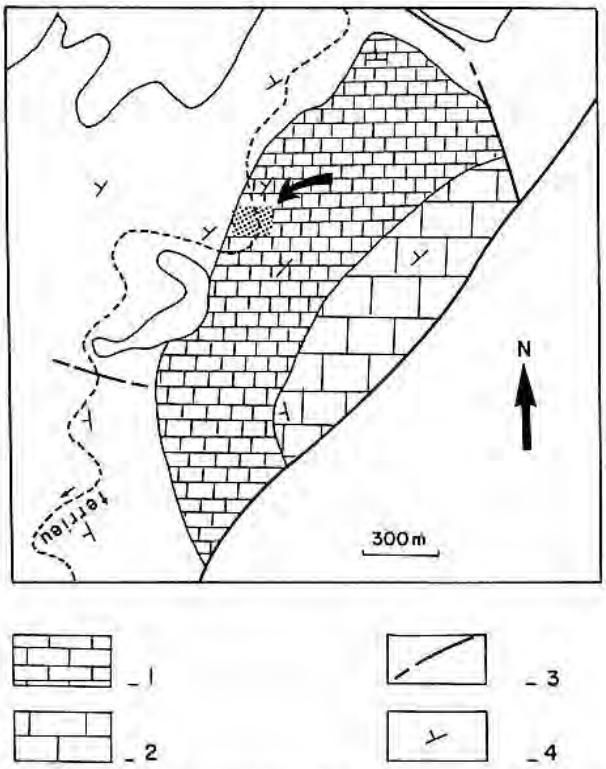

Fig. 3a. The Terrieu experimental site—location and geological setting (1: Lower Cretaceous; 2: Upper Jurassic; 3: fault; 4: dip).

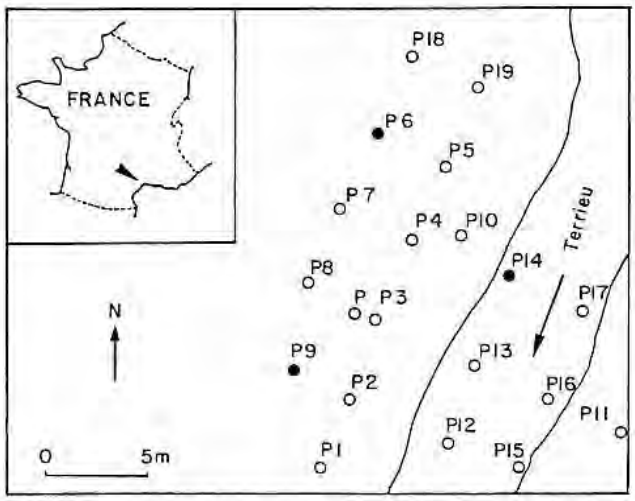

Fig. 3b. The Terrieu experimental site—the boreholes marked by black circles are those mentioned in the present study: P6 (estimation of the longitudinal dispersion); P9 (continuous recording of water level); P14 (time series of hydrochemical logs).

1976). Temperature profiles along the boreholes exhibit a strong horizontal heterogeneity: the mean low-water temperature gradient may differ up to a two-to-one ratio from one borehole to another (Drogue, 1985). Significant variations in the geothermal flux or in rock thermal conductivity are unlikely to occur at such a small scale, and the unperturbed temperature profiles show that the effect of natural convection is unimportant. Thus, vertical advection is the most reasonable explanation for the observed disparity in the temperature gradients. Besides, the deformation of thermal profiles during a high-water period, which is specific to each borehole, indicates the main inflow of water just infiltrated, which has not reached temperature equilibrium with the rock matrix (Figure 4).

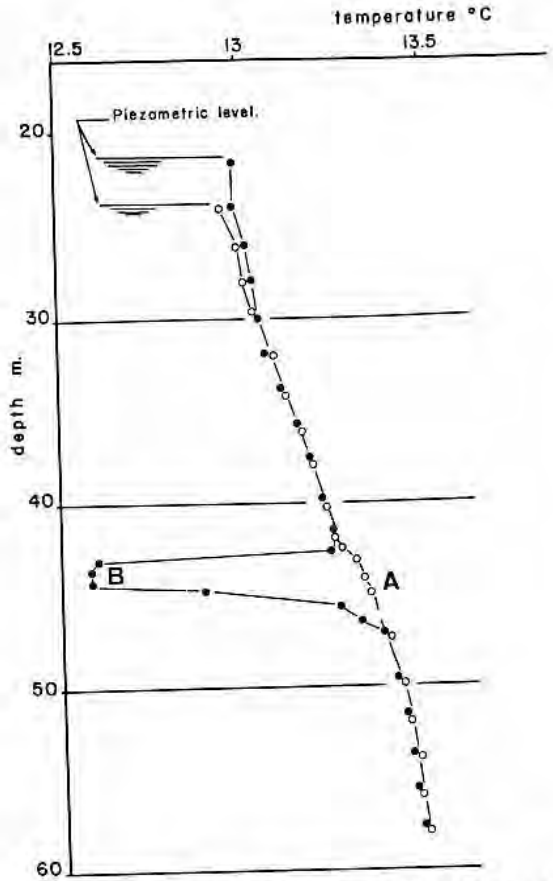

Fig. 4. Typical unperturbed (A) and perturbed (B) temperature profiles in a borehole with a major fracture at Terrieu.

Estimation of Advection Flow Velocities Along the Borehole

The experimental hydrochemical logs concern borehole P14, during the period between November 13 and December 14, 1984. On November 14-15 and November 30-December 1, heavy rains were followed by an abrupt increase in the water level. The water level on P14 is fairly similar to that on P9, which is continuously recorded (Figure 5). The hydrochemical logs (Figure 6) extend to a depth of 50 m, below which the borehole has collapsed. For each log, water samples are taken out of the borehole at a variable step (1 to 4 m) and passed through a 0.45 μm filter. The sampling volume is small (250 cm^3) to minimize any

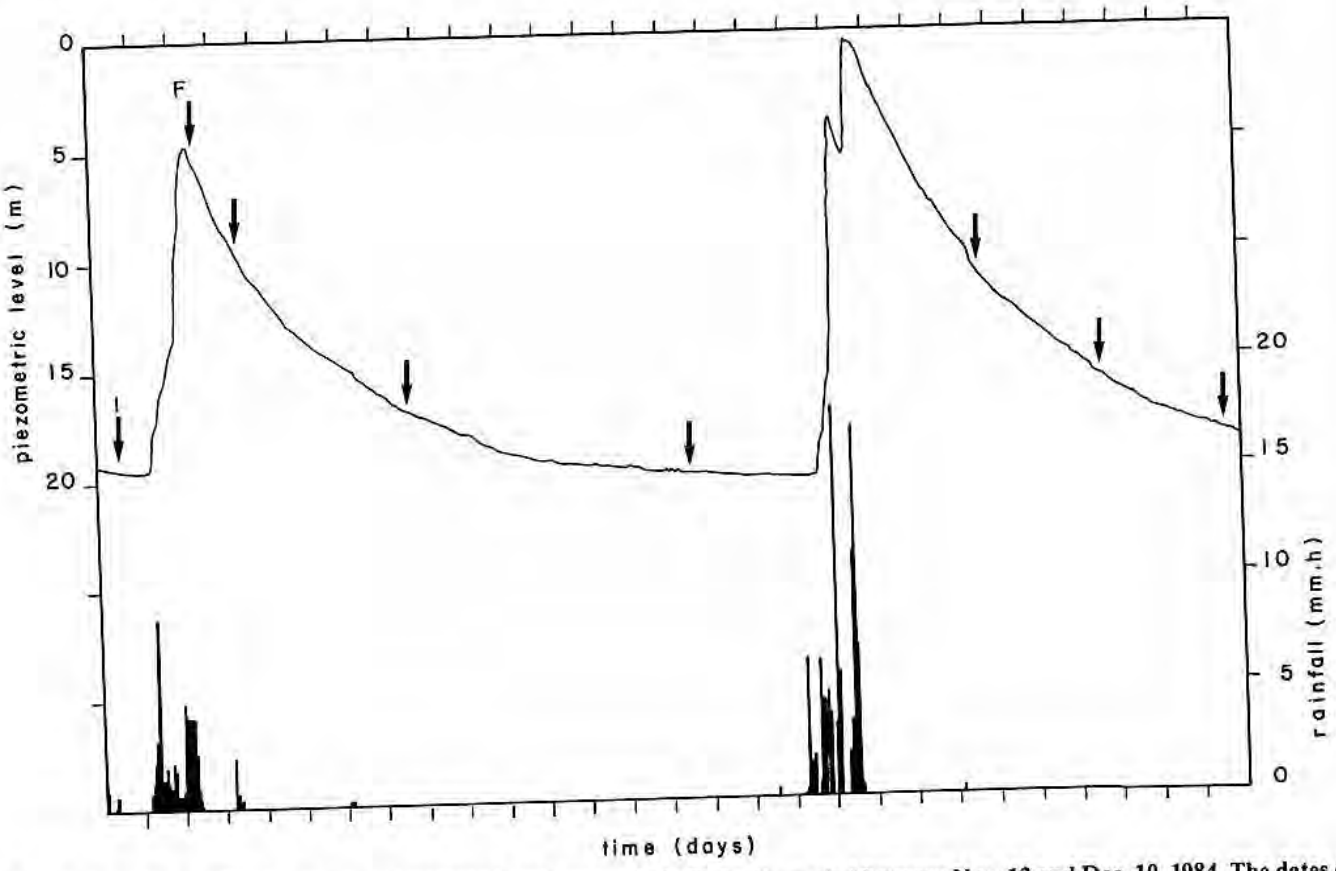

Fig. 5. Rainfall at the Terrieu site and piezometric level on borehole P9 for the period between Nov. 13 and Dec. 10, 1984. The dates of hydrochemical logs are shown by arrows. The dates of initial and final profiles used for the adjustment of fracture flow parameters are indicated by the letters "I" and "F," respectively.

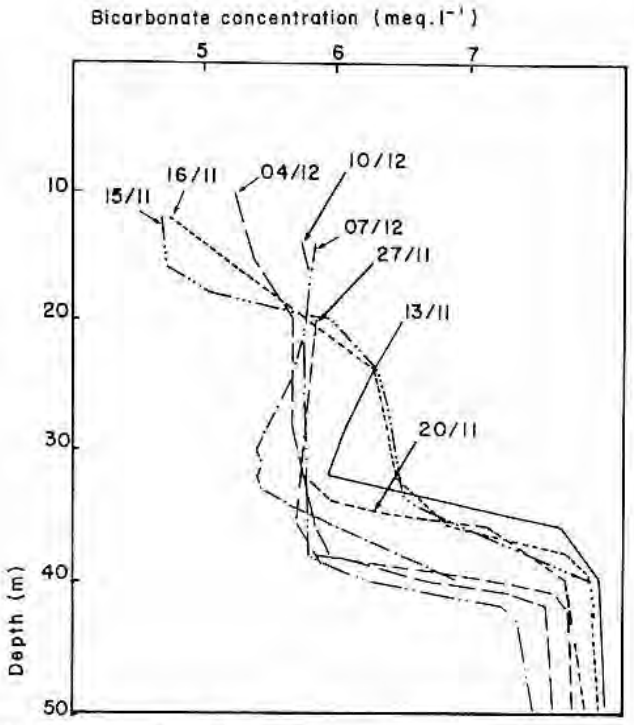

Fig. 6. Observed bicarbonate concentration profiles in borehole P14 at eight different dates.

perturbation to the system. Bicarbonate concentration is immediately determined by a potentiometric titration, using the Gran method (reproducibility: 0.5% accuracy: 1%). The following analysis is based on bicarbonate that has proved to be a good indicator of ground-water flow. It may seem paradoxical to choose such a reactive element, but concentration in less reactive elements does not differ significantly enough from one inflow to another and hence exhibits flats, uninterpretable profiles. At the time scale of a rainy episode (several days), it is reasonable to assume that calcite dissolution mainly occurs in the fractures, where the contact area is large, rather than at the well wall. Nonlinearities in mixing are expected to be unimportant, because inflows with composition of similar types are involved.

The dispersion coefficient D has been estimated by observing the spread of deionized water in a borehole at the same site (Bidaux, 1987). This second borehole does not cross any major fracture, and the experiment has been carried out during a low-water period (summer) so that the advective transport can be neglected. The obtained value, $2 \times 10^{-5} m^2.s^{-1}$, is four orders of magnitude larger than ion diffusion in water. Such difference can be explained by the existence of thermal convection cells (Sammel, 1968). Small cells, even if they do not appear on temperature profiles, may drastically enhance large-scale dispersion by generating recirculation (Pomeau, 1985). The parabolic flow velocity distribution may also contribute to longitudinal dispersion, the borehole diameter (115 mm) and the inflow values estimated below yield Reynolds numbers from less than 1 to the 100 range. In addition, dispersion effects related to the flow velocity distribution in a horizontal cross section are probably increased by the irregularity of the borehole walls. However, a detailed analysis of dispersion along a borehole falls beyond the scope of the present paper. The experimentally determined dispersion coefficient is considered as a macroscopic, 1D number that globally integrates the several possible small-scale phenomena mentioned hereabove.

The piezometric variations considered on P14 to constrain the fit are based on both discrete measurements on P14 and the continuous recording on P9 (Figure 7). Five periods are so distinguished; each one has its specific set of constant fracture inflow parameters and hence exhibits a linear variation in the piezometric level. An indicator of the quality of the match is given by the following expression:

$$\Delta C_m = \sqrt{\frac{1}{n} \sum_{i=1}^{n} [C_{exp}(i) - C_{sim}(i)]^2} \qquad (4)$$

in which $[C_{exp}(i), i = 1,n]$ are the n experimental final values and $[C_{sim}(i), i = 1,n]$ are the corresponding simulated values. In the present case, a simple set of fractures (approximate depths: 10 m, 20 m, 35 m, and other fractures in the lower part of the borehole, below 42 m and may be in the collapsed section, between 51 and 60 m) and the fracture inflow parameters given in Table 1 yield a satisfactory value of ΔC_m (below 0.04 $meq.l^{-1}$). Experimental and simulated concentrations for the final date (Nov. 15) are in good agreement (Figure 8). Let us mention that the circulation in the lower part of the borehole can be quantified, but not localized with precision, because it occurs in a portion where the concentration gradient is very low.

Hydraulic Interpretation and Discussion

The values given in Table 1 have been obtained by trial and error, and there is no evidence that the provided solution is unique. Other sets of inflow parameters may yield equally good matches. However, our results for the analysis of the hydrochemical logs hereabove will be validated by the following discussion, in which a consistent schema is proposed for the hydraulic evolution of the system during the studied time interval. The piezometric level h results from the hydraulic potential values h_f in the fractures, near their

Table 1. Fracture Inflow/Outflow Parameters Giving the Best Fit for the Hydrochemical Evolution of P14 for the Studied Time Interval

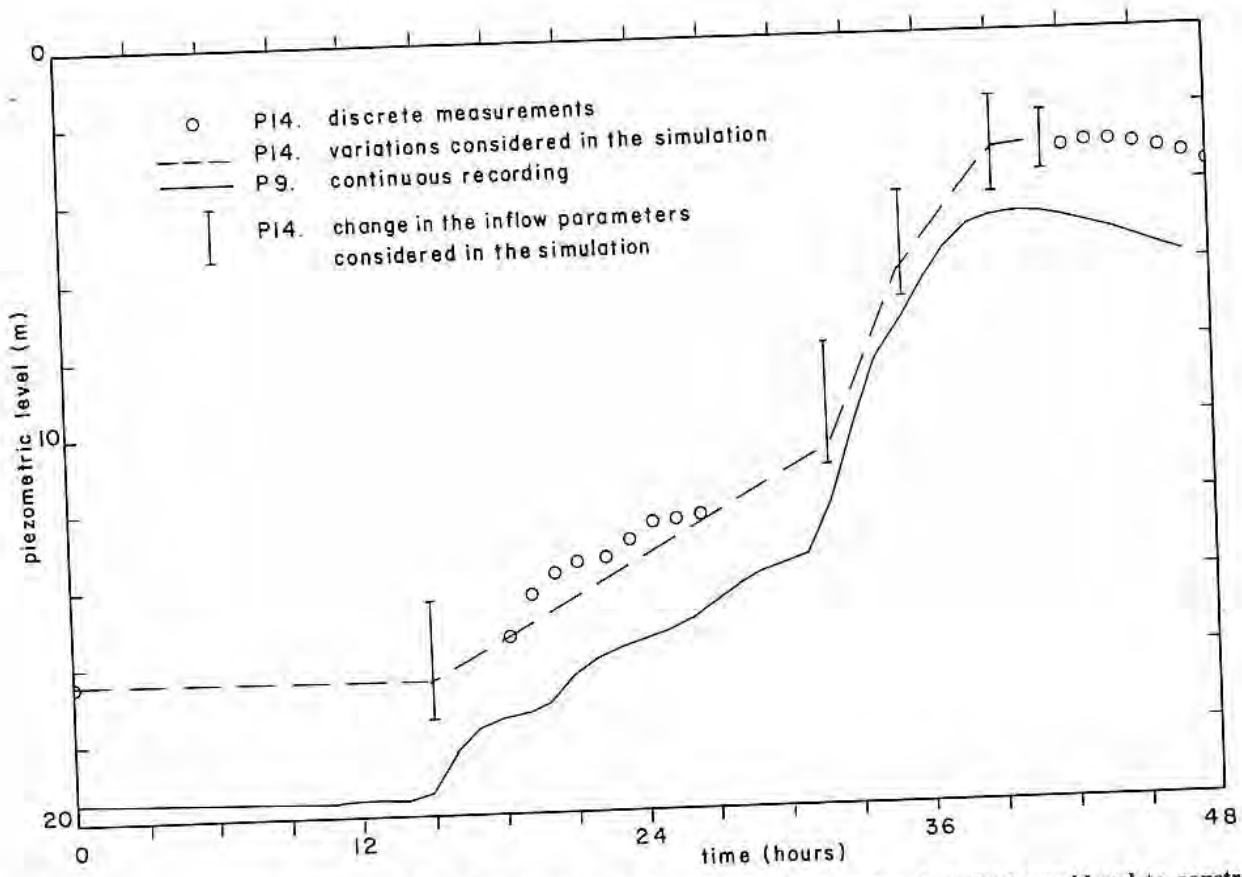

Fig. 7. Discrete piezometric measurements and hypothetical continuous variations on borehole P14 considered to constrain the simulation: comparison with the continuous record from borehole P9.

intersection with the borehole. A given fracture discharges water if $h_f > h$ and absorbs water if $h_f < h$. The rain causes a rise in the h_f values, but each fracture behaves distinctly, because it is more or less sensitive to the rain, reacts after some delay, and has specific hydraulic parameters. In light of these considerations, the four main fractures intersecting the borehole can be characterized. The top fracture ($z_f = 10$ m) responds sharply and rapidly to rainfall, which attests a good connection with the ground surface. The sudden increase in the inflow value (from 0.95 to 5.16 $cm^3 s^{-1}$) corresponds approximately to the time at which the water level in the borehole reaches the fracture and may be linked to the fact that a permeable zone at that level becomes saturated and hence exhibits a higher hydraulic conductivity. The second fracture ($z_f = 20$ m), on the contrary, absorbs water during the whole time interval. This behavior corresponds to a good connection with the drainage system and a rather poor connection with surface fractures. The third fracture ($z_f = 34$ m) and the fourth fracture (below 42 m) have symmetric behaviors: both exhibit inversions. The former discharges, then absorbs water while the latter absorbs, then discharges. That may result from the distinction between the two types of porosity that characterize a karstic aquifer: conductive channels in which the pressure perturbation occurs immediately after rainfall; and capacitive, finely fissured blocks in which the pressure wave is delayed and damped. Hence, the fracture at $z_f = 34$ m, which responds at once, is probably more conductive than the lower fracture.

Also, the bicarbonate concentration in fractures appears to remain stable throughout the studied episode, but differs

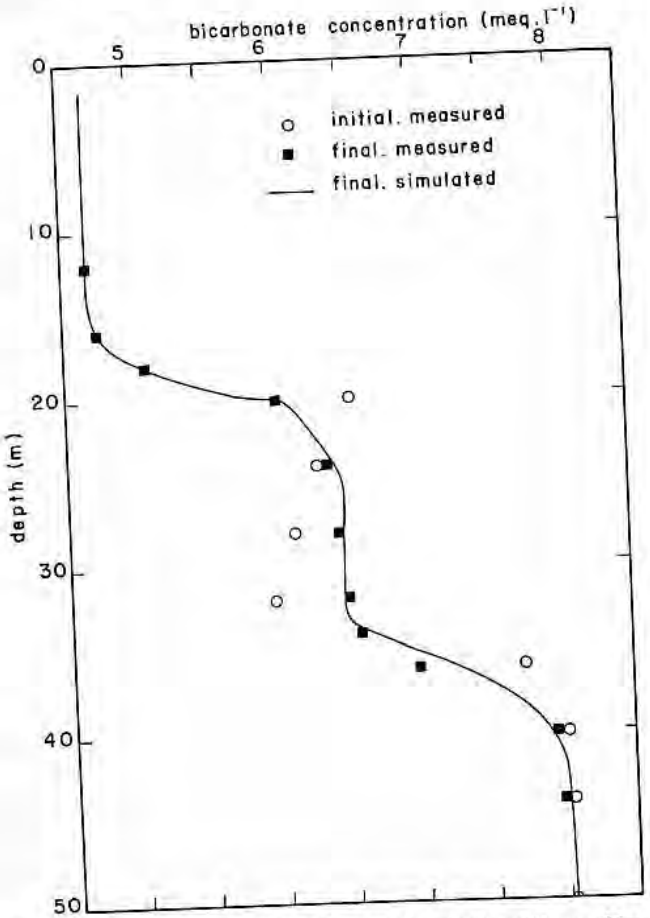

Fig. 8. Measured and simulated hydrochemical profiles on Nov. 15 (final values), and measured profile on Nov. 13. The best simulated log is obtained with the fracture flow parmeters given in Table 1 using the measured values on Nov. 13 as initial conditions.

from one fracture to another: the deeper the fracture, the more mineralized is the water. A longer residence time and flow in narrow fractures for the deeper water may explain that higher concentration, while inflows in the upper part correspond to water just infiltrated, flowing in wide channels, therefore dissolves a moderate quantity of carbonate rock.

Another explanation may be a heterogeneous context of CO_2 pressures, that results in a heterogeneous distribution of bicarbonate concentrations at saturation. Deep CO_2 forming would be in line with the tectonic context and temperature anomalies observed at the regional scale (Champagne, 1984). This would also account for the very high measured bicarbonate concentrations: lower values are found in karsts in Southern China (Bidaux et al., 1988), although the surface CO_2 pressures are presumably much higher there than at Terrieu, according to the climate and to the vegetation. These hydrochemical considerations are also in agreement with the hydraulic scheme discussed above; because the structure of the karst is strongly heterogeneous and discontinuous, the effects of deep CO_2 would be expected to have an irregular spatial distribution.

Comparison Between Hydrochemical and Thermometric Data

The observations hereabove are consistent with the previously mentioned heterogeneity in the temperature gradients of the boreholes at the site. At a larger depth scale, temperature profiles are distorted by ascending or descending water flow, which induces respectively an increase or a decrease of the temperature gradient near the ground surface (Drogue, 1985). Such vertical flows do exist, as shown for borehole P14 which intersects fractures with distinct hydraulic potentials. Besides, two out of the four zones of fracture flow revealed by hydrochemical logs in P14 coincide with thermometric results. According to temperature profiles (Figure 9), inflows occur in the upper part of the borehole and other flows are observed at about a depth of 35 m. However, the fracture flows at a depth of 20 m and deeper than 42 m do not appear.

The following development discusses how hydrochemical and thermal logs complement each other and how their combined use provides the optimal information on groundwater flow. The main point is the difference between heat and solute transfer processes, although both obey a similar mathematical formulation. At the well wall, chemical fluxes between water and rock matrix are very small and can be neglected, as the kinetics of chemical processes are very slow and the contact area is small. But heat conduction through rock matrix is the main factor which controls the temperature of water in the borehole. Therefore, a thermal reference profile can be defined which corresponds to an equilibrium between borehole water and the surrounding rock whose temperature is given by the geothermal gradient. Conversely, no hydrochemical reference profile exists because the water in the borehole does not reach a chemical equilibrium with the minerals in the surrounding rock. For that reason, a single hydrochemical log does not generally provide reliable information concerning fracture flow into and out of the borehole. Successive logs should be run in order to identify fracture flow parameters by studying advection in the borehole. On the other hand, from a single temperature profile, it is possible to observe directly whether the borehole is perturbed or not. As a consequence of heat conduction through rock matrix, a thermally perturbed borehole is rapidly brought back to equilibrium after the perturbing inflow stops (between 3 and 10 days if the flood is not too strong). But a chemical perturbation in the borehole, caused by an inflow of water of another composition, does not dissipate so easily. The anomaly may move upwards or downwards, mix with water previously in the borehole and spread by dispersion. It does not disappear until it is completely flushed out of the borehole. The hydrochemical profile remains in a modified status for a very long time and another perturbation may occur before the first one has disappeared. A steady state may never be reached. Besides, the thermal diffusion coefficient in water is about 100 times larger than the diffusion coefficient of ions. Hence, a temperature perturbation vanishes more quickly than a chemical perturbation.

Conclusion

Although the sampling technique and the assumptions of the model are quite simplistic, and the degree of uniqueness of the solution needs further investigation, hydrochemical logging provides valuable information concerning the location and the intensity of ground-water flow in karstic rocks. Hydrochemical logging is also applicable to other types of fissured or fractured media, and the results of its processing may be used as an input to constrain sophisticated three-dimensional simulators of transient flow and transport in fracture networks, such as Karasaki's (1988). The model also could be easily extended in order to take regional flow inside the fractures into account. Flow patterns in fractures would be similar to those studied by Bidaux and Tsang (1989, 1991) for a porous aquifer.

The analysis of hydrochemical logs in a borehole during a rainy episode has allowed flow rates and bicarbonate concentrations from and into the intersected fractures to be evaluated. The connections of the fractures with the ground surface, the drainage system, and the deep karst, have been characterized.

While temperature appears to be an instant indicator of high velocity flow, hydrochemistry can identify low velocity flow, which cannot be detected by temperature measurements. Thus, the combined use of thermal and hydrochemical logs seems to be a suitable tool for the study of groundwater flow in karstic rocks. High velocity flow, which occurs in high permeability channels, and low velocity flow, which occurs in low secondary permeability, slightly fissured blocks, can be characterized. Consequently, the proposed technique consists in a quantitative approach of the karst model that has already been recognized qualitatively by several authors (Milanovic, 1981; Cui Guangzhong et al., 1988; Drogue, 1988; White 1988).

Can Contaminant Transport Models Predict Breakthrough?

by Wei-Shyuan "Stone" Peng, Duane R. Hampton, Leonard F. Konikow, Kiran Kambham, and Jeffrey J. Benegar

Abstract

A solute breakthrough curve measured during a two-well tracer test was successfully predicted in 1986 using specialized contaminant transport models. Water was injected into a confined, unconsolidated sand aquifer and pumped out 125 feet (38.3 m) away at the same steady rate. The injected water was spiked with bromide for over three days; the outflow concentration was monitored for a month. Based on previous tests, the horizontal hydraulic conductivity of the thick aquifer varied by a factor of seven among 12 layers. Assuming stratified flow with small dispersivities, two research groups accurately predicted breakthrough with three-dimensional (12-layer) models using curvilinear elements following the arc-shaped flowlines in this test.

Can contaminant transport models commonly used in industry, that use rectangular blocks, also reproduce this breakthrough curve? The two-well test was simulated with four MODFLOW-based models, MT3D (FD and HMOC options), MODFLOWT, MOC3D, and MODFLOW-SURFACT.

Using the same 12 layers and small dispersivity used in the successful 1986 simulations, these models fit almost as accurately as the models using curvilinear blocks. Subtle variations in the curves illustrate differences among the codes. Sensitivities of the results to number and size of grid blocks, number of layers, boundary conditions, and values of dispersivity and porosity are briefly presented. The fit between calculated and measured breakthrough curves degenerated as the number of layers and/or grid blocks decreased, reflecting a loss of model predictive power as the level of characterization lessened. Therefore, the breakthrough curve for most field sites can be predicted only qualitatively due to limited characterization of the hydrogeology and contaminant source strength.

Introduction

The flow of contaminated ground water at many sites is simulated using computer models. These models are used to calculate the concentration of a contaminant at an exposure point where a potential receptor exists. This concentration is compared with regulatory standards to determine whether human health or the environment is at risk.

Many of the computer models used for this purpose are based on MODFLOW (McDonald and Harbaugh 1988), a ground water flow model that has become a true industry standard because it is comprehensive, widely available, accepted by courts and government agencies, well-documented, supported, and easily modified. MT3D (Zheng 1990) is a full-featured three-dimensional (3D) transport model that links with MODFLOW. MODFLOW-SURFACT (HydroGeoLogic 1995) is an enhanced version of MODFLOW linked with a transport model. MODFLOWT (GeoTrans 1996) and MOC3D (Konikow et al. 1996) are 3D flow and transport models that incorporate MODFLOW. These numerical models are versatile and powerful. In this study we use one well-controlled field experiment as the basis for evaluating the viability of these models for quantifying contaminant transport.

Our ultimate goal is to assess whether such sophisticated numerical models can be used "off the shelf" by modelers in industry, many having limited prior contaminant modeling experience, and still have any predictive value. Many factors complicate this assessment of the potential

Pages 104–113

of modeling for predictive power, including adequacy of site data, budget for modeling effort, and modeler training. Therefore, we would like to narrow our focus, and ask an easier question. Given sufficient time, budget, training, hardware and software, and an ideally characterized site with a well-quantified contaminant source, can experienced ground water modelers use these numerical models to successfully predict contaminant transport? If we cannot successfully predict contaminant transport using these models under ideal conditions, we doubt that contaminant transport predictions resulting from time- and resource-limited studies of less-well characterized sites and contaminant sources will be reliable.

Field Test

Site Description

This study focuses upon a best-case scenario, a site where the hydrogeology is thoroughly characterized and the contaminant input was measured over time. It is also an appropriate site because two groups (Huyakorn et al. 1986; Molz et al. 1986) have independently predicted the contaminant breakthrough with success using sophisticated models without using the previously measured breakthrough curve to calibrate their models and adjust their predictions. Thus, we know that predicting breakthrough within a reasonable confidence interval is achievable. A two-well tracer test was conducted in a confined aquifer near Mobile, Alabama (Molz et al. 1986). The surficial deposits at this site along the western flank of the Mobile River consist of a Quaternary fluvial terrace deposit comprised of interbedded sand and clay units. The 71-foot (21.6 m) thick unconsolidated sand aquifer is confined between clayey units. In the experiment by Molz et al. (1986), two wells that fully penetrate this confined stratum were used. Water was pumped out of one well and disposed at a safe distance from the test area. Water was simultaneously injected at the same rate within ± 1%, 250 gallons per minute (0.9464 m^3/min), in the other well, 125 feet (38.3 m) away. After a steady flow pattern was established, the injected water was spiked with a bromide tracer solution for 76.6 hours. Tracer-free water was injected thereafter. The bromide concentration in the pumping well was measured for 32.5 days.

This confined sand aquifer had been characterized previously during experiments investigating seasonal hot water storage underground. Parr et al. (1983) calculated an average transmissivity of 12,160 to 12,270 ft^2/day (1130 to 1140 m^2/day), a longitudinal dispersivity of 0.3 feet (9.1 cm), a ratio of horizontal to vertical hydraulic conductivity of 6.71, and a storage coefficient ranging from 0.00047 to 0.00069. Parr et al. (1983) also reported without justification the following values: a regional gradient of 3.3×10^{-4}, an *estimated* porosity of 0.33, and a hydraulic conductivity of 176 ft/day (53.6 m/day). This reported hydraulic conductivity differs slightly from the values calculated using the transmissivities of 12,160 to 12,270 ft^2/day (1130 to 1140 m^2/day) divided by the aquifer thickness, 71 feet (21.6 m), or 171 to 173 ft/day (52.3 to 52.8 m/day). The aquifer is composed of medium to fine sand

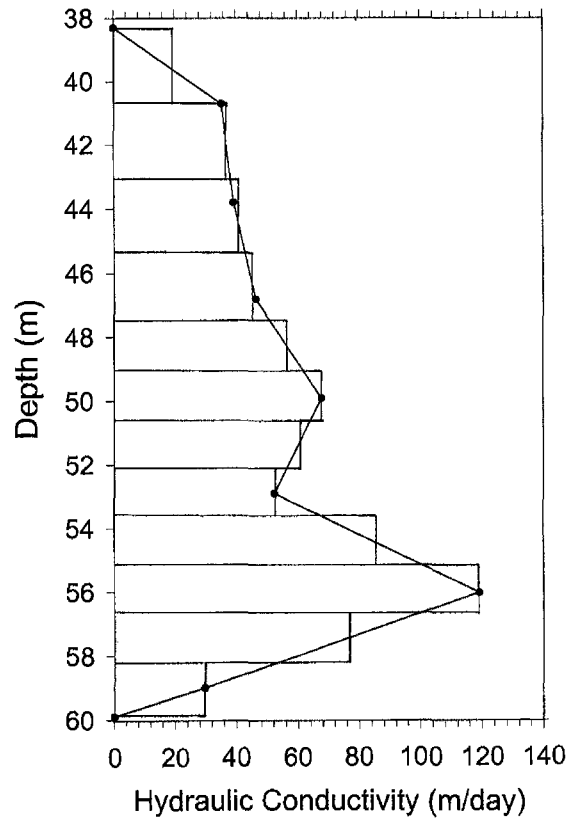

Figure 1. Twelve-layer hydraulic conductivity discretization of measured values.

containing from 1% to 15% silt and clay (Molz et al. 1985). The aquifer appears to coarsen slightly downward, with a horizon at a depth of 184 feet (56 m) having fewer fines than the other depths sampled (Molz et al. 1985).

Single-well tracer tests were performed to determine the vertical distribution of horizontal hydraulic conductivity (Molz et al. 1985). In these tests, a conservative tracer solution was injected into the aquifer for a period and then withdrawn through the same well. The tracer concentration was measured periodically at the injection/withdrawal well and at a nearby observation well with seven distinct monitoring levels. Tracer concentration and electrical conductivity data from the fourth test were used to infer tracer breakthrough times for different aquifer depths. These breakthrough times were the basis of the vertical distribution of horizontal hydraulic conductivity, K_h, shown as a jagged line with seven nonzero data points in Figure 1. The K_h values in this aquifer varied by up to a factor of four among seven different vertical intervals reported in Molz et al. (1985). Molz et al. (1986) and Huyakorn et al. (1986) represented this variation in K_h using 12 discrete layers whose normalized conductivity values are presented in Table 1 and are depicted in Figure 1. The K_h values in this aquifer varied by up to a factor of seven among 12 different vertical intervals, which were 4.9 to 7.2 feet (1.5 to 2.5 m) thick.

Previous Simulations

The two-well test was simulated by the two independent groups cited previously using the models described

Table 1
Two-Well Test Parameters Used to Predict Breakthrough Curves

Layer (i)	Thickness (m)	K_i/K_{max} Normalized K_i	Q_i/Q_{Total} Normalized Q_i	$K_z = K_i/6.71$ m/day
1	2.4	0.15	0.037	2.66

11	1.5	0.65	0.100	11.54
12	1.75	0.25	0.045	4.44

K_{max} = 391 ft/day (119.1 m/day)
Q_{Total} = 250 gpm (0.9464 m^3/min)

Table 2.
Additional Two-Well Test Parameters Used to Predict Breakthrough Curves

Additional Parameters	Value
Longitudinal dispersivity	0.5 ft (0.15 m)
Transverse (horizontal) dispersivity	0.16 ft (0.05 m)
Transverse (vertical) dispersivity	0.033 ft (0.01 m)
Tracer injection time	3.19 days
Total injection time	32.5 days
One-half well spacing	62.8 ft (19.14 m)
Radius of injection and production wells	3 in (0.08 m)
Injection and production rates	250 gpm (0.9464 m^3/min)
Porosity	0.35
Aquifer thickness	71 ft (21.6 m)
Molecular diffusion coefficient	1.1×10^{-8} ft^2/s (1×10^{-9} m^2/s)

by Huyakorn et al. (1986) and Guven et al. (1986). Data supplied to the modelers came directly from field measurements or calculations derived from field measurements, with the exceptions of dispersivity and porosity (Table 2). Molz et al. (1986) explained how they arrived at a porosity estimate of 0.35 (instead of the previously estimated value of 0.33), and justified using an estimated longitudinal dispersivity of 0.5 feet (15 cm) (instead of the measured value of 0.3 feet, or 9.1 cm). The dispersivity of 0.3 feet (9.1 cm) was measured for an injection test over a distance of 50 feet (15.2 m) from the injection well. This experiment, with the wells 125 feet (38.3 m) apart, would likely be described by a larger dispersivity. Pickens and Grisak (1981) measured dispersivities that increased with the scale of the tracer test. Note that a longitudinal dispersivity of 0.5 feet (15 cm) is much smaller relative to the transport distance of 125 feet (38.3 m) than dispersivities commonly used in models, which are usually a percentage of the block size (e.g., 33% to 50%) or of the plume length (e.g., 10% as proposed by Pickens and Grisak 1981). Hence, this situation is dominated by advection as one would expect in a forced-gradient tracer test. The modelers were also given the measured injected bromide concentrations shown in Figure 2.

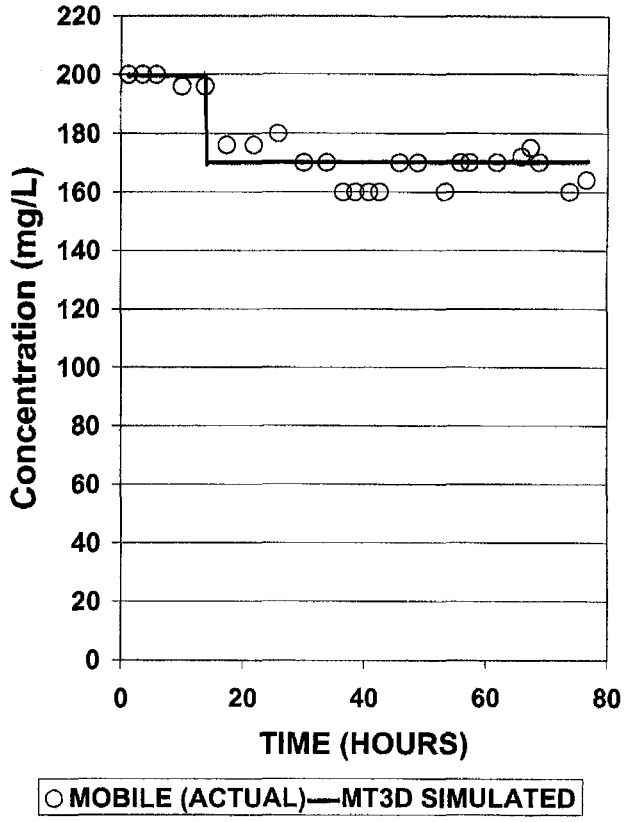

Figure 2. Bromide concentrations in injection well.

The first model was a 3D finite-element flow and transport model specially adapted by GeoTrans to follow the arc-shaped flowline pattern (Figure 3) created by a pumping/injection well pair (Huyakorn et al. 1986). It was based on 3D curvilinear coordinates so the element sides coincided with ground water flowlines. This coincidence of the element boundaries and flowlines minimizes numerical dispersion. To simulate the two-well tracer test, stratified and steady horizontal flow was assumed within each layer. By representing the measured permeability variations explicitly in the 12 layers, dispersion could be accounted for using the small value in Table 2. The model evaluated the ground water velocity distribution based on the pattern for steady flow between an injection and production well, and used it to solve the advection-dispersion equation written in 3D curvilinear coordinates.

The second model used to simulate the two-well test, called the Two-Well Advection Model, was described by Guven et al. (1986). This model assumes steady horizontal flow in perfectly stratified layers. This finite-difference model is based on the velocity field obtained from a steady-state analytical solution, ignoring completely any local hydrodynamic dispersion. Again, the finite-difference grid "blocks" consist of arc-shaped crescents that follow the flowlines. The results of applying this model to the Mobile site were reported by Molz et al. (1986).

Both simulations did a remarkable job of predicting the bromide breakthrough curve (Figure 4). Each group predicted the bromide concentration versus time, or breakthrough curve, at the production well without access

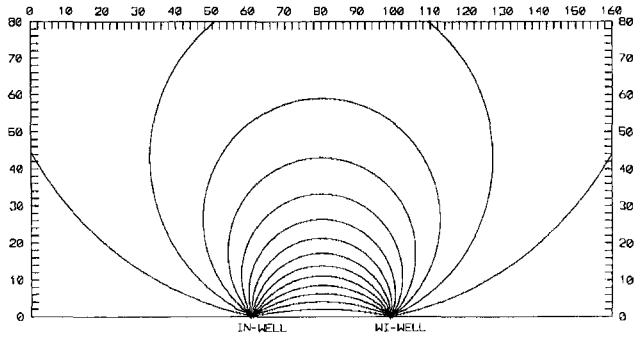

Figure 3. Flowlines linking injection and production well pair.

to the previously measured curve. The results were not calibrated. The agreement between these simulations and the measured breakthrough curve suggests that the spreading of the tracer slug over the distances involved in the two-well test depended largely on velocity variations that were controlled by the 12-layer hydraulic conductivity distribution. The use of a small dispersivity by Huyakorn et al. (1986) or no dispersivity in the model of Guven et al. (1986) assured that the computed breakthrough curve was dominated by advection.

Methods

We simulated this two-well test using four model combinations: MODFLOW with MT3D (version 1.85 from S.S. Papadopulos & Associates Inc.), MODFLOWT (version 1.13 from HSI GeoTrans), MODFLOW-SURFACT (M-S) (version 1.0 from HydroGeoLogic), and MOC3D (version 1.2 from the U.S. Geological Survey). The models were run on microcomputers. More recent versions of these models have become available since we performed this work. For example, MT3D is now available as MT3D96 or MT3DMS.

The model discretization and boundary conditions are described in the following paragraphs. In all cases, the domain simulated was half of the real domain. We exploited the symmetry of the problem, which has a straight flowline linking the pumping and injection wells, by modeling only one side of that flowline and diminishing the pumping and injection rates by 50%. The wells were both fully penetrating. Well flow rates were allocated among layers in the 3D simulations by dividing the total flow into layer-by-layer flows proportional to the transmissivity of each layer (Table 1). For the MOC3D, MODFLOWT, M-S, and most MT3D simulations, the domain was 525 feet (160 m) long parallel to the flowline linking the two wells on one side, and 262.5 feet (80 m) wide (Figure 3). Each grid block measured 6.6 feet (2 m) on each side, requiring an 80 × 40 grid. No-flow boundary conditions were used on all four sides for the simulations reported here, but other runs were made using constant-head boundaries on three sides for comparison purposes. (The boundary passing through the two wells must always be a no-flow boundary.) The constant-head breakthrough curves were lower than the curves obtained using no-

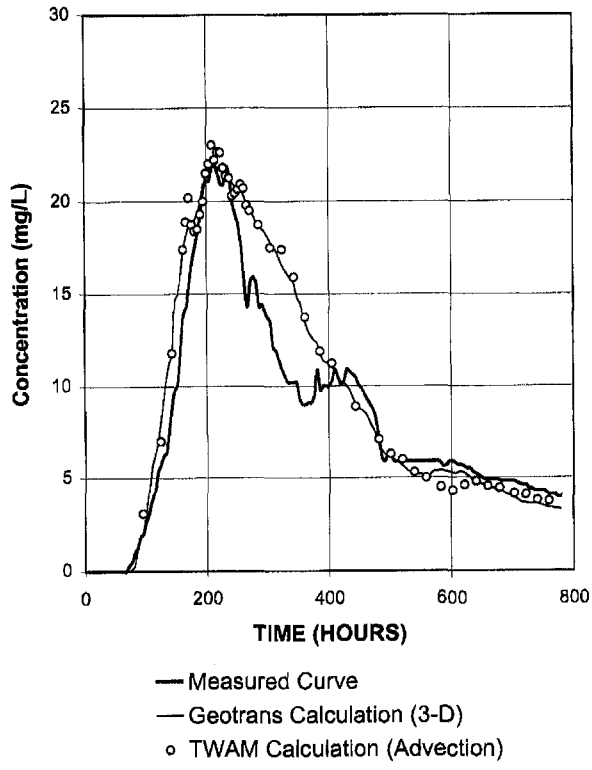

Figure 4. Measured and predicted bromide breakthrough curves for two-well test.

flow boundaries, showing that mass was lost out of the system (about 12%). Further runs using a 1063 × 531.5 foot (324 × 162 m) domain showed only 3% mass was lost out the constant-head boundaries.

MT3D (Zheng 1990) features four different solution schemes: explicit finite-difference (FD), method of characteristics (MOC), modified MOC (MMOC), and hybrid MOC (HMOC), which is a combination of MOC and MMOC exploiting the advantages of each method. All four of these methods were used initially. After comparing the results of these four methods, we used only FD and HMOC since the MOC and MMOC methods had later peaks and more numerical dispersion than HMOC results. We report here primarily the FD results to facilitate a fair comparison with the two other models that use finite-difference methods. The explicit FD method incorporates upstream weighting of the advective terms, which leads to more numerical dispersion than the other three methods. The FD method has two important advantages over the other three MT3D methods in this comparitive study. It is much faster, and produces smooth curves that are visually more satisfactory and that facilitate comparison. The alternate MT3D methods produce noisy breakthrough curves having seemingly nonphysical spikes, which is characteristic of particle-tracking methods in general, but is more severe in this problem due to its point source and sink and the problem geometry. The most recent version of MT3D-MT3DMS-has another option available besides the FD and MOC options: total variation diminishing (TVD), which is an advanced finite-difference option.

MODFLOWT (GeoTrans 1996) simulates ground water flow and advective-dispersive transport through the implicit finite-difference technique. Model users may choose between upstream weighting and central differencing for the advective terms in the finite-difference approximation of the partial differential equation for solute transport. In this study, central differencing is used because it introduces no numerical dispersion into the approximation of the advective terms. The simulation was run using sufficiently small constant time steps to maintain the Courant number criterion (less than one). The implicit time discretization employed in MODFLOWT allows for larger time steps to be used than in MT3D, which uses an explicit time discretization. Also, the Orthomin (Vinsome 1976) solver package option of MODFLOWT was used. This iterative solution scheme is similar to conjugate gradient (CG) methods for solving systems of linear equations. However, unlike CG techniques, the ORTHOMIN procedure guarantees convergence for unsymmetric matrices, such as those generated in solving the transport equation.

MODFLOW-SURFACT (M-S) (HydroGeoLogic 1995) is an enhancement of MODFLOW. M-S simulates advective-dispersive transport of up to five chemical species with linear/nonlinear retardation and first-order degradation with generation of transformation products. Time discretization may be performed using fully implicit, fully explicit, or Crank-Nicolson schemes. Spatial discretization of the advective terms is performed using the TVD scheme with a van Leer flux limiter (van Leer 1979; Harten 1983; Osher and Chakravarthy 1984). Upstream weighting, central differencing, and mixed spatial weighting schemes are also available. This study uses the TVD scheme with Crank-Nicolson time discretization to minimize numerical errors. Grid-block and time-step sizes were the same as for the other models to permit comparisons.

MOC3D (Konikow et al. 1996) is an updated version of the classic USGS 2D model of flow and transport, MOC. It is integrated with MODFLOW to simulate the transient, 3D transport and dispersion of a solute subject to decay and retardation. This implementation of the method of characteristics uses particle tracking to represent advective transport and explicit finite-difference methods to calculate the effects of other processes. MOC3D can be applied to a subgrid (of uniform rectangles) of the primary MODFLOW grid that is used to solve the flow equation. This method is most accurate and efficient for advection-dominated problems such as the one studied here.

Predictive power of the different models could be assessed several ways. The most straightforward way was to visually compare the model-predicted breakthrough curve with the measured breakthrough curve as was done in Figure 4 by previous researchers. Another option we might have chosen was to measure goodness-of-fit of the modeled to the measured breakthrough curves using a metric like root mean squared error or mean absolute error (Anderson and Woessner 1992). These metrics would sum up measures of the deviations between the two curves at many specific times. We did not choose to use these quantitative measures of prediction quality because each model produced concentration predictions over time based on their time-stepping schemes, and those times did not match the times from other models or when measured concentrations were available. Hence, the comparisons between models using these metrics would not have been fair or accurate, nor could we apply these metrics to the previous studies shown in Figure 4. Finally, one could argue that there are more important points in the breakthrough curve, such as when the first nonzero concentration is measured (or the breakthrough time), and the time and concentration at which the breakthrough curve peaks. Accurately predicting these two points is most important from a regulatory viewpoint. Another important part of the curve to fit from a remediation viewpoint is the falling limb of the curve that follows the peak. We elected to present the curve comparisons visually so each reader can assess the quality of the curve fit according to his or her own criteria.

Results and Discussion

The results from MT3D (FD option), MODFLOWT, and MODFLOW-SURFACT simulating the 12-layer data set closely match the observed breakthrough curve (Figure 5). These results are based on using a dispersivity of 0.5 feet (15 cm) and a porosity of 0.35 as well as all other parameters as specified in Table 2. Sensitivity studies of MT3D (HMOC option primarily; also FD option) showed that changing the porosity values by 0.05 made a noticeable difference (a bigger difference with HMOC

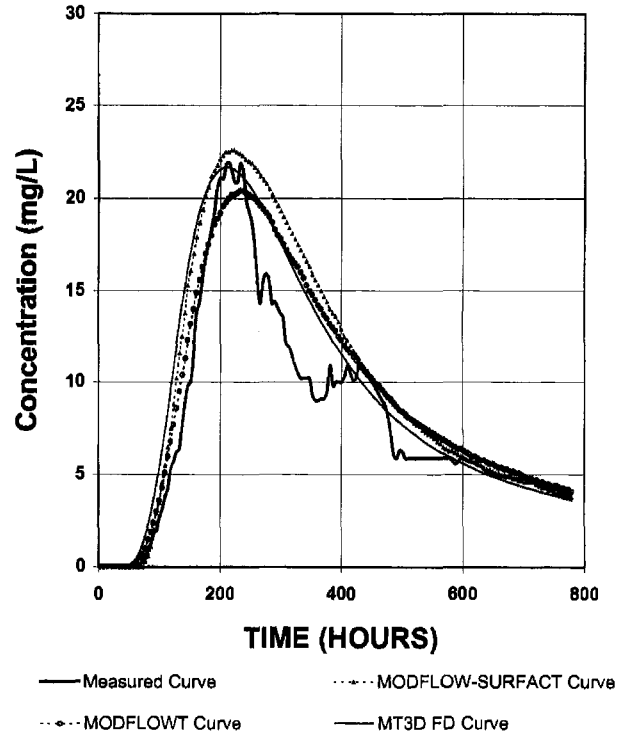

Figure 5. Comparison of bromide breakthrough curves calculated by MT3D (FD option), MODFLOWT, and MODFLOW-SURFACT with the measured breakthrough curve.

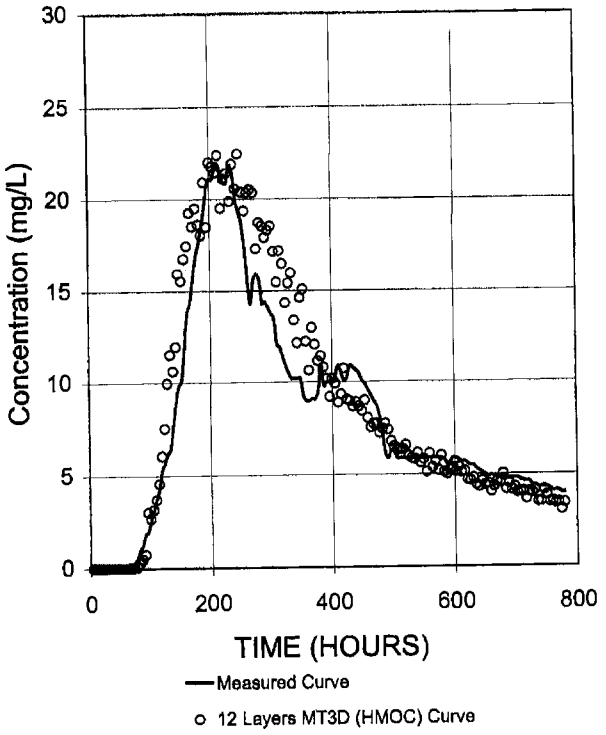

Figure 6. Comparison of bromide breakthrough curves calculated by MT3D (HMOC option) with the measured breakthrough curve.

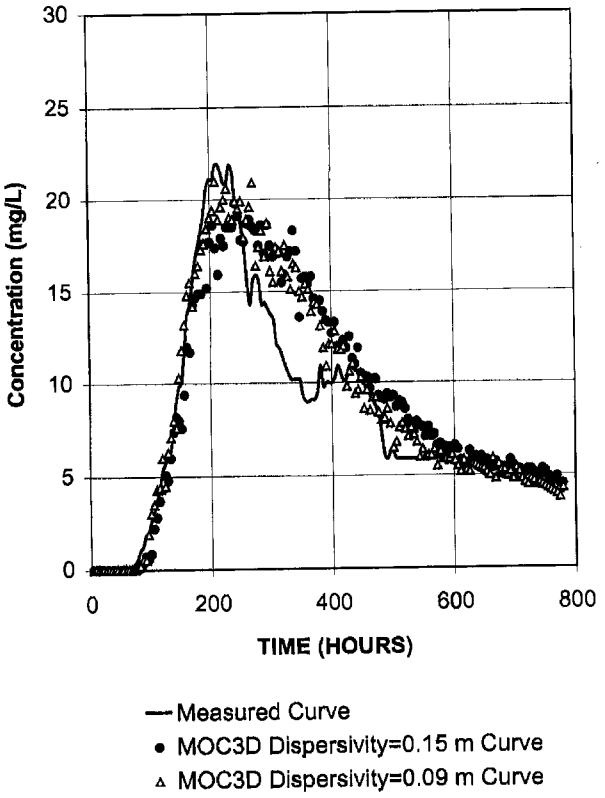

Figure 7. Breakthrough curves calculated by MOC3D using (porosity, dispersivity) of (0.33, .09 m) and (0.35, 0.15 m) versus the measured curve.

than with FD, perhaps due to the damping inherent in FD). Changing the dispersivity values from 0.5 to 3 feet (15 to 90 cm) for this advectively-dominated case resulted in only minor changes in the breakthrough curve. The MT3D curve exhibits early breakthrough due to numerical dispersion caused by upstream weighting used in the FD solver, but fits best the peak and lag portions of the bromide breakthrough. The HMOC results from MT3D, shown in Figure 6, fit as well. The 12-layer results from all three "off-the-shelf" models with rectangular blocks were almost as close to the measured curve as those obtained with the specialized computer models using arc-shaped grid "blocks."

The results obtained using the USGS MOC3D model to simulate this problem also fit the observed breakthrough curve well (Figure 7). The better-fitting curve of the two results shown is based on using the previously measured value of dispersivity, 0.3 feet (9 cm), and earlier estimate of porosity, 0.33. The MOC3D breakthrough curve did not match as well (Figure 7) when the larger dispersivity (0.5 feet, or 15 cm) and porosity (0.35) values were used, the same values used for the simulations shown in Figures 4, 5, and 6. As stated before, MOC solutions are more sensitive to porosity variations than are finite-difference solutions. Note that the concentrations shown in Figures 6 and 7 fluctuate more than in the finite-difference curves shown in Figure 5. This is a characteristic of results from particle-tracking models, such as MOC3D and MT3D (any of the three MOC options), because of the discrete nature of particles. In a sense these non-smooth results reflect the fluctuations of the measured curve better than the smooth finite-difference solutions do (but they are numerical artifacts).

For the MT3D, MOC3D, MODFLOWT, and M-S simulations the domain was 525 feet (160 m) long parallel to the flowline linking the two wells on one side, and 262.5 feet (80 m) wide (Figure 3). Each grid block measured 6.6 feet (2 m) on each side, requiring an 80 × 40 grid. No-flow boundary conditions were used on all four sides for the simulations previously shown in Figures 5, 6, and 7, as well as those shown subsequently. A larger domain of 1880 by 938 feet (573 by 286 m) also was modeled using an expanding 80 by 40 grid surrounded by impermeable boundaries. The results were essentially identical with those for the 525 by 262.5 feet (160 by 80 m) domain (Figure 8), validating the use of a smaller domain.

An important factor affecting the curves is dispersivity. The longitudinal, transverse, and vertical dispersivities were all kept small (Table 2), less than 0.2 m. Some numerical methods inherently introduce numerical dispersion. This numerical dispersivity adds to the specified dispersivity parameters to produce larger overall dispersivities, resulting in faster breakthrough times, lower peak concentrations and longer tailing of the breakthrough curve. For example, the finite-difference method typically adds numerical dispersion about equal to half of the grid block size, which was 2 m for most simulations. Therefore, the numerical dispersion greatly increased the overall longitudinal dispersion. Nevertheless, in this advectively dominated problem, dispersion has a

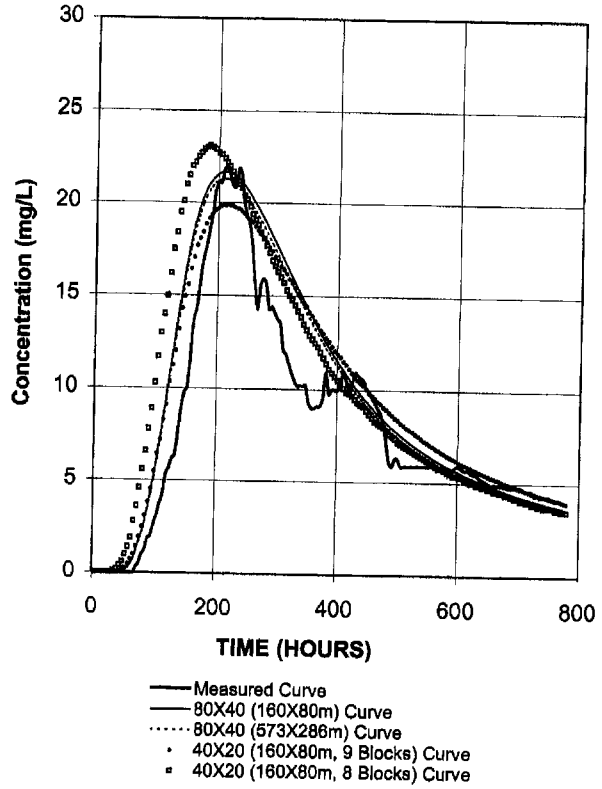

Figure 8. MT3D FD 12-layer breakthrough curves for different grids versus measured curve.

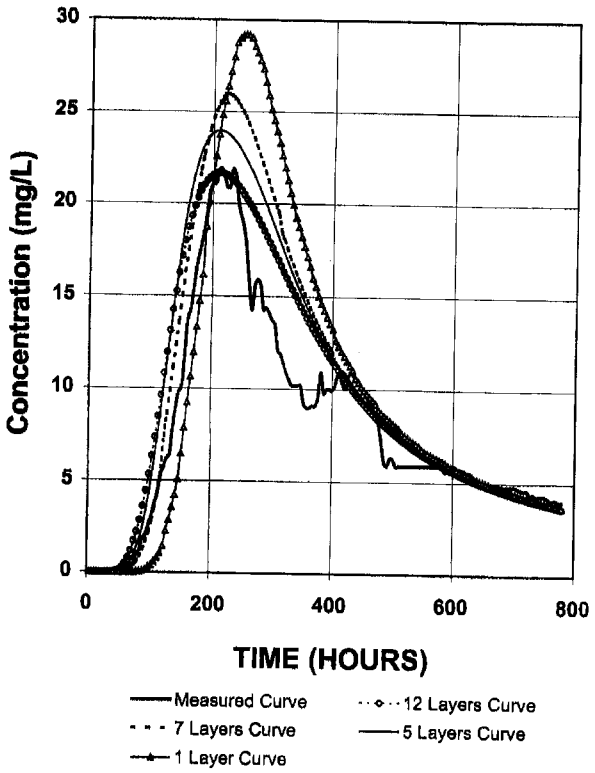

Figure 9. MT3D FD breakthrough curves for different numbers of layers versus measured curve.

secondary impact on the breakthrough curve because of the limited travel time and distance during which dispersion could spread out the tracer.

When the grid block size for the 525 by 262.5 feet (160 by 80 m) domain was increased to 13.1 feet (4 m) on a side, leading to a 40 by 20 grid, the peak height decreased significantly (Figure 8) due to the increased numerical dispersion, especially using the HMOC option (not shown). The injection and production wells are supposed to be 125 feet (38.3 m) apart. In the 80 by 40 grid, the grid blocks containing these wells are separated by 18 6.6-foot (2-m) blocks. In the 40 by 20 grid, the grid blocks containing these wells could be separated by eight or nine 13.1-foot (4 m) blocks. Using nine blocks provides a better match with the results from the 80 by 40 grid. Using eight 13.1-foot (4 m) blocks between the well blocks leads to an earlier breakthrough time, increased peak height, and earlier peak time. All subsequent 40 by 20 grid simulations were based on using nine 13.1-foot (4 m) blocks between the wells. Decreasing the grid block size from 6.6 feet (2 m) to 3.3 feet (1 m) resulted in a slight delay in breakthrough time due to decreased numerical dispersion and a slight decrease in the peak concentration.

To see if having detailed geologic data was necessary to achieve predictive power, we simulated this problem using MT3D with 12 layers, seven composite layers, five layers, and a single, average layer. While the curve calculated using MT3D with 12 layers closely matched the measured curve, the seven- and one-layer simulations (Figure 9) resulted in curves that exhibited late breakthroughs, late peaks, and high peak concentrations. The results would normally show a better fit as the number of layers increases. In Figure 9, the predicted breakthrough curve for five layers was better than that for seven layers because the hydraulic conductivity discretization we chose for five layers captured the high and low conductivity values better than our seven-layer discretization did. For this problem, with source and sink wells closely spaced in a confined aquifer and the resulting advectively dominated transport of bromide, using 12 layers (rather than seven, five, or one) was a hydrogeologic detail necessary for predictive power. Most of the natural dispersion present in this aquifer was due to the tracer traveling at different speeds in layers of different hydraulic conductivities.

For simulations using less than 12 layers, the measured peak height could be better matched when the dispersivity was increased by a large multiplicative factor. This increased dispersivity substitutes for the dispersion introduced by multiple layers with different hydraulic conductivities. The ASTM recommendation is to use a dispersivity that is one-tenth the plume length or distance of travel. Because the two wells are separated by 125 feet (38.3 m), the dispersivity resulting from adopting this recommendation would be 12.5 feet (3.83 m). We simulated this problem on an 80 by 40 grid using a single layer with this 12.5-foot (3.83 m) dispersivity as well as six other dispersivity values ranging from 1.64 feet (0.5 m) to 32.8 feet (10 m). The best curve match was achieved with a dispersivity of 12.5 feet (3.83 m) using the HMOC option (not shown). Using the FD option, the smaller 8.2-foot (2.5 m) dispersivity produced as good a fit as 12.5 feet (3.83 m) (Figure 10), implying that the optimal value

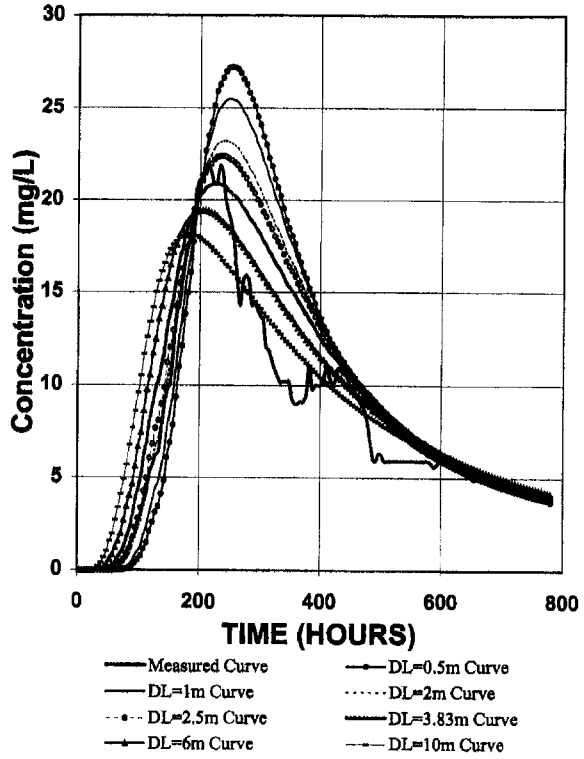

Figure 10. MT3D FD one-layer breakthrough curves for different dispersivities on 80 × 40 grid versus measured curve.

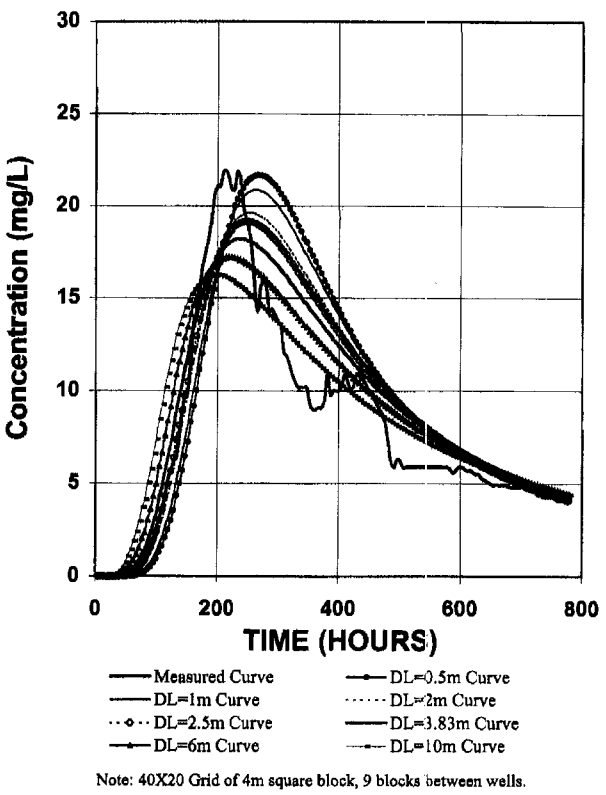

Figure 11. MT3D FD one-layer breakthrough curves for different dispersivities on 40 × 20 grid versus measured curve.

was somewhere between these two values. This slight disparity in the optimal dispersivity values makes sense given that the FD option has more inherent numerical dispersion than does the HMOC option, bringing the total dispersivity using the FD option into agreement with that used in the HMOC option.

To test whether we could use the ASTM standard dispersivity with a one-layer model and thereby dispense with characterizing the layering, we decreased the grid density to 40 by 20 (with nine blocks between the well blocks) and repeated these runs. After all, a modeler does not automatically know how many grid blocks to use in modeling a particular domain. Figure 11 shows that peak times are later and peak heights are lower for the curves from the 40 by 20 grid than those for corresponding curves on an 80 by 40 grid. The lower peak heights are due to increased numerical dispersion caused by the larger grid blocks. The shift in the predicted breakthrough curves caused by using a different grid density resulted in a different best-fitting curve on the 40 by 20 grid than on the 80 by 40 grid. (Although none is a good fit, the curve for a dispersivity of 1.64 feet [0.5 m] seems closest.) While these assessments of the best-fitting curves are qualitative, the important point is that one cannot arbitrarily pick a dispersivity for a one layer simulation and achieve a good fit. The dispersivity that produces the best fit at one grid density will not always be the best choice at a different grid density. Hence, the use of too few layers leads to loss of predictive power.

Decreasing the number of layers used to describe the vertical variation of horizontal hydraulic conductivity in the aquifer while trying to match the measured curve required increasing the dispersivity (e.g. for a one-layer simulation, multiplying by a factor of 3 to 26). This multiplicative factor depended strongly upon the number of layers, the grid spacing and the numerical transport simulation option chosen. Predictive power was lost when the model used insufficient hydrogeological detail.

The breakthrough curve was sensitive to changes in the rate of pumping and injection. When this rate was increased by 20%, the peak height increased by about 20% and the breakthrough occurred earlier. When the rate was decreased by 20%, the peak height decreased by about 20% and breakthrough was delayed.

This forced-gradient tracer test in a confined aquifer is perhaps the simplest tracer test to simulate with predictive power. A natural-gradient tracer test conducted over longer times and distances would be a greater challenge to successfully predict because one would also have to account for changes in the hydraulic gradient and for lateral changes in horizontal hydraulic conductivity. If a natural-gradient test were conducted in a water-table aquifer one would also have to account for recharge as a function of space and time. A tracer test in a fractured aquifer or in a karst setting would be even more challenging to simulate given the difficulty of characterizing the hydrogeology. Perhaps the most challenging conservative tracer test to simulate would be a multiphase flow situation with tracers in both the water and NAPL phases. The likelihood

of successfully predicting tracer movement in the multiphase case would be small given the difficulty of characterizing the multiphase flow relationships in heterogeneous aquifers. If the tracers used were nonconservative due to biodegradation, sorption, or other abiotic processes, the tracer test breakthrough curves would become virtually impossible to predict quantitatively.

Interestingly, the results of the most complicated tracer experiment are probably easier to predict than the breakthrough curves at typical contaminant sites. At many sites the contaminant source strength over time and space is unknown, and the hydrogeology can only be inferred using boring logs from the dozen or so wells present and the past plume positions over a few years. We often use a snapshot of the contaminant concentration as an instantaneous source because we cannot accurately reconstruct the contaminant input as a function of time and space. But even in an optimal case with a dense 3D network of more than 5000 sampling points—Waterloo's Borden aquifer site—Freyberg (1986) and Roberts et al. (1986) could only partially reconstruct the known masses of the original release using the detailed snapshot of two conservative salt tracers. Using an assumed constant concentration or flux source in a model without corroborating data is likely to be even less accurate than using a snapshot of the concentrations.

Summary and Conclusions

In conclusion, given sufficient time, budget, training, hardware, and an ideally characterized site with known contaminant input, all four MODFLOW-based transport models tested can predict breakthrough as accurately as a previous generation of research software. Predictive power is possible in a model only if it captures sufficient hydrogeologic details. If we have adequately characterized the hydraulic conductivity distribution for a 3D case, a small estimated dispersivity value can be used while preserving predictive power because the advective flow field can be modeled in detail and dispersion represents only a small part of the overall contaminant movement. Aquifers are often inadequately characterized, necessitating use of a larger dispersivity to compensate for ignorance of the true velocity field. Predictive power is lost when a large estimated dispersivity is used. Another difficulty for modelers is that we rarely know the contaminant input function at real sites. When the hydrogeological and chemical characterization data are less than ideal, transport models are less able to predict breakthrough and therefore should be used more qualitatively.

Dampening of Transverse Dispersion in the Halocline in Karst Limestone in the Northeastern Yucatan Peninsula

by Ronald K. Stoessell[a]

Abstract

A range of hydrodynamic dispersion coefficients was estimated for fracture-fluid and combined fracture and pore-fluid flow within the halocline of the limestone aquifer forming the surface of the northern Yucatan Peninsula. The coefficients are fit parameters in a model reproducing observed halocline profiles in a sinkhole and in a borehole near the northeastern coast. Fitted coefficients range from 10^{-7} to 10^{-4} cm^2/sec, of which molecular diffusion, without transverse (vertical) dispersion, can account for 10^{-7} to 10^{-5} cm^2/sec. The mechanical stability of the vertical density gradient in the halocline dampens transverse dispersion in pore fluids and in fracture fluids that are transitional between laminar and turbulent flow. The dampening is proportional to the ratio of the energy needed for the fluid to rise and displace a less dense fluid to the vertical component of the kinetic energy of the fluid. The ratio of these two energies is at a maximum during the initial stage of development of a halocline and decreases as the halocline widens.

Introduction

The northern Yucatan Peninsula (Figure 1) is a flat, low-lying, semitropical, Cenozoic limestone platform, having karst topography and lacking through-flowing rivers. Annual rainfall ranges from 0.5 m along the northern coast to 1.5 m along the eastern coast. The dimensions of the region are about 320 km east-west and 200 km north-south, with a maximum surface elevation of about 30 m (Back and Hanshaw, 1976). The peninsula is the site of rapid growth in population due to the developing tourist industry.

The surface limestone aquifer serves as the fresh-water aquifer for the peninsula. This aquifer contains a narrow fresh-water lens overlying saline water (sea water modified by water-rock interactions). The hydraulic head of the ground-water table at Chichen Itza, in the center of the peninsula (Figure 1) and 150 km from the eastern coast, was only 1.2 and 1.4 m above mean sea level in 1924 and 1966 (Back and Hanshaw, 1976). These hydraulic heads correspond, respectively, to 48 and 56 m thick fresh-water lenses in static, isostatic equilibrium with underlying sea water; although, the actual thickness will differ because the system is not static and perhaps not in isostatic equilibrium (Moore et al., 1992). The fresh-water lens thickness decreases towards the coast, becoming 30 and 18 m thick at Cenote Angelita and cenote Chemuyil, respectively, which are 12 and 6 km inland from the northeastern coast (Figure 1).

The coastal water-table elevation varies on the order of 0.1 to 0.2 m between rainy and nonrainy seasons; however, the total thickness of the coastal fresh-water lens does not vary significantly between seasons or on a yearly basis (Moore et al., 1992; Stoessell et al., 1993). The daily tidal range along the Caribbean coast is about 0.3 m and does not appear to affect the water-table elevation or the thickness of the fresh-water lens at distances greater than 2 km inland from the coast (Moore et al., 1992).

The limestone aquifer is a dual-porosity rock containing fractures and pores. In agreement with Wilson (1989), the author envisions fracture-fluid flow dominating over pore-fluid flow in the ground-water system. Fluids within the pores are likely to intersect fractures and join the fracture flow. Although some fracture fluids move out of the fractures into pores, the bulk of fracture fluids move within the fractures towards the coast. Fluids within the rock pores in the coastal region may have had significant fracture-flow portions of their travel path from the interior of the peninsula.

Received October 1993, revised April 1994, accepted October 1994.

Recently, Moore et al. (1992) reported measured average linear ground-water velocities in large fractures along the northeastern coast of the Yucatan Peninsula. The maximum measured fracture-flow velocities in fresh water increased from 1 cm/sec to 12 cm/sec along a 10 km coastward traverse, from Cenote Carwash to Cenote Tancah, along the Caribbean coast (Figure 1). This increase is presumed to result from the coastal wedging-out of the fresh-water lens as well as increased funneling of ground water from smaller fractures into larger fractures as the coast is approached (Moore et al., 1992). The fracture-fluid velocities are high values for ground-water flow; however, Worthington (1993) argues that the velocities within the fractures should be even higher.

Moore et al. (1992) also estimated average linear water velocities in pore fluids from point-dilution tests in an uncased borehole 2.6 km from the coast. These represented maximum velocity estimates and were 0.02 cm/sec in the fresh-water lens and 0.08 cm/sec in the underlying sea water, reflecting the nearby presence of a fracture. These two pore-fluid velocities are point measurements and are not necessarily representative of the pore-fluid environment.

The zone of brackish water separating the fresh water from the underlying saline water is called the halocline. The halocline thickness is surprisingly narrow, only 1 and 1.5 meters in width in Cenotes Angelita and Chemuyil, about 12 and 6 km, respectively, from the coast and 150 km from the interior of the peninsula (Figure 1). The narrowness of the haloclines suggests that diffusion, a slower process than transverse dispersion, is primarily responsible for their development. A less dense fluid (fresh water) overlying a more dense fluid (saline water) may act to dampen transverse dispersion.

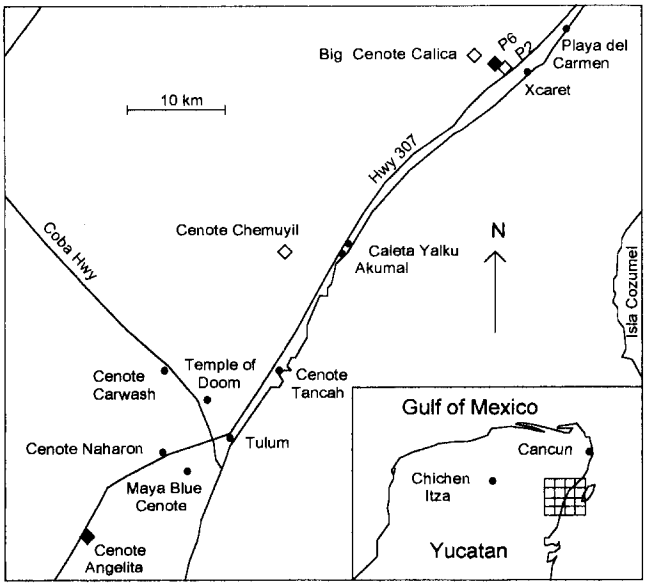

Fig. 1. Location map of the study area showing the sampling sites (marked with a diamond) for the depth-salinity profiles in Figure 3.

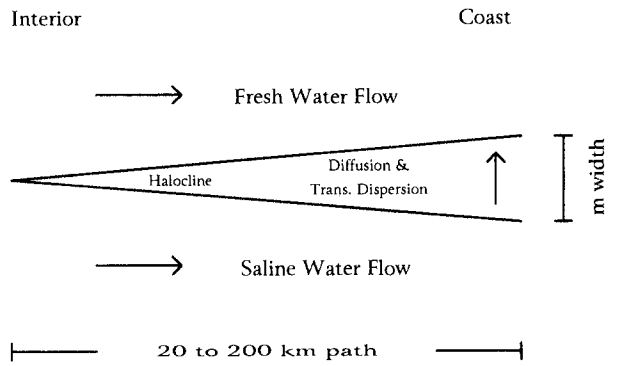

Fig. 2. Schematic model of the development of the halocline between underlying saline waters and overlying fresh waters.

Pollution problems are expected to increase in the fresh-water aquifer as the population increases. Pollutants injected in saline waters below the halocline may cross into the overlying fresh waters. In the absence of vertical advection, the rate of crossover will be controlled by transverse dispersion and molecular diffusion. For modeling purposes, the effects of these two processes are usually combined into the hydrodynamic dispersion coefficient, the parameter estimated in this study.

There are two purposes to this study. The first is to use the observed depth-salinity in a sinkhole and within a coastal borehole to estimate hydrodynamic dispersion coefficients. The second is to use these coefficients to assess the relative importance of diffusion versus transverse dispersion in developing the halocline and explain the apparent dampening of transverse dispersion.

Model Description and Assumptions

The simple molecular diffusion and transverse dispersion model is shown schematically in Figure 2. The fresh water and underlying saline water are assumed to flow horizontally towards the coast, from the interior of the peninsula, at equal velocities. Initially, the two ground-water zones are separated by a sharp interface. As the ground water flows coastward, molecular diffusion and transverse dispersion widen the interface into a brackish zone or halocline. Aquifer heterogeneity produces transverse dispersion during pore-fluid flow, and transitional turbulent flow produces transverse dispersion during fracture-fluid flow. Because transverse dispersion involves nonhorizontal fluid movement, a minor amount of vertical movement is included in the model in transverse dispersion.

Estimated path lengths of ground-water movement and a range of average linear flow velocities, constrained by field measurements, set limits on the time available for developing the brackish zone. The model is not intended to be used within a few km of the coast where wedging-out of the fresh-water lens has significantly increased fresh-water velocity, and tidal pumping causes vertical mixing.

The assumption that the underlying saline waters are not static and move towards the Caribbean Sea is consistent

with the saline waters, near the halocline, acting as the return arm of a sea-water convection cell (Cooper, 1959; Whitaker and Smart, 1990; Moore et al., 1992). The assumption of equal velocities of the underlying saline waters and the overlying fresh waters is an approximation suggested by the observed salinity-depth profiles at some of the field sites. If the saline waters are static or moving significantly more slowly than the fresh waters, diffusivity processes will result in a steeper depth-salinity gradient in the saline portion compared to the fresh-water portion of the halocline.

The depth-salinity gradient in the halocline can be modeled independently of horizontal flow if the saline waters and overlying ground water are moving at nearly equal velocities. Longitudinal dispersion can be neglected because of the large flux of solutes in the horizontal direction (Sudicky and Frind, 1981; 1982). The distribution of dissolved salts in a vertical column of water, at a given point along the horizontal ground-water flow path, is assumed to have resulted from molecular diffusion plus transverse dispersion. The model calculates the halocline width and vertical salinity gradient using estimated flow-path times.

Observed Salinity-Depth Profiles

Salinity-depth profiles, taken near the end of the dry season from 1990 to 1993, are shown in Figure 3 for several cenotes and for two coastal boreholes, located approximately 150 km from the center of the peninsula. The data are from the hydrology study by Moore et al. (1992), the water-quality studies by Stoessell et al. (1993) and Marcella (1994) and an unpublished 1992 study by Ron Stoessell. The salinities have been computed from conductivity measurements and calibrated with analytical measurements of the compositions of water samples. The salinity-depth profiles do not vary from year to year, indicating stable steady-state conditions.

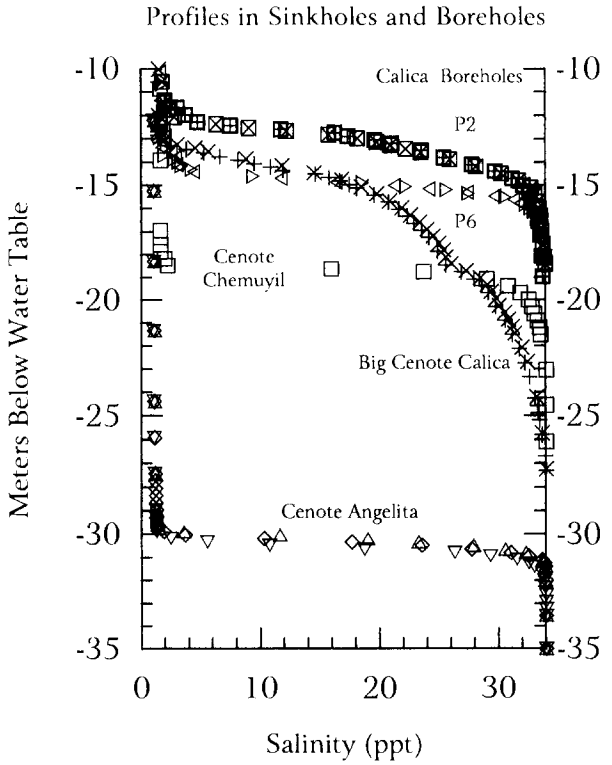

Fig. 3. Depth-salinity profiles at the following sites: Cenote Angelita (5/91, ▽; 4/92, △; 4/93, ◇), Cenote Chemuyil (4/92, □), Big Cenote Calica (4/92, ×; 4/93, +), Calica Borehole P2 (8/90, ⊞; 5/91, ⊠), and Calica Borehole P6 (8/90, ▷; 5/91, ◁).

The halocline profiles have similar shapes in Cenotes Angelita and Chemuyil and in Calica Boreholes P2 and P6. The distances from the coast for Cenotes Angelita and Chemuyil and Calica Boreholes P6 and P2 are about 12, 6, 3.6, and 2.6 km, respectively, and the halocline widths are approximately 1, 1.5, 2, and 3 m, respectively. The increased width in the halocline in the boreholes is generally due to the slower pore-fluid flow rates, providing more time for the haloclines to develop and perhaps to increased mixing in the less saline portion of the halocline as the fresh-water flow velocity increases towards the coast. Tidal effects would increase mixing in the more saline portion of the halocline and may be important in Borehole #2 which is the site closest to the coast.

At all sites, the average depth-salinity gradient is slightly steeper to much steeper in the more saline halocline zones, indicating the fresh-water flow velocity is greater than the saline-water flow velocity. In this study, the author has used the Cenote Angelita and Calica Borehole P6 sites where the gradients are **approximately the same** in both fresh-water and saline-water portions of the halocline. For these two locations, the resulting fit of the model to the data suggests the saline-water flow velocity approaches the fresh-water flow velocity in the vicinity of the halocline.

The data from Big Cenote Calica are included to show situations where simple diffusion and transverse dispersion cannot account for the salinity-depth distribution. Big Cenote Calica lies about 6 km inland from the coast (Figure 1). The discontinuity in the profile of the Big Cenote Calica is thought to reflect channeling of high salinity water in fractures within the halocline. The simple model used in this study does not fit the flow system at Big Cenote Calica.

Estimated Flow-Path Lengths, Average Flow Velocities and Flow-Path Times, and Turbulent Flow

The linear distance from the coastal region to the interior of the peninsula is about 150 km. Because the starting point for ground water reaching the northeastern coastal region is not known, a range in linear path lengths must be assumed. A range of path lengths of 20 to 200 km has been used in this study.

The measured average linear fracture-flow velocity 10 km from the coast was about 1 cm/sec which was the lower detection limit of the flow meter used by Moore et al. (1992). This value is greater than the average linear fracture-flow velocity from the interior, because it includes the effect of the coastal wedging-out of the fresh-water lens. For this study, I have assumed a range of average linear fracture-flow velocities from 0.05 to 0.5 cm/sec for ground water reaching Cenote Angelita. The range in time for ground water to

reach Cenote Angelita through fractures along pathways of 20 to 200 km is 0.1268 to 12.68 years.

As previously mentioned, less information is available on pore-fluid velocities. Complicating the problem is that a significant amount of the flow-path to a pore-fluid site probably occurred in fractures. For this study, the author has assumed the range of average linear flow velocities in the combined pore and fracture path leading to Calica Borehole P6 is an order of magnitude lower than in the fractures alone, or 0.005 to 0.05 cm/sec. The range of time for ground water to reach Calica Borehole P6 through the combined fracture and pore path along pathways of 20 to 200 km is 1.268 to 126.8 years.

The range in linear fracture-flow velocities of 0.05 to 0.5 cm/sec corresponds to 25° C Reynolds numbers for pure water of 55 to 555, respectively, assuming a fracture width of 1 cm. These values represent transition conditions between laminar and turbulent flow which occur at Reynolds numbers between 60 and 600 (Fetter, 1988). Within fractures the transverse dispersion results from turbulent flow.

Mathematical Model

The analytical solution to the diffusion plus transverse dispersion model for developing the halocline is given by Crank (1970, p. 12 and Fig. 2.3).

$$C_{(z,t)} - C_f = 0.5\,(C_s - C_f)\ \mathbf{erfc}[z/(4Dt)^{0.5}] \qquad (1)$$

where $C_{(z,t)}$ is the salinity at time t (sec) at a distance z (cm) from the original interface at time zero. The interface fluid maintains the average salinity of the two end-member fluids. C_s is 34 ppt, the initial salinity of the saline water. C_f is the initial salinity of the fresh water and is 1 ppt in Cenote Angelita and 2 ppt in Calica Borehole P6. D is the **fit parameter** in the model, the hydrodynamic dispersion coefficient which is the sum of the molecular diffusion coefficient plus the transverse dispersion coefficient. Selected values for **erfc**[z], the error-function complement are listed in Crank (1970, Table 2.1).

Results

The salinity data from Cenote Angelita and Calica Borehole P6 in Figure 3 have been replotted, respectively, in Figures 4 and 5 as a function of distance from the interface. The interface fluid has the average composition of the fresh water and saline water. The curves on Figures 4 and 5 have been computed from equation (1) for constant values, in cm units, of the equation parameter $(4Dt)^{0.5}$.

Curve b on Figure 4 provides the best fit to the Angelita data with an equation parameter of 40 cm. The parameter is used, with the previously estimated range in time for the ground water to reach Cenote Angelita of 0.1268 to 12.68 years, to calculate a range in D of 1×10^{-6} to 1×10^{-4} cm^2/sec. The estimated value of D is proportional to the linear ground-water velocity so that the maximum value corresponds to the maximum velocity of 0.5 cm/sec used in this study.

Curve b on Figure 5 provides the best fit to the Calica Borehole P6 data with an equation parameter of 65 cm. The parameter is used, with the previously estimated range in

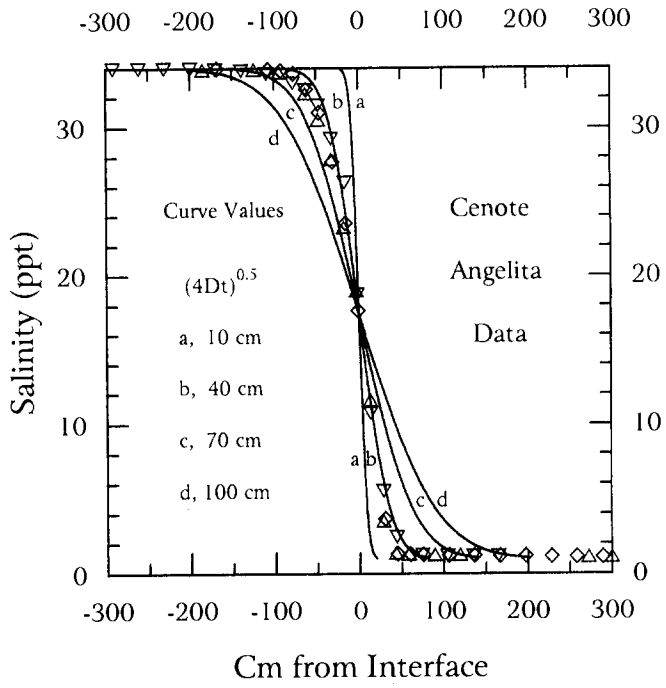

Fig. 4. Cenote Angelita salinities (5/91, ▽; 4/92, △; 4/93, ◇) plotted as a function of distance from the interface marking the average composition of fresh and saline waters. The solid curves were computed from equation (1) for constant values of $(4Dt)^{0.5}$.

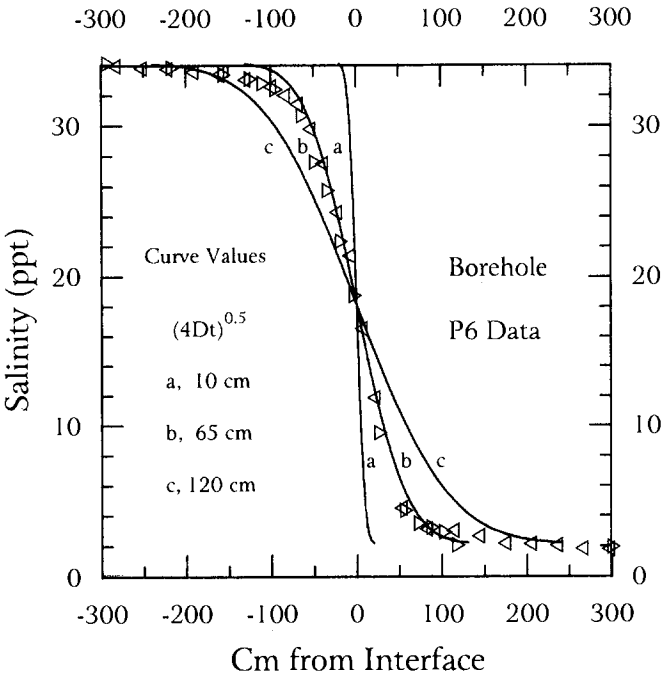

Fig. 5. Calica Borehole P6 salinities (8/90, ▷; 5/91, ◁) plotted as a function of distance from the interface marking the average composition of fresh and saline waters. The solid curves were computed from equation (1) for constant values of $(4Dt)^{0.5}$.

time for the ground water to reach Borehole P2 of 1.268 to 126.8 years, to calculate a range in D of 2.6×10^{-7} to 2.6×10^{-5} cm^2/sec.

The variability in the curves as a function of the equation parameter leads to an estimated error of less than 5 cm in picking the equation parameter which best fits the data. Taking this error into account increases the range in D to 2.3×10^{-7} to 1.3×10^{-4} cm^2/sec.

Discussion

The hydrodynamic dispersion coefficient can be split into the molecular diffusion coefficient D_m and the transverse dispersion coefficient D_t.

$$D = D_m + D_t \quad (2)$$

D_m in fluids has an expected value of about 1.5×10^{-5} cm^2/sec in an aqueous solution of 25° C which is the coefficient for NaCl diffusion in a 0.5 molar solution (Lerman, 1979). D_m in a porous or fractured medium has to be corrected for the solid matrix through which diffusion cannot occur. The correction involves multiplying the aqueous diffusion coefficient by the porosity fraction and dividing by the tortuosity squared (Stoessell, 1987). In the open-fracture pathway leading to Cenote Angelita, the porosity fraction is taken as one, the maximum possible value. In the combination fracture and pore system pathway leading to Calica Borehole P6, the average porosity fraction is taken as 0.5, an intermediate value between open fractures and the pores of the rock. The tortuosity, the ratio of the true path-length distance to the shortest distance, is assumed to range from 1 to 2 in the linear fracture system pathway leading to Cenote Angelita (Weidie, 1985) and between 2 and 3 in the combination fracture and pore system pathway leading to Calica Borehole P6. The overall tortuosity and porosity range corresponds to an overall range in D_m from 1.5×10^{-5} to 8.3×10^{-7} cm^2/sec. This range covers the lower portion of the estimated range in D, the hydrodynamic dispersion coefficient.

The maximum value of D_t, computed from equation (2) with the maximum estimate of D and the estimates of D_m, would be of the order of magnitude of 10^{-4} cm^2/sec. Hydrologists usually estimate D_t from the relation

$$D_t = a_t v \quad (3)$$

where a_t is the transverse dispersivity in cm, and v is the longitudinal (horizontal in this study) velocity.

Sanford and Konikow (1989a, 1989b) modeled Yucatan ground-water movement along the northeastern coast in a two-dimensional flow of a fluid of variable density through a heterogeneous, anisotropic, confined aquifer. Their model coupled equilibrium calcite dissolution with fluid flow to predict porosity development over tens of thousands of years. Sanford and Konikow used values of 50 cm for a_t, predicting steady-state vertical dimensions of the coastal haloclines between 20 and 40 m thick. These vertical dimensions are much larger than in the observed haloclines shown in Figure 3 and by Stoessell et al. (1989, Figure 3; 1993, Figure 2).

The maximum value of a_t, consistent with the maximum estimated value of D_t (for v equal to 0.5 cm/sec) is only 2×10^{-4} cm. This low value of a_t reflects the reduced effect of transverse dispersion, consistent with the observed haloclines having vertical dimensions of only a few meters.

The process of transverse dispersion in the halocline fluids requires packets of fluids to undergo vertical displacement. The path of the fluid packets is probably not vertical, but inclined at a small angle to the horizontal, resulting in a vertical displacement. However, the vertical density gradation in the halocline fluids is mechanically stable, with less dense fluids overlying more dense fluids. This mechanical stability dampens transverse dispersion, reducing the transverse dispersion coefficient.

The dampening effect on transverse dispersion in the halocline can be related to an energy ratio. Let N be the ratio of the displacement energy needed, for a unit volume of fluid to rise vertically a characteristic distance z and displace an equivalent volume of less dense fluid, to the vertical component of the kinetic energy possessed by the fluid.

$$N = g(p_f - p_{ldf})\, z/[0.5p_f(v_h \tan \alpha)^2] \quad (4)$$

p_f and p_{ldf} are the densities of the fluid and the less dense fluid respectively, g is the acceleration due to gravity, v_h is the horizontal fluid velocity, and α is the angle between the horizontal component of the flow velocity and the actual flow direction of the fluid packet undergoing dispersion. The term ($v_h \tan \alpha$) is the vertical component of the fluid velocity.

The larger the value of N, the greater the dampening effect on transverse dispersion. In this study N is at a maximum during the initial stage of formation of the halocline whan a sharp interface separates the overlying fresh water from the saline water (i.e., modified sea water). The maximum density difference would be between modified sea water and fresh water (with 1 ppt) with densities of about 1.025 and 1.001 g/cm^3, respectively. The angle α will be some small angle, assumed to be about 1 degree. For this situation with z equal to 1 micron (0.0001 cm), N ranges from 600,000 to 60 over the range of ground-water velocities used in this study, 0.005 cm/sec to 0.5 cm/sec. N is decreased by increasing the angle α and increased by increasing the vertical distance z. In a pore fluid, z would correspond to the grain diameter. Assuming α is 45 degrees and that z is one mm results in a range of N of 180,000 to 18 over the velocity range of 0.005 to 0.5 cm/sec.

As the halocline widens, the density difference decreases across z. At a density difference of 0.0001 g/cm^3, the range in N decreases from 2,500 to 0.25, assuming α is 1 degree and z is a micron. This decrease in N, as the halocline widens, reduces the dampening effect on dispersion, increasing the importance of transverse dispersion relative to molecular diffusion.

Data-Analyses Methods for Determining Two-Dimensional Dispersive Parameters

by Jiu J. Jiao[a]

Abstract

Two methods for calculating two-dimensional hydrodynamic dispersion parameters by analyzing experimental data, the dispersive-plume-area (DPA) method and the linear-graphic (LG) method, are proposed in this paper. The DPA method determines the dispersive parameters by analyzing the dispersive plume area after injection of a salt-water slug into an aquifer. The transverse and longitudinal dispersivity and even the porosity of an aquifer may be derived. The LG method transforms the concentration-time curve into a straight line. Using the slope of the line, dispersivity and velocity can be obtained. Both methods are examined using theoretical considerations and practical examples.

1. Introduction

Two methods of determining two-dimensional dispersive parameters are described in this paper: the dispersive-plume-area (DPA) method and the linear-graphic (LG) method. The DPA method uses concentration contours of a dispersive plume to estimate dispersive parameters. The concentration contours can be obtained from a multiple well observation system or through surface geophysical methods. If the plume is traceable by surface measurements, only a tracer injection well is needed, which could be more economical than the traditional multiwell monitoring network. This method is demonstrated using the data from a tracer test at a landfill near Borden, Ontario, Canada. The LG method requires concentration-time data from two wells, one along the main axis of flow and one off the main axis of plume migration. Using the values for maximum concentration and time, the method transforms the concentration-time curve into a straight line. From the slope of the line, dispersivity and velocity can be obtained. This method is demonstrated using tracer test data from a laboratory experiment.

2. Basic Equations

For this development, the aquifer is assumed to be homogenous and isotropic, and ground-water flow is one-dimensional. If the direction of flow is taken as parallel to the x-axis and a tracer injection point (well) is located at the origin, then the movement of the tracer plume after instantaneous injection into the aquifer can be described in rectangular coordinates by (Fried, 1975):

$$C(x, y, t) = \frac{m/\mu}{4\pi t(D_l D_t)^{1/2}} \exp\left[-\frac{(x - ut)^2}{4D_l t} - \frac{y^2}{4D_t t}\right] \quad (1)$$

where C is the concentration of the tracer point (x, y) and time t (ML^{-3}); D_l, D_t are the longitudinal and transverse dispersive coefficients, respectively (L^2/T); μ is porosity (dimensionless); m is the mass of the tracer injected instantaneously over unit thickness of the aquifer (M/L); u is the flow velocity (L/T).

The dispersive coefficients and dispersivities are assumed to conform to the relationship:

$$D_l = \alpha_l u \qquad D_t = \alpha_t u \quad (2)$$

where α_l, α_t are the longitudinal and transverse dispersivities, respectively (L).

3. Dispersion-Plume-Area Method

There have been several methods proposed to obtain two-dimensional hydrodynamic dispersion parameters from field experimental data (Fried, 1975), but each of these methods requires that the data be from a multiple well monitoring network in which one well is used for tracer injection and the other wells for collection of water samples.

[a]School of Civil Engineering, Birmingham University, P.O. Box 363, Birmingham B15 2TT, United Kingdom.

Received April 1991, revised August 1991 and March 1992, accepted April 1992.

Discussion open until July 1, 1993.

The disadvantages are that observation wells are expensive, and the process of obtaining concentration data is complicated. Also, monitoring wells should be located in a distribution downgradient of the injection well. Precise determination of the direction of the flow is difficult. Once a monitoring array is established and a tracer is injected into a well, if the estimated flow direction is incorrect, the tracer may move in a direction away from the observation wells.

The data-analysis method proposed in this section is called the dispersive-plume-area (DPA) method. This method does not require direct concentration data at given points, but only the overall movement of the dispersive plume of the tracer. The movement of the plume could be followed by surface electrical resistivity measurements which are cheaper than multiple well observation systems and can be easily adjusted for changes in direction of tracer movement. Surface resistivity measurements have been well-established by previous researchers. Fried (1975) used field examples to describe single well geophysical methods to determine ground-water velocities. MacFarlane et al. (1983) used an electrical conductance method to delineate the plume near a landfill in Borden, Ontario, Canada. White (1988) used surface resistivity measurements to determine the direction and velocity of ground-water flow and the hydraulic conductivity of an aquifer.

The DPA method is illustrated by using the data from a tracer test completed at a landfill near Borden, Ontario, Canada. The tracer test was made by Sudicky et al. (1983) who obtained the dispersive parameters using traditional analytical methods. The agreement between the parameters acquired by the DPA method and those by Sudicky et al. (1983) shows the new method is applicable.

3.1 Theoretical Development

Rearranging equation (1) yields:

$$\frac{(x-ut)^2}{4D_l t}+\frac{y^2}{4D_t t}=\ln\frac{m/\mu}{4\pi tC(D_lD_t)^{1/2}} \qquad (3)$$

This equation shows that the distribution of tracer in an aquifer takes the shape of an ellipse with its center at the point (ut, 0). The ellipse is moving forward with the speed u. Rearranging equation (3) expressions for lengths of the major and minor axes of the ellipse can be obtained:

$$a=[4D_l t\ln\frac{m/\mu}{4\pi tC(D_lD_t)^{1/2}}]^{1/2} \qquad (4)$$

$$b=[4D_t t\ln\frac{m/\mu}{4\pi tC(D_lD_t)^{1/2}}]^{1/2} \qquad (5)$$

where a, b are half lengths of the major and minor axes of the ellipse, respectively.

From equations (4) and (5), it is easy to determine:

$$a/b=(D_l/D_t)^{1/2} \qquad (6)$$

Equation (6) indicates that the ratio of the lengths of the two axes is a constant and reflects the difference in magnitude between the longitudinal and transverse dispersion coefficients.

The area of the ellipse enclosed by the contour with concentration C at time t can be described as:

$$S=\pi ab=4\pi t(D_lD_t)^{1/2}\ln\frac{m/\mu}{4\pi tC(D_lD_t)^{1/2}} \qquad (7)$$

Equation (7) can be rearranged as:

$$S=4\pi t(D_lD_t)^{1/2}\ln\frac{m/\mu}{4\pi t(D_lD_t)^{1/2}}-4\pi t(D_lD_t)^{1/2}\ln C \qquad (8)$$

Equation (8) indicates that at time t the relationship between the area S and the concentration C is linear in a semilogarithmic coordinate system. The slope of the line is:

$$k=-4\pi t(D_lD_t)^{1/2} \qquad (9)$$

Equation (9) can be rewritten as:

$$-k/4\pi t=(D_lD_t)^{1/2} \qquad (10)$$

Solving equations (6) and (10), D_l, D_t can be obtained. If one also measures the S = 0 intercept (let it be d = lnC) of the line, then equation (8) becomes:

$$-k\ln\frac{m/\mu}{-k}+kd=0 \qquad (11)$$

From equation (11), an expression for porosity can be obtained:

$$\mu=-m/(ke^d) \qquad (12)$$

If the value of porosity is known, equation (12) can be used to estimate the mass injected into the aquifer.

In addition, equation (7) can also be rewritten as:

$$S/t=4\pi(D_lD_t)^{1/2}\ln\frac{m/\mu}{4\pi C(D_lD_t)^{1/2}}-4\pi(D_lD_t)^{1/2}\ln t \qquad (13)$$

This shows that if the areas enclosed by contours of a given concentration can be obtained, the relationship between S/t and t is linear in a semilogarithmic coordinate system. A method similar to that described above can be used to estimate the dispersive coefficients after measuring the slope and intercept of the line.

3.2 Field Example

Near Borden, Ontario, Canada, a tracer test was conducted to investigate the migration of contaminants in ground water near a landfill by Sudicky et al. (1983). Approximately 0.7 m^3 of salt water with a chloride concentration of 580.7 mg/l was injected into the ground water. After injection, the tracer slug gradually split into two plumes moving forward with different velocities. One of them, with an average ground-water flow rate of 2.9×10^{-6} m/s, evolved into a Gaussian form. The spatial distribution of chloride after 121 days of transport is shown in Figure 1. The injection and observation well system, shown in Figure 1, consisted of nearly 70 monitoring points. After all the point concentration data was collected, Sudicky et al. (1983)

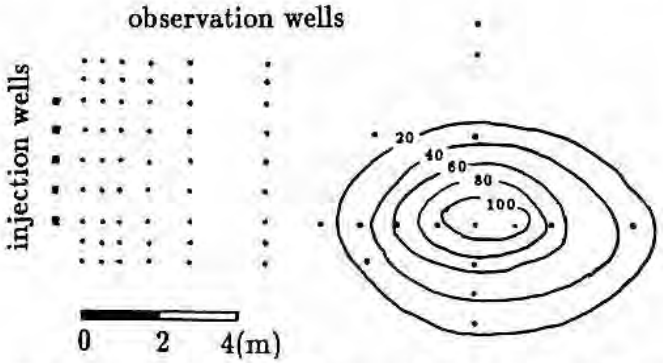

Fig. 1. Chloride distribution in ground water at the Borden Site 121 days after tracer injection [after Sudicky et al. (1983)].

obtained aquifer dispersivities by trial-and-error matching of observed data using an analytical solution:

$$\alpha_l = 0.08 \text{ m}, \qquad \alpha_t = 0.03 \text{ m}$$

The same problem can be solved by the DPA method. First, the lengths of the major and minor axes of the ellipse corresponding to different contours with different concentrations can be measured from Figure 1. After converting the scaled measurements to actual dimensions, the areas and ratios between the major and minor axes of the plume can be calculated. All these data are enumerated in Table 1.

A semilogarithmic plot of the calculated plume area versus concentration produced the relationship shown in Figure 2. The slope of the S-ln C line is measured as $k = -18.45$. Using equation (10) with $t = 121$ days yields:

$$D_l D_t = 3.102530 \tag{14}$$

From Table 1, an average value for a/b can be obtained. Then by using equation (6), one can have:

$$D_l / D_t = 0.000147 \tag{15}$$

Coupling equations (14) and (15), D_l and D_t can be calculated as:

$$D_l = 0.2138 \text{ (m}^2\text{/d)} \qquad D_t = 0.0069 \text{ (m}^2\text{/d)}$$

From field measurements the average velocity is known to be:

$$u = 2.9 \times 10^{-6} \text{ (m/s)} = 0.2506 \text{ (m/d)}$$

Then by using equations (2), one can have:

longitudinal dispersivity:

$$\alpha_l = D_l / u = 0.09 \text{ (m)}$$

transverse dispersivity:

$$\alpha_t = D_t / u = 0.03 \text{ (m)}$$

These results are very similar to those obtained by Sudicky et al., but the method is much simpler and more easily understood than the method used by Sudicky et al. (1983).

Table 1. Data for the DPA Method

a/b	C(mg/l)	a(m)	b(m)	lnC	$S(m^2)$
2.239	100	1.119	0.500	4.605	1.758
1.732	80	1.642	0.948	4.382	4.890
1.667	60	2.239	1.343	4.094	9.447
1.604	40	3.172	1.978	3.689	19.711
1.565	20	4.040	2.575	2.996	32.601

The concentration contours were obtained by analyzing water samples from the observation wells because the test monitoring network was designed for conventional tracer tests and other purposes of researching the aquifer. If the contours were obtained by surface resistivity measurements, then the whole process of data collection and analysis could be much more economical and simple.

4. Linear-Graphic Method

The method outlined in this section is called the linear-graphic (LG) method. It is also based on the use of equation (1) and is designed to estimate dispersivity and velocity. Wang et al. (1987) also developed a line graphical method to estimate dispersive parameters. After rearranging equation (1), Wang et al. found that there is a linear relationship between $H' [= d(\ln(Ct))/dt]$ and $T (= 1/t^2)$. The disadvantage of this method is that it is very difficult to perform the derivative computation H′ from actual data, which is usually very erratic and noisy. The LG method discussed in this paper uses the values of maximum C_m and corresponding time t_m and then, using much simpler procedures, transforms the observed concentration-time curve into a straight line.

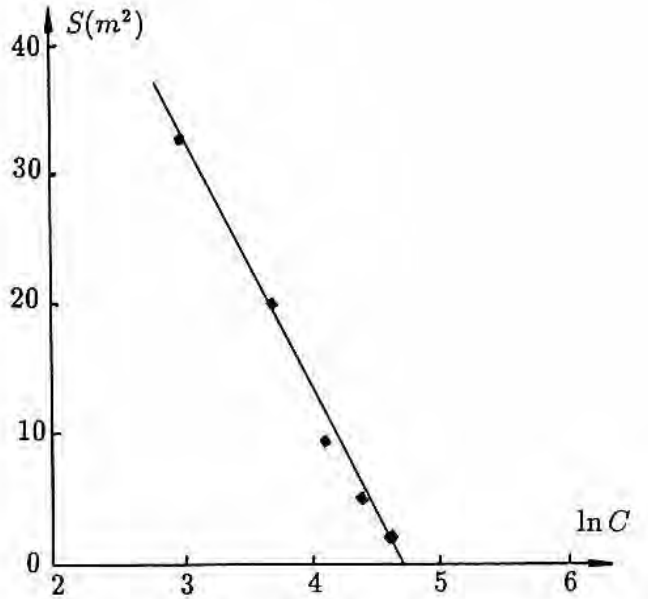

Fig. 2. Plot of S verse lnC developed from Sudicky et al. (1983) tracer dispersion study at the Borden site.

4.1 Theory Development

The theoretical development of the LG method requires taking the derivative of equation (1) with respect to t

$$C' = \frac{m/\mu}{4\pi t^2 (D_l D_t)^{1/2}} \left[\frac{x^2 - u^2 t^2}{4 D_l t} + \frac{y^2}{4 D_t t} - 1 \right] \exp\left[- \frac{(x - ut)^2}{4 D_l t} - \frac{y^2}{4 D_t t} \right] \quad (16)$$

The local maximum values for (1) are found by setting $C' = 0$:

$$\frac{x^2 - u^2 t^2}{4 D_l t} + \frac{y^2}{4 D_t t} - 1 = 0 \quad (17)$$

or

$$(x^2 - u^2 t^2) D_t + y^2 D_l - 4 D_l D_t t = 0 \quad (18)$$

If the time corresponding to $C' = 0$ is designated as t_m, then equation (18) becomes

$$t_m = \frac{D_l}{u^2} \left[\left(4 + \frac{u^2 x^2}{D_l^2} + \frac{u^2 y^2}{D_l D_t}\right)^{1/2} - 2 \right] \quad (19)$$

The concentration corresponding to t_m is noted as C_m. From equation (1), C_m can be solved as:

$$C_m = \frac{m/\mu}{4\pi t_m (D_l D_t)^{1/2}} \exp\left[- \frac{(x - ut_m)^2}{4 D_l t_m} - \frac{y^2}{4 D_t t_m} \right] \quad \ldots . (20)$$

If the observation point is located on the x-axis, then equation (18) is simplified as:

$$x^2 - u^2 t_m^2 - 4 D_l t_m = 0 \quad (21)$$

or

$$D_l = (x^2 - u^2 t_m^2)/4 t_m \quad (22)$$

which can be rewritten as

$$D_l = \frac{x^2}{4 t_m [u^2 t_m^2/(x^2 - u^2 t_m^2) + 1]} \quad (23)$$

letting

$$k = u^2 t_m/(x^2 - u^2 t_m^2) \quad (24)$$

equation (23) then becomes

$$D_l = \frac{x^2}{4 t_m (k t_m + 1)} \quad (25)$$

Substituting (24) into (22) and solving for u yields:

$$u = 2(D_l k)^{1/2} \quad (26)$$

Equations (25) and (26) indicate that D_l and u can be obtained if k is known. The parameter k can be obtained in the following manner:

Using equations (1) and (20) (letting $y = 0$) and rearranging,

$$\frac{C_m t_m}{Ct} = \exp\left[\frac{(x - ut)^2}{4 D_l t} - \frac{(x - ut_m)^2}{4 D_l t_m} \right] \quad (27)$$

or

$$\ln \frac{C_m t_m}{Ct} = \frac{(t - t_m)(u^2 t t_m - x^2)}{4 D_l t t_m} \quad (28)$$

Substituting (22) into (28),

$$\ln \frac{C_m t_m}{Ct} = \left(\frac{t - t_m}{t} \right) \left(\frac{u^2 t t_m - x^2}{x^2 - u^2 t_m^2} \right) \quad (29)$$

adding $(t - t_m)/t$ to both sides of the above equation and then rearranging the right-hand side, the following equation is obtained:

$$\ln \frac{C_m t_m}{Ct} + \frac{t - t_m}{t} = \frac{u^2 t_m}{x^2 - u^2 t_m^2} \frac{(t - t_m)^2}{t} \quad (30)$$

Equation (30) is the equation of a straight line of the form

$$Y = kX \quad (31)$$

where

$$\left.\begin{aligned} X &= (t - t_m)^2/t \\ Y &= \ln(C_m t_m/Ct) + (t - t_m)/t \end{aligned}\right\} \quad (32)$$

k is the slope of the straight line.

Procedures to estimate dispersive parameters using the LG method can be summarized as follows: read t_m and C_m from a C-t curve; calculate values of X and Y using equation (32); plot the transformed data and measure the slope k; calculate D_l and u using equations (25) and (26); then use data from an observation point (x', y') (not located on the x-axis) to obtain t_m'. The value of D_t can then be obtained from equation (18):

$$D_t = -y'^2 D_l/(x'^2 - u^2 t_m'^2 - 4 D_l t_m') \quad (33)$$

It should be noted that the relationship involving C_m and C in equation (32) is independent of the units used. Therefore, if the measured data are conductivity or resistivity instead of concentration, it is not necessary to transform the data to concentration values as long as the values are directly proportional to concentration.

4.2 Laboratory Example

Two-dimensional dispersion experiments were conducted at China University of Geosciences in 1986, using salt water as a tracer [for details see Jiao et al. (1988)]. The electrical conductivity (G) and time (t) data from one of the experiments is shown in Table 2. The corresponding curve is shown in Figure 3. The value of t_m can be read as 159.8 (min.). The distance from the tracer injection point to the observation point is 80 cm. The G-t data is transformed to X-Y data using equation (32).

The ascending and descending portions of the G-t curve (Figure 3) correspond to the two straight lines in the X-Y plane (Figure 4). The points a, o, b in Figure 3 correspond to the points a', o', b' in Figure 4. Theoretically, if the movement of the tracer does not violate any of the assumptions behind development of equation (1), the two straight lines should coincide. For this example, deviation of the

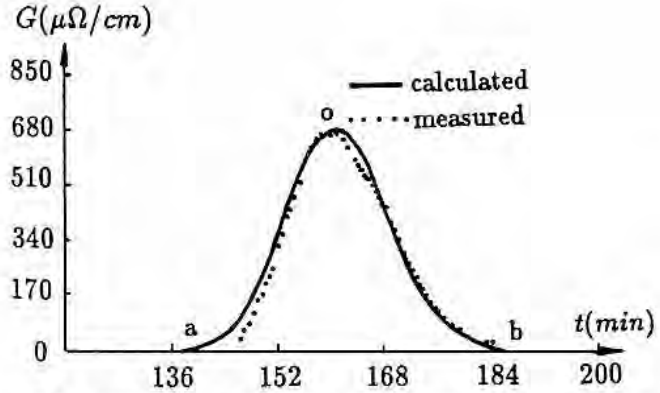

Fig. 3. Comparison of calculated and experimental conductivity changes as a function of time during a laboratory tracer dispersion study.

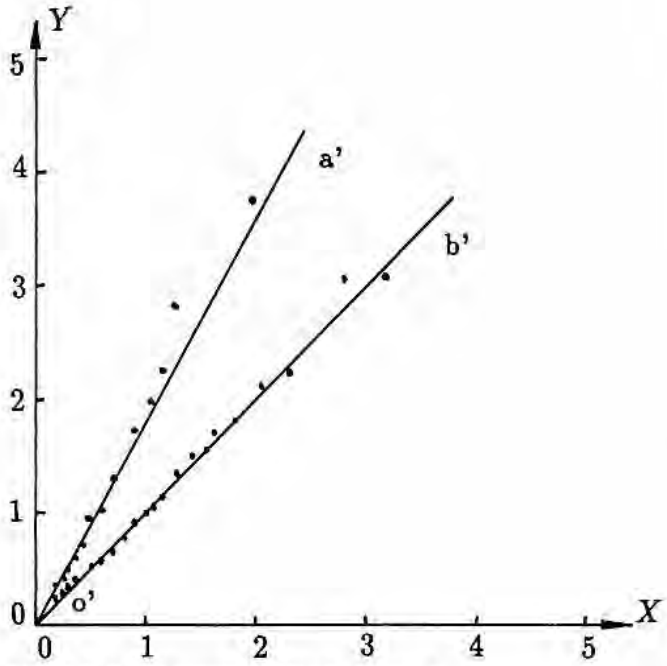

Fig. 4. X-Y line corresponding to Figure 3.

data points from the lines increases as X and Y increase. The deviation is an indication of the difference between the theoretical equation and the real situation. There are three possible explanations: (1) some of the assumptions for equation (1) may not be valid for this case; (2) the values t_m and C_m read from the C-t curve are not the exact values of t_m and C_m; or (3) the data are more erroneous at the time when the tracer first appears and at the time when it finally disappears at the observation point compared with the observed data near time t_m.

In this case, two slope values k_a (= 1.86) and k_b (= 1.0) are used. Employing equation (25) yields:

$$D_l = 80^2/[4 \times 159.8(159.8k_a + 1)] = 0.0335$$

Using equation (31):

$$u = 2(0.0335 \times k_a)^{1/2} = 0.4997$$

If k_b is used, then:

$$D_l' = 0.0622 \qquad u' = 0.4990$$

Averaged values of D_l and D_l', and u and u' are used as the final values $\bar{D}_l$ and $\bar{u}$

$$\bar{D}_l = (D_l + D_l')/2 = 0.0479(cm^2/min.)$$

$$\bar{u} = (u + u')/2 = 0.4993(cm/min.)$$

For this dispersion experiment, the observation points in the y direction were too far and did not intercept the tracer, so the data in the y direction were not available. D_t could not be obtained by using equation (33). Another method (Jiao et al. 1988) is used to obtain D_t to be 0.015 (cm^2/min.). Figure 4 shows that the fit between the real data and the calculated data is generally good.

5. Conclusion

Two methods of estimating dispersive parameters are described in the paper. The most interesting point in the DPA method is that for the first time it demonstrates that the aquifer dispersivities may be estimated by the shape of the dispersive plume, not necessarily the actual concentration. The example data in the text were collected with actual ground-water measurements, but the paper treats them in a way as if they were from resistivity measurements. So it may be reasonable to modify surface resistivity measurement methods to estimate aquifer dispersive parameters using the DPA method. This could be much more economical than using the traditional multiwell monitoring network to determine aquifer dispersive parameters. It may also be worthwhile to note that the DPA method does not necessarily need historical observation data (concentration-time data) which are often not available for field problems. In addition, it seems that this method can be used with data defining any plume resulting from instantaneous injection of a conservative material, even if the initial mass is not known. But it should be noted that the DPA method can only be used when the assumptions associated with equation (1) are valid, and the surface geophysical methods are applicable if the plume data are to be obtained through the surface measurements.

The LG method transforms the concentration-time curve into a straight line. Dispersivity and velocity can be estimated after measuring the slope of the line. This method is more economical and easier to perform compared to the method by Wang et al. (1987) which may suffer from the influence of erratic experiment data points on the derivative computation. On the other hand, the method in this paper is sensitive to the values of C_m and t_m. Attention should be paid to choose C_m and t_m properly.

Acknowledgment

The author gratefully acknowledges the advice given by Professor C. X. Chen in writing this paper. My thanks also to A. Hughes and B. Patel, as their comments resulted in an improved text. Comments from three anonymous reviewers were extremely helpful and appreciated.

AVAILABILITY OF BOOKS AND MAPS OF THE U.S. GEOLOGICAL SURVEY

Instructions on ordering publications of the U.S. Geological Survey, along with prices of the last offerings, are given in the current-year issues of the monthly catalog "New Publications of the U.S. Geological Survey." Prices of available U.S. Geological Survey publications released prior to the current year are listed in the most recent annual "Price and Availability List." Publications that may be listed in various U.S. Geological Survey catalogs (**see back inside cover**) but not listed in the most recent annual "Price and Availability List" may be no longer available.

Order U.S. Geological Survey publications **by mail** or **over the counter** from the offices given below.

BY MAIL

Books

Professional Papers, Bulletins, Water-Supply Papers, Techniques of Water-Resources Investigations, Circulars, publications of general interest (such as leaflets, pamphlets, booklets), single copies of Earthquakes & Volcanoes, Preliminary Determination of Epicenters, and some miscellaneous reports, including some of the foregoing series that have gone out of print at the Superintendent of Documents, are obtainable by mail from

U.S. Geological Survey, Information Services
Box 25286, Federal Center, Denver, CO 80225

Subscriptions to periodicals (Earthquakes & Volcanoes and Preliminary Determination of Epicenters) can be obtained ONLY from the

Superintendent of Documents
Government Printing Office
Washington, DC 20402

(Check or money order must be payable to Superintendent of Documents.)

ASR - UK: ELUCIDATING THE HYDROGEOLOGICAL ISSUES ASSOCIATED WITH AQUIFER STORAGE AND RECOVERY IN THE UK

FOREWORD

The term Aquifer Storage Recovery (ASR) was originally coined by David Pyne of CH2M-Hill in the 1980's to describe the technique of creating additional storage at existing water treatment works by injecting surplus potable, treated water into aquifers underlying the works. Injection is via dual-purpose, recharge/abstraction boreholes, often by adapting existing abstraction boreholes. The technique caught on in the US because it provided answers to questions, including:

- How do we meet growing demand without large capital investment in new surface reservoirs?
- How can we design schemes with acceptable impacts on the environment?
- How can we be confident of regulatory approval and avoid lengthy public enquiries?

The steadily increasing number of ASR projects across the US since the late 1980s is testament to the cost-effectiveness of the technique and its operational flexibility.

In the UK, the water industry became interested in ASR* as a real option in the latter part of the 1990s. This was partly, but not wholly, as a result of the higher national profile water resource planning took on since the summer of 1995 and the associated pre-AMP3 regulatory guidance on water resource options. Thus, from OFWAT, we had the useful guideline that options should be small-scale and cost-effective and from the Environment Agency the threefold criteria of sustainability, sustainability and sustainability.

Interest in ASR also came from UK hydrogeologists who realised that because the injected potable water displaces the native groundwater to create a "bubble," the technique could work successfully in unused, non-potable aquifers. Successful development of ASR schemes into saline aquifers in the Florida Keys ably demonstrated this principle. Clearly, an innovative way of utilising the storage potential in hitherto untapped UK aquifers had now opened up. In the era of planning for climate change this indeed represents a huge opportunity for creating sustainable storage.

ASR in the UK is currently progressing up the steep part of the learning curve. To date there have been several ASR pilot investigations but, as yet, no schemes have been commissioned. This initial phase of work has met with mixed success and has drawn out several technical issues and uncertainties, most of which have become the focus of this study.

From the water resource planning perspective, ASR has many plus points and is a key option in the Environment Agency's Water Resources Strategy for England and Wales. However, from an asset investment perspective the current technical uncertainties

around ASR mean that other options, more certain of success,** albeit possibly more costly and environmentally less sustainable, may be given higher priority. The outputs from this project will help greatly in providing a better understanding of the technical problems that may be encountered and thereby enable the design of an appropriate feasibility study, and staged development programme, to minimise risk of failure.

The outputs from this project consist of this summary report, a web site, interim technical reports and models on the web site and the attached CD, as well as several scientific publications. Together these provide greater understanding and analytical elucidation of the environmental impacts, yield potential and quality changes associated with ASR in UK aquifers.

Finally, for those water companies who believe that they will not need to develop new water resources over the next 25 years this project will be of academic interest only. However, for the rest of us I would suggest that assimilating the outputs of the project is a compulsory exercise. Whilst water resource strategists and planners need to understand the key messages herein, it will be the front-line practitioners, largely hydrogeologists, who will gain most from the project's technical findings and analytical tools. With AMP4 on the horizon, this jointly-funded project represents not only good value for money but is also a timely and needed addition to our planning armoury.

Brian Connorton

UKWIR technical member of project Steering Committee

---

* The term ASR has been adopted by UK hydrogeologists to describe recharging, hitherto unused or under-used aquifers, via dual-purpose, abstraction/recharge boreholes to create an ASR "bubble." In this regard ASR is a sub-set of artificial recharge. The latter is the generic term applied to any technique for transferring water into aquifers (intentionally or as a result of other activities) either indirectly through surface recharge basins or directly by borehole injection. Thus hydrogeologists tend not to refer to the large scheme in North London (NLARS) as an ASR scheme but rather as an artificial recharge scheme. This is because it has numerous injection points into a widely-used potable aquifer and the management principle is not so much to create a recharge bubble under each site, but to manage the aggregated recharge mound over a large extent of the confined Chalk aquifer.

** Success is here regarded as having achieved the designed deployable output at the budgeted cost and with the necessary regulatory approvals.

Executive Summary

Objectives

- Promote ASR through research into generic issues related to risks that are currently constraining development of ASR to British aquifers, namely:

  – impacts of the dual-porosity behaviour of the Chalk and other aquifers on recovery efficiency

  – geochemical interactions; water/water and water/rock in different aquifers

  – environmental impacts in relation to operational cycles

- Facilitate the exchange of information through the usual media as well as the Internet. Convene annual national symposia on ASR for the water suppliers, regulators and researchers and support a strong presence at international fora.

Conclusions

- British aquifers can be considered as part of a continuum ranging from single porosity unconsolidated aquifers (e.g. Lower Greensand) to fractured dual-porosity aquifers (Chalk).

- The response of these aquifers to ASR varies in a predictable manner that is controlled by the proportion of fracture and matrix porosity, both from the physical mixing and geochemical interaction perspectives. This aquifer 'continuum' and the impact trends are illustrated below.

Increasing <u>single</u> porosity Character

- "bubble" of injected water
- mixing limited to edges of "bubble"
- less interaction with native water
- stronger injection water-rock interaction

Increasing <u>dual</u> porosity Character

- more diffusive exchange
- larger mixing area
- strong native component in recovered water
- stronger chemical interaction between the two waters

- The conclusions from the work undertaken in this study give generic indications of how aquifers will respond to ASR. Because of geological variability, it must be stressed that this is only intended to act as a basis for site-specific assessments. Some modelling tools have been developed to assist in these assessments.

Recommendations

- As data become available from trials in the Sherwood Sandstone and Lower Greensand aquifers it should be used to refine the physical and geochemical models, provide relevant feedback and compare results with those from the trials.

- Apply relevant models developed by this project to current and prospective ASR schemes to assist in decision making, particularly in relation to the environmental impact assessment.

- The modelling has identified the parameters that are of most significance in a variety of hydrogeological environments. There are very few measurements of some key parameters, such as aquitard properties, and a database needs to be compiled in order to facilitate future developments.

Benefits

- A clearer understanding has been gained of the response of British aquifers to ASR from both the physical and geochemical perspectives.

- Simple modelling tools have been developed (supplied with this report) to assist in decision-making from the early stages of ASR schemes. These tools are designed to help assess the environmental impacts of the scheme and to identify the parameters that need to be determined in order to proceed.

- Physical (SWIFT) and geochemical (PHREEQC) models have been applied to ASR schemes and an initial attempt to link the two was made. This will form the basis for improved understanding of the processes determining the efficiency of ASR scheme as more are developed in different aquifers.

- Regulatory considerations have been reviewed with respect to ASR in the light of new and forthcoming EU Directives and their implementation.

Contents

1 Background and aims of the project

The results of a study, funded by BGS, UKWIR and EA, and undertaken between 1995 and 1998, indicated that there is a large potential for development of Aquifer Storage Recovery (ASR) schemes in the UK at a wide range of scales (Jones et al., 1998). The study stimulated considerable interest and, at that time, three water companies had initiated field trials. Several other schemes were at the desk study stage.

Experience from the United States shows that ASR is frequently a cost-effective solution to a wide variety of water supply, as well as water quality problems. The potential of the technology in Britain needed to be more fully evaluated, in order to optimise the use of our water resources, both fresh and wastewater. However, several uncertainties were highlighted by this study that could constrain the acceptance and utilisation of ASR as a component in strategies for sustainable management of water resources.

The project reported here, ASR-UK, addresses some of the issues identified through generic research and the development of guidelines and models to assist in decision-making throughout the investigative, development and implementation stages of schemes. The issues addressed are:

- Research into the controls on dispersion and diffusion of injected water and their impacts on recovery efficiency. Models were developed to predict the extent and movement of "bubbles" of stored water in aquifers as well as changes in water quality with time. Work initially focused on the Chalk aquifer but other aquifers were also investigated.

- The impacts of geochemical interactions between native and injected water as well as water-rock interactions. The adverse as well as the beneficial effects need to be predicted in order to address them in the most cost-effective manner. The project therefore aimed to assess the significance of these reactions on the permeability of aquifers, the quality of recovered water and the efficiency of schemes.

- During the life of the project, the importance of the environmental impacts of ASR schemes, in relation to the operational cycle used, became increasingly apparent. Quantification of these impacts is required throughout all phases of a study, from the initial assessment of the potential of a site, through the staged testing to implementation and commissioning of a scheme.

The project was designed to address these issues through review of current knowledge and the application and development of models, some of which can be used as tools in current and future investigations. It was initially planned that the development of these models would be closely aligned with on-going investigations and field trials, which would provide data to validate the models as well as providing feedback to the investigation. This proved to be the case with the investigations in the Chalk aquifer but little data were available from other aquifers.

2 ASR – using aquifers to store water in the UK

2.1 Introduction

Artificial Recharge (AR) is a means of supplementing natural infiltration into an aquifer; it involves storing water in an aquifer at times when there is a surplus, potentially for use at times of scarcity. Traditionally, the technique has utilised aquifers containing potable water.

Artificial recharge is defined here to include any technique used to introduce water into an aquifer, via boreholes or basins, for any purpose. It can be used strategically where an aquifer is already over-exploited, such that no further abstraction would be allowed without artificial recharge taking place, or where lack of natural recharge prevents its utilisation. In these cases, the water could be abstracted from the same wells as used for injection, or from additional wells or natural discharges down hydraulic gradient. This technique is employed only in potable aquifers, as the water being abstracted is not necessarily the same water that was injected. The net water balance would however be zero or positive.

Artificial recharge has been carried out in many forms for centuries. A more recent development occurred around 50 years ago, when the first investigations of injecting potable water into saline aquifers were carried out (Cederstrom, 1957). This involved recharge of freshwater into the brackish aquifers of the coastal plains of Virginia in 1946; the injected water forming a lens or bubble of potable water within the saline body of groundwater. This practice has become known as Aquifer Storage Recovery (ASR).

Pyne (1995) defines ASR as:

> The storage of water in a suitable aquifer through a well during times when water is available, and recovery of the water from the same well during times when it is needed.

The use of non-potable aquifers greatly increases the potential for using artificial recharge, and in the last couple of decades, the concept has been developed widely in the United States. However ASR is not a proven technology for UK aquifers, which can be quite distinct from aquifers that are used in the USA. The risks have been perceived as being too great to consider development of such schemes in the UK but, in recent years, several trial schemes have been undertaken, and the data and experience gained from these, are providing valuable support for the technique.

Areas where ASR are most likely to be considered in Britain would be in confined parts of aquifers that have not been used for productive water supply because of poor quality. It follows that little hydrogeological information is available, so embarking on a scheme becomes more speculative and the risk factors increase. Use of potable aquifers at outcrop for ASR schemes is less likely to occur as the aquifer may be fully licensed, natural recharge will occur and the groundwater-surface water interaction will be more immediate, and hence have environmental impacts. However, each case needs to be judged on its individual merits as ASR schemes can store valuable quantities of water in relatively small volumes of aquifer, so local hydrogeological environments could prove to be suitable.

2.2 Application of ASR

There are a large number of possible applications for ASR, some of which are listed in Table 2.1. It is envisaged that in the UK, ASR will typically be used to meet short-term peaks in demand by recharging aquifers during periods of low demand and recovering the water during periods of high demand. ASR should always be viewed in the context of alternative methods of resolving water supply or quality issues, as part of a broader strategy. In particular, the environmental benefits should be factored into the decision process.

Table 2.1 Applications of ASR (adapted from Pyne 1995)

Category	Application
Water storage	- Seasonal storage and recovery
	- Long term storage
	- Emergency storage
	- Diurnal storage
Water quality	- Chlorination by-product removal
	- Nitrate removal
	- Stabilisation of aggressive water
	- Control of contaminant plumes
Environmental improvement	- Restoration of groundwater levels, 'low flow' rivers and groundwater fed wetlands
	- Reduction of subsidence
	- Reduce/prevent saline intrusion
	- Enhancement of baseflow to streams
Operational advantages	- Maintenance of distribution system pressure and flow
	- Deferment of the expansion of treatment facilities
	- Deferment of the development of new sources

Ideally, ASR sites should be located in a confined, single porosity aquifer at sufficient distance from the outcrop to have an acceptable impact on flows in streams. The delay of this impact can be engineered to have maximum effect during periods of high stream flow, when it becomes insignificant. Sub-vertical hydraulic boundaries or a moderate value of transmissivity, are needed to constrain the distance at which the effects of injection and recovery are significant. A readily accessible source of water for injection is also needed and access to an existing treatment works could be important if the recovered water is not wholly potable. As with the development of a conventional groundwater supply, the site-specific factors determine its impact on the environment, the resource and other users. These issues also need to be addressed in ASR schemes,

together with those specifically pertinent to ASR, in order to optimise the management and use of water resources.

2.3 Drivers for the use of ASR in the UK

The aquatic environment is regulated by the Environment Agency in England and Wales, the Scottish Environment Protection Agency (SEPA) and the Department of the Environment for N. Ireland. Their agendas are determined by implementation of the regulations established by government, in order to comply with EC Directives, notably the Water Framework Directive (2000) and the Habitats Directive (1997).

Demands for water from a wide variety of users have to be accommodated. These include not only the Water Companies for potable supply and effluent dilution but also navigation, fisheries, irrigation as well as private and industrial abstractions. Environmental demands also have to be met to ensure acceptable river flows and maintenance of wetland habitats.

Demand management techniques such as leakage reduction, metering, industrial reuse, consumer use reduction and other water saving techniques have been successful but become less applicable as the cost/benefit ratio increases. In many areas the available water resources are fully licensed and in some cases the impacts of abstraction will result in the need to reduce or surrender a licence to abstract groundwater.

The options for replacement of these sources are limited, particularly where environmental concerns are valued highly. Construction of surface impoundments tend to meet strong opposition on the grounds of loss of land, habitats and negative environmental impacts and can take decades to come to fruition. Although construction of an additional borehole source can be relatively rapid, this option is often precluded on the grounds that aquifers are fully licensed or that the impacts on surface water and wetlands are unacceptable. Construction of pipelines to improve distribution networks, or importing water from considerable distances need to be assessed on their cost-effectiveness. The number of viable schemes will tend to diminish with time as the most cost-effective schemes are implemented.

Schemes such as desalination and wastewater reuse are high cost options that are usually only viable in small, limited and exceptional circumstances. In comparison, ASR becomes an increasingly attractive option, the main advantages being:

- Minimum environmental impact as the net water abstraction is zero or negative
- Installations can usually be located at or near where storage/demand problems need to be addressed
- Staged development to spread costs and to meet increasing demand
- Costs are usually less than alternative schemes
- *In-situ* improvements in water quality can reduce the need for treatment on abstraction

ASR is therefore a sustainable water resources and quality management technique that can be applied to address a wide range of problems as part of a broader water management strategy.

2.4 Potential for ASR in the UK

2.4.1 Introduction

There is a limited history of artificial recharge schemes in Britain. These include trial schemes on the Triassic sandstones at Clipstone and Edwinstowe (IWES, 1986) and at Stourbridge (Jones, 1983), and on the Lower Greensand at Hardham (O'Shea, 1984). However, the North London Artificial Recharge Scheme (NLARS), which recharges the Chalk and the overlying Tertiary sands, is the only major operational scheme. In more recent years, trial ASR schemes have provided data and experience on British aquifers, most notably the trials in the Chalk in East Anglia and the extensive testing programme in the Chalk at Lytchett Minster, Dorset.

Currently trials are being undertaken on the Sherwood Sandstone aquifer at Loftsome Bridge in Yorkshire and on the Lower Greensand aquifer at Stockbury in Kent. In addition, several agricultural supply schemes have been developed in the Nottinghamshire where groundwater is abstracted from the Permian limestone and stored in the overlying Sherwood Sandstone for later use as irrigation water. Yeilds from boreholes in the limestone are insufficient to meet the short-term intensive requirements and, as the Sherwood Sandstone aquifer is fully licensed, abstraction can only be permitted subsequent to addition of water; the net abstraction being zero or negative.

A regional assessment of ASR potential of the aquifers in England and Wales was carried out by Jones et al. (1998). Within the scale of the assessment, it was not possible to consider the potential for ASR in each of the minor aquifers, and therefore the study focused on the majors aquifers (Table 2.2). This does not mean that all minor aquifers should be dismissed, as they can be important on a local scale. Figure 2.1 shows the locations of the major aquifers in the UK together with the locations of ASR, and other Artificial Recharge investigations.

2.4.2 Chalk and Upper Greensand

The Chalk, in hydraulic connection with the Upper Greensand in some areas, is an important aquifer over much of southern and central England. Although porosity is high (up to 40%), the pore throats are narrow, and most of the usable storage is within the fractures and larger pores. As a result, the Chalk frequently has high transmissivity, but low storage coefficient, resulting in high diffusivity, so the impact of ASR schemes on the aquifer at outcrop needs to be carefully assessed. Where the Chalk is in hydraulic continuity with overlying deposits (e.g. the drift in East Anglia, or the Palaeogene in the London Basin) or underlying formations (e.g. the Upper Greensand), storage is increased, and the combined aquifer may have enhanced potential for ASR.

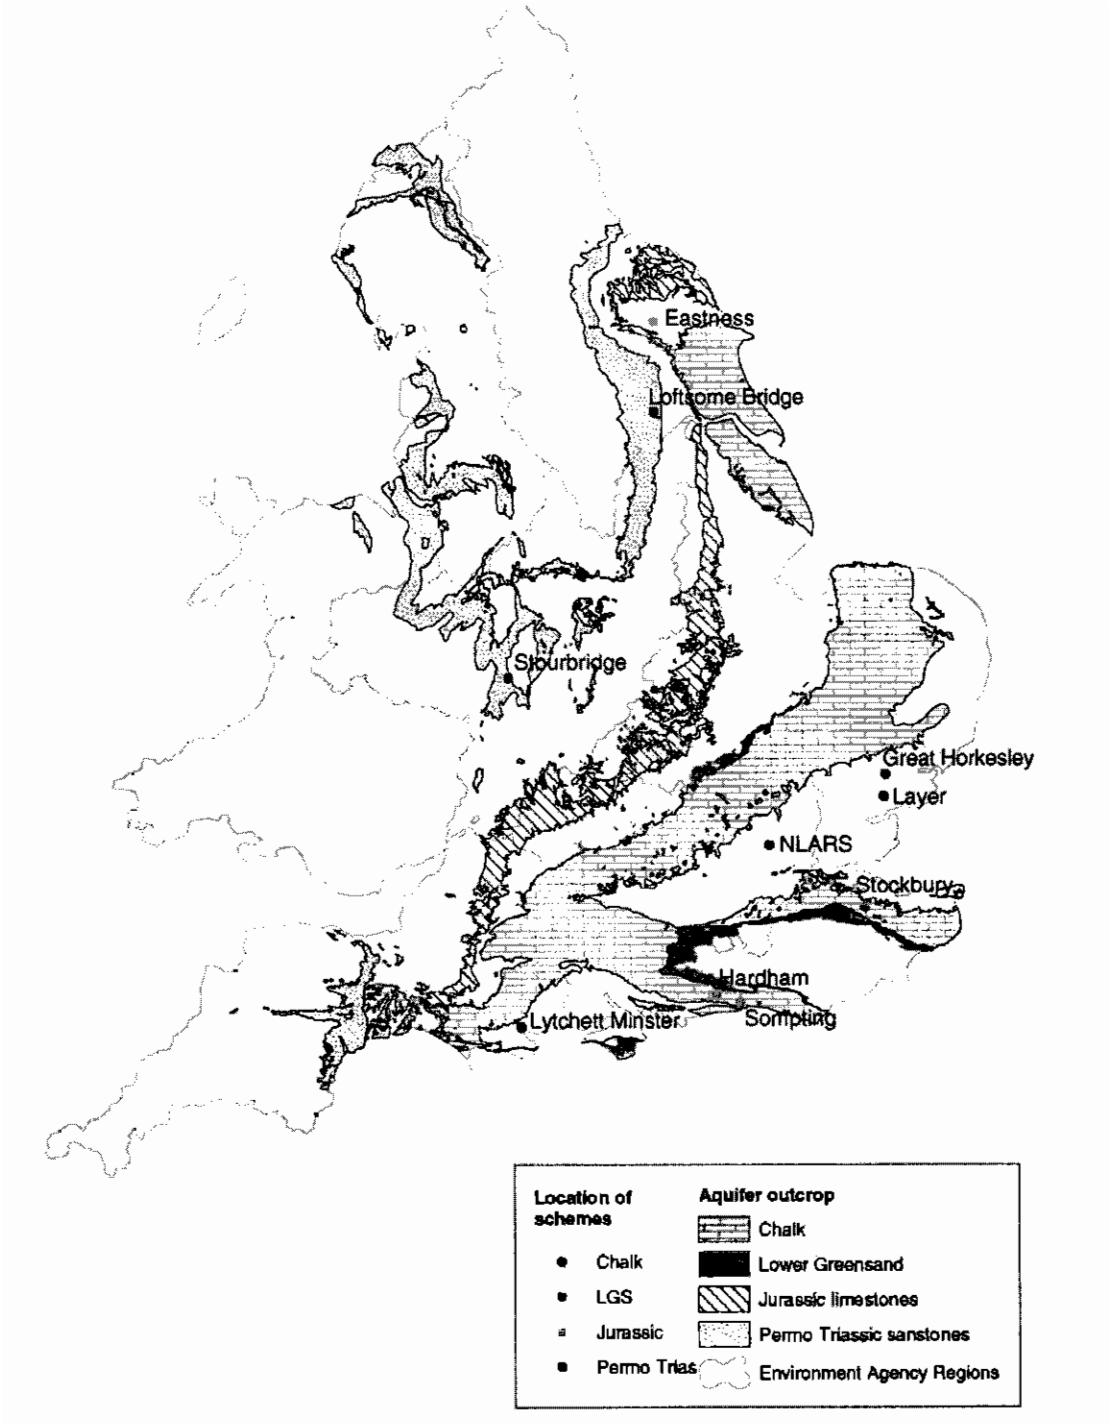

Figure 2.1 The location of ASR and other artificial recharge schemes in relation to the major aquifers in the UK

ASR may be constrained in the Chalk aquifer where the native groundwater is saline or brackish. When fresh water is injected it will tend to flow through the fractures, rather than through the matrix of the rock. Saline native groundwater in the matrix will then diffuse across a large interface and thus reduce the quality of the water subsequently recovered from the fractures. The significance of this process is discussed further in Section 4.3 of this report. In some cases the lack of environmental impacts of ASR may outweigh this water quality issue, which can be dealt with through treatment or dilution on recovery. Where the native groundwater has no serious limitations in terms of water quality, and the hydraulic parameters are satisfactory, the Chalk aquifer will have good potential, as illustrated by the success of the North London Artificial Recharge Scheme (NLARS) (O'Shea et al., 1995).

The Upper Greensand may also have potential for ASR due to its high storage capacity. Impermeable horizons within the formation can act as confining layers, thus creating a multi-layered aquifer and offering the opportunity for stacking. The degree of hydraulic continuity between the Chalk and Upper Greensand varies but where there is continuity, the combined aquifer may have greater potential. High iron in solution in some areas could pose a problem with plugging of boreholes due to the precipitation of iron oxides when injecting oxygenated water into a reducing environment. However, if this process is understood, it can be controlled and managed.

Table 2.2 Potential for ASR in England and Wales

Region (Env. Agency)	Chalk	Lower Greensand	Jurassic Limestones	Permo-Triassic Sandstone
Anglian	Moderate	Good (south of Region)	Lincs Lst: Mod. in south	
Midlands				Moderate to good
North East	Moderate to low (south of Region)		Corallian: Low to moderate	Moderate to good (best in south)
North West				Moderate to good
Southern	Moderate UGS: good in southwest	Good (southwest of Region)		
South West	Moderate to good (east of Region)		Moderate to low (east of Region)	Moderate to good (east of Region)
Thames	Good (East London)	Good (west of Region)	Moderate?	
Welsh				Low

n.b. Empty cells indicate absence of, or insignificant aquifer in region

2.4.3 Lower Greensand

The Lower Greensand is an important aquifer in parts of southern England, mainly in Bedfordshire and Cambridgeshire, and to the south of London around the Weald and on the Isle of Wight, as well as other smaller outliers elsewhere. It has a limited area of outcrop, although its high storage and generally good water quality render it important locally. Water quality can be exceptionally good, even where the aquifer is deeply confined, for example at Slough.

The Lower Greensand has good potential for ASR as transmissivity values, even where confined, are generally reasonable, and storage coefficients are high. It is most likely to be of use where it attains maximum thickness, and where intergranular flow is dominant, for example in the west of the Weald.

2.4.4 Jurassic Limestones

The Jurassic sediments outcrop in a broad band from the southwest to the northeast of England. The two main limestones are the Great Oolite Limestone and the Inferior Oolite. The minor limestones are frequently relatively thin, and rarely extend over large areas. Intergranular permeabilities are generally low, and the dominant flow mechanism is through solution-enlarged fractures. The high transmissivity combined with low storage results in the aquifers having a high diffusivity and hence rapid response times to pumping or injection. This may result in impacts in the unconfined part of an aquifer, even where boreholes are several kilometres from outcrop.

Water quality is good close to outcrop, but tends to becomes more saline down dip, beneath confining strata. Thus, although the limestones may have some potential for ASR, the potential is only likely to occur at a local scale.

2.4.5 Permo-Triassic Sandstones

The Permo-Triassic sandstones crop out across southwest, central, northeast and northwest England, and the Vale of Clwyd. They comprise a thick (up to 1000 m), variable sequence of predominantly sandstone, with inter-layered fine-grained horizons. Although matrix porosity and permeability are fairly high, the aquifer frequently relies on fractures for much of the groundwater flow close to boreholes. Although fractures generally close with increasing depth of burial, they have been reported even at depth, to be sufficiently open to maintain a high transmissivity. For example, during investigations for the Stourbridge scheme, Jones (1983) reported a fracture at 158 m depth in the recharge borehole. Faults have been reported to compartmentalise the aquifer in some areas, for example the West Midlands. Such isolated aquifer blocks could be particularly useful in terms of ASR.

The great thickness of the sandstones combined with their high matrix porosity and the influence of fractures, may result in injected water being "lost" unless very large quantities are injected. To minimise this loss, ASR schemes should be located in sections of aquifer that are confined by marl, or other low permeability strata, with as few fractures as possible. The injected water will then tend to displace inter-granular water around the borehole, thus increasing recovery efficiency.

2.4.6 Magnesian Limestone

The Magnesian Limestone occurs in a narrow north-south strip from Sunderland to Nottingham. It comprises two or three limestone horizons, separated by marls and siltstones. In the north, the aquifer is divided into three, with the Middle Magnesian Limestone having the greatest porosity. The transmissivity of the Magnesian Limestone is controlled by fracturing, hence aquifer properties are very variable and unpredictable. The reliance on fracture flow may limit its potential for ASR.

2.4.7 Carboniferous Limestone

The Carboniferous Limestone occurs in Derbyshire, the Mendips, north and south Wales, and in northwest Yorkshire. The matrix of the Carboniferous Limestone has a very low porosity and permeability, and the formation functions only as an aquifer by virtue of the secondary network of solution-enlarged fractures. It is characterised by very rapid groundwater flow, the direction of which may be difficult to predict. Boreholes yields are unpredictable and may have very high yields if they intercept fractures, and be non-productive if they fail to do so. Much of the yield from the aquifer is from spring discharge so, in general, the aquifer is unsuitable for ASR.

2.4.8 Minor aquifers

Other **minor aquifers** should be considered on an individual basis. ASR schemes require areas of aquifers in the order of tens of hectares so suitable, local geological settings can be adequate. Aquifers identified as having some potential include the **Fell Sandstone, Millstone Grit, Kellaways Rock** and some **Upper Lias Sands.** When considering these aquifers their potential can by reviewed in respect of the "aquifer continuum", ranging from unconsolidated arenaceous deposits with high matrix porosity (Lower Greensand), through consolidated sandstone aquifer with high matrix porosity and some fracture flow (Sherwood Sandstone), fracture-flow dominated, high diffusivity aquifers (Jurassic Limestone) to fracture flow dominated aquifers with dual porosity mixing being the dominant process (Chalk).

3 Environmental benefits and constraints

3.1 Introduction and modelled scenarios

ASR schemes can utilise aquifers, at relatively small cost, that would otherwise be considered as marginal or useless. ASR can also have benefits when used in conjunction with potable aquifers in situations where the resource within the aquifer is limited. Examples of these situations are when an aquifer has limited recharge, or where an aquifer is already being exploited fully and where environmental impacts may restrict the amount of groundwater that can be abstracted during certain seasons. In this chapter, the factors that might affect the operation of an ASR scheme are examined and methods for their quantification presented.

Of particular concern is the impact that an ASR scheme may have on water levels in adjacent aquifers or in the unconfined zone of the target aquifer. As ASR schemes are designed to not result in a net abstraction from the aquifer, the normal water resources considerations about environmental impacts are not relevant and different factors need considering. In the long-term, there may be some net addition of water to the aquifer, but this should be small in relation to the overall resource. However, it does not necessarily follow that environmental impacts (e.g. water levels at outcrop) are negligible during the injection or abstraction phases.

A scheme that injects and then abstracts the same volume of water will, as a long-term steady state average, have no impact on local or regional groundwater levels. However, the seasonality of the scheme means that the local water levels will first be increased and then reduced. The timing and absolute value of these changes are of importance in assessing the eventual impact of a scheme. The work described here investigates the short-term effect on water levels and flows caused by the addition of water to the aquifer, and its subsequent removal.

Several situations have been considered and numerical and analytical models have been developed to examine these situations. The first is the case when the target aquifer is confined but is overlain (above the confining layer) by another aquifer (in this case, an unconfined aquifer). The impact that injecting water into the underlying aquifer has on the upper aquifer will be considered in terms of a change in flow between the two aquifers. Another case, which is investigated, is that of a target (confined) aquifer which outcrops at some distance from the proposed ASR scheme. The effect on water levels at the point where the aquifer becomes confined is estimated using a numerical model, for a range of transmissivity values and aquifer dimensions. Consideration has also been given to the time at which the maximum effect occurs. Descriptions of the models that have been used to investigate these situations are included in this report. It is anticipated that they will be used at an initial stage of ASR investigations, using parameters appropriate to the particular hydrogeological setting. The software is appended on disk and the models are discussed in greater detail in Williams et al. (2001).

It is envisaged that these 'first-pass' hydrogeological models will give one of three indications for a particular site:

- The impact on the adjacent water table is negligible
- The impact is definitely significant and the site is not suitable

- Further investigation is required; perhaps including more detailed modelling.

3.2 Confined ASR aquifer overlain by unconfined aquifer

Before work on assessing 'environmental impact' can be started it is important to decide what exactly is meant by the term and how it is best measured. On initial inspection it would appear that the best way to measure the 'impact' on an overlying aquifer (as depicted in Figure 3.1) would be in terms of a change in head caused by the operation of the ASR scheme. However, further consideration suggests that this may not be the case. The first problem that is encountered is the question of where this change in head should be calculated. It is obvious that the maximum change will be directly above the abstraction point i.e. at the ASR well. However it is equally obvious that the change at this point is not of any great interest as not only will it be in an area controlled by the operators of the ASR scheme but it will also be very much the worst case.

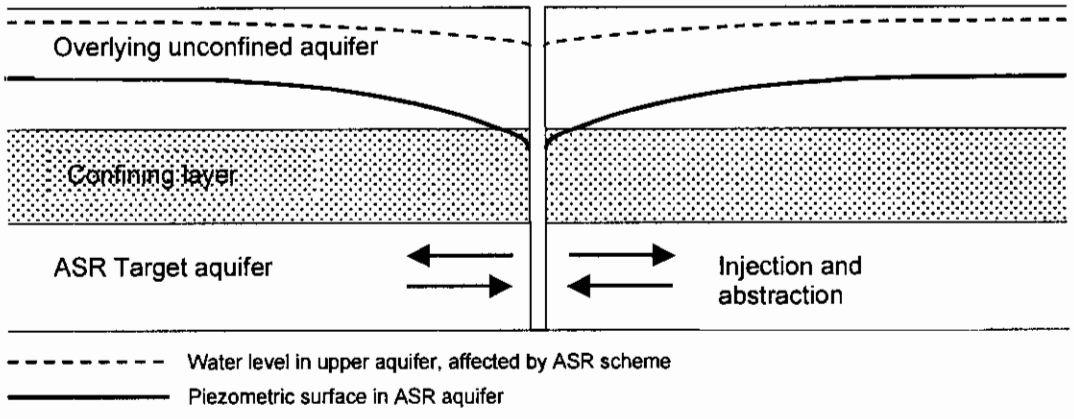

Figure 3.1 Schematic of modelled situation

The change in head at a specified distance (say 100 m), or distances, from the ASR well might be more useful and appropriate. The choice of distance should probably be influenced by the hydraulic properties of the overlying aquifer, as a cone of depression will have a different shape depending on the permeability (a lower permeability aquifer will have a deeper, less extensive cone than a higher permeability aquifer). The estimated effect, in metres, at the chosen point could then be used to decide whether or not the ASR scheme would have a significant impact on the overlying aquifer and the surface environment. The significance of the impact would probably be compared to the natural groundwater level fluctuations expected on an annual basis, or some similar criterion. Thus the decisions, which have to be taken are: a) where to estimate the change in head and b) with what to compare it?

Both of these decisions depend in part on the properties of the overlying aquifer. It would be more convenient to have a measure of the environmental impact of an ASR scheme that is independent of these properties. An ASR scheme will 'impact' on the overlying aquifer if it alters the water resources available in that aquifer or alters surface water features such as streams and wetlands. Thus a useable measure of impact would be the flux created into or out of the upper aquifer as a consequence of operating the ASR scheme. This value could sensibly be compared with the water resource available

in the upper aquifer before starting the ASR scheme, as measured by the annual recharge rate, for instance. Alternatively, the leakage out of the upper aquifer could be considered as a new 'abstraction' within the aquifer, where the magnitude of the leakage is compared to an abstraction rate.

The equations, which describe the flow of water within the aquifer system, have been solved analytically and the solution (effectively an extension of the Theis solution) has been incorporated into a spreadsheet. The spreadsheet allows the impact of an ASR scheme operating under variable cycling regimes to be estimated. The relevant parameters, which are required, are the storage coefficient of the aquifer containing the ASR well, and the vertical permeability, thickness and specific storage of the intervening aquitard.

Interestingly, the transmissivity of the target (ASR) aquifer is not a required parameter. This is because the focus is on *total* leakage through the aquitard, and not on how it is distributed areally. Another point of interest is that it is the properties of the aquitard that dominate. This is important, as these parameters are often not well known and this suggests that some effort should be focussed towards measuring these parameters, as there is no database of aquitard parameters for the UK.

The spreadsheet model has been used to show how the leakage from the upper aquifer varies during an ASR scheme run for five annual cycles (Williams et al. 2001). The effect of different aquitard hydraulic parameters and physical parameters can also be shown. The key findings are:

- Aquitards with low vertical hydraulic conductivity (k_v of less than 10^{-3} m/d) result in an impact in the upper aquifer which is of the same magnitude as that in the target aquifer with effectively no time delay, i.e. the system behaves as one aquifer.

- The higher the storage coefficient of the ASR aquifer, the less the impact on the upper aquifer.

- If the aquitard is compressible (i.e. high aquitard specific storage) the impact on the upper aquifer becomes negligible.

3.3 Effect of an ASR scheme on the outcrop area of the target aquifer.

In order to give an indication of the effect that an ASR scheme might have in the outcrop area of a target aquifer, a numerical model has been developed. It is possible that an ASR scheme may have an adverse environmental effect on streams or wetlands in the area where the target aquifer becomes unconfined.

Streams and wetlands are influenced by the water level in the aquifer that feeds them. Therefore, in this case, the head change within the aquifer near where it becomes unconfined ***is*** a useful measure of environmental impact of an ASR scheme. This can be related easily to the heads required to maintain stream flow or wetland function. The numerical model has been used to show the drawdown (i.e. the lowering of the water level) which will occur at the outcrop at the closest point to the ASR well. This will give a worst-case as the drawdown will be smaller further from the ASR well. Figure

3.2 shows the layout simulated in the numerical model. This is described in more detail in Williams et al. (2001).

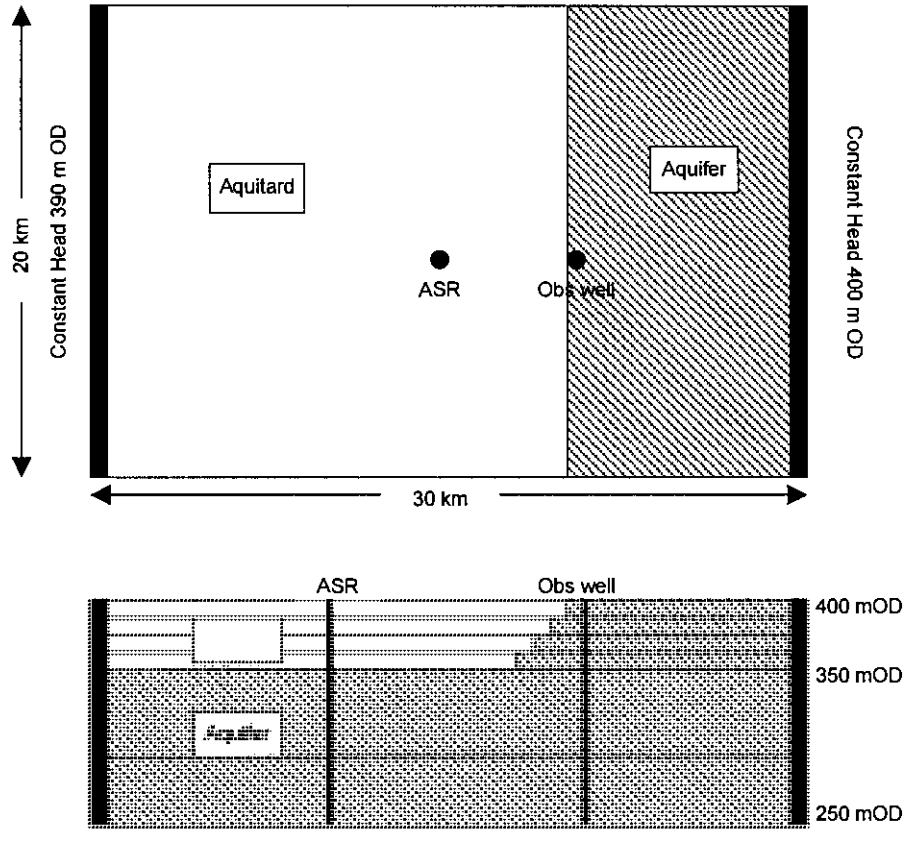

Figure 3.2 Schematic plan and cross-section of the modelled scenario.

The numerical model makes it possible to estimate the drawdown at the edge of the outcrop for different values of the aquifer and aquitard properties. It is also possible to change the thickness of the layers within the model. This makes it a very useful tool for initial investigations of the potential environmental impacts. Examples of the influence of the various aquifer parameters are given in Williams et al. (2001) and the model itself is appended to this report on disk.

For example, the modelling shows that the ***distance*** from the ASR well to the outcrop makes a significant difference to the potential impact of the ASR scheme. The estimated drawdown at the edge of the outcrop area, after five annual ASR cycles, changes from 0.25 m to 0.04 m as the ASR well is moved from 2 km to 15 km from the outcrop (Figure 3.3).

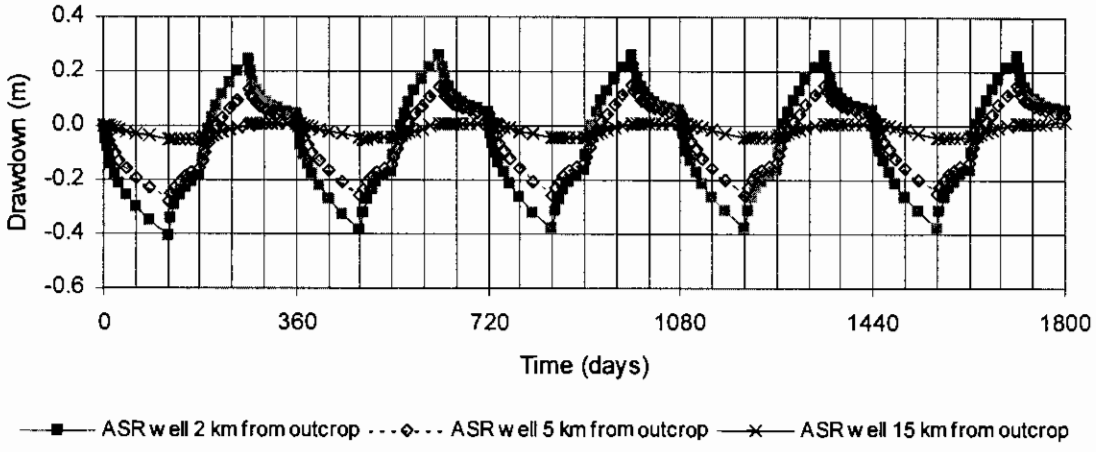

Figure 3.3 The impact of changing the position of the ASR well relative to the outcrop of the aquifer over five annual ASR cycles

It is also interesting to note that the maximum drawdown at the outcrop area occurs sometime after the maximum effect at the ASR well, i.e. the maximum impact of the ASR scheme is delayed beyond the end of pumping. The magnitude of this delay is greater when the aquifer transmissivity is smaller and when the storage coefficient is larger. The delay may be more than several months for an ASR well 10 km from the outcrop area in an aquifer with a transmissivity of 100 m^2/d and a storage coefficient of 10^{-3} (Figure 3.4). This factor may be very important when considering whether a change in head in the aquifer is significant in relation to annual variations. A change in water level that is significant in the summer months, when stream flows are low, may be insignificant in the winter.

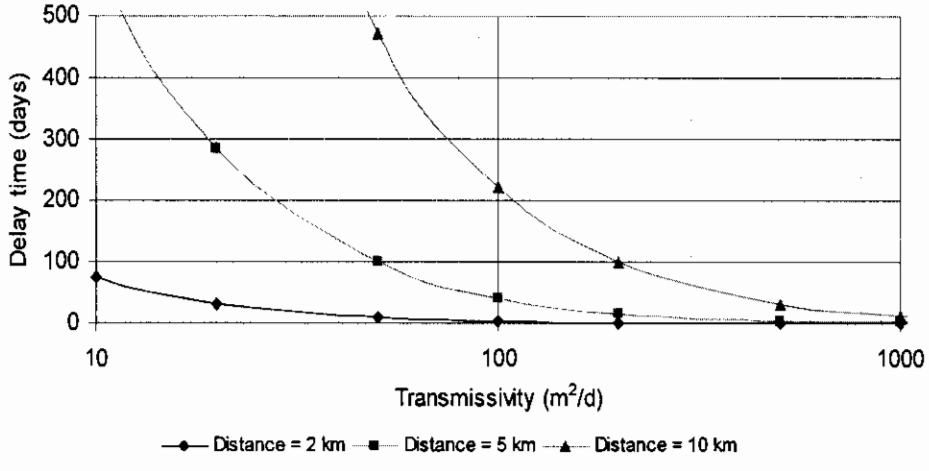

Figure 3.4 Time after the end of a 60-day pumping period when the maximum effect occurs ($S=10^{-3}$).

The model has also been used to demonstrate the difference between an ASR scheme and a conventional abstraction-only scheme (Figure 3.5). The model was set-up with some effective recharge across the outcrop area, and so may not be representative of

regions where ASR might be used (where it is assumed that all the available water resources are already 'allocated' to abstractions or environmental requirements). However, even in this 'best-case' (for the abstraction-only scheme), it is clear that abstraction-only results in much greater drawdown at the outcrop compared to the ASR scheme. The maximum drawdown simulated is 0.3 m at the end of the fifth year of abstraction and this drawdown is slowly increasing year-on-year. However, as the net abstraction with the ASR scheme is zero, the maximum drawdown does not increase year-on-year and is only half that of the abstraction-only scheme.

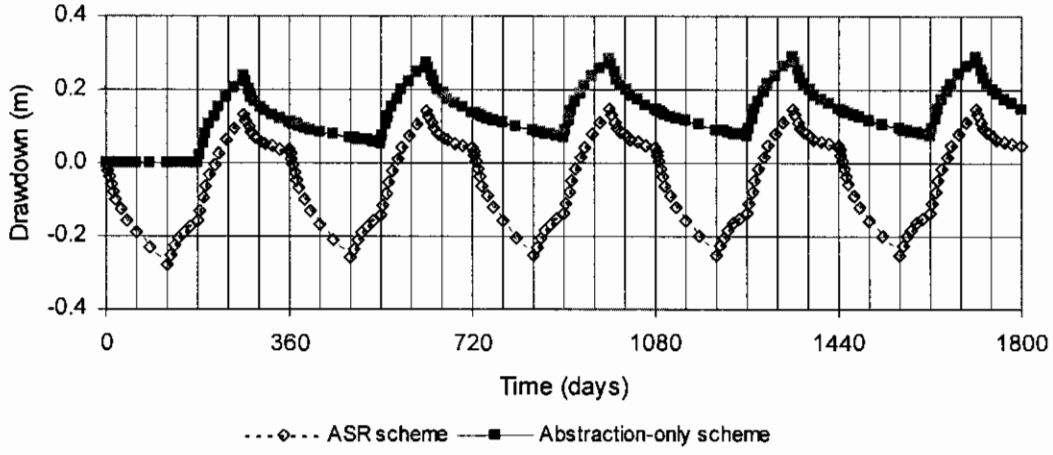

Figure 3.5 Comparison of ASR scheme with an abstraction only scheme.

3.4 Conclusions

Modelling tools have been developed which can give a useful insight into the possible effect of an ASR scheme in a variety of different hydrogeological settings. These first-pass tools can be used to indicate which aquifer parameters have the greatest effect on the impact and thus which parameters it is important to measure. As the tools are easy to use they can be applied to a wide variety of possible ASR sites very simply and thus reduce the cost of initial investigations.

Using the models has shown that under some circumstances there is a significant time delay between the maximum drawdown at the abstraction well and the maximum effect at outcrop. This means that in some cases ASR schemes could well have an advantageous environmental impact. This would occur when the drawdown at outcrop was delayed by several months so that maximum drawdown occurred at high river flow, possibly inducing recharge, and maximum water level rise occurs during low flow periods, contributing to river flow.

4 Significance of aquifer parameters in major aquifers

4.1 Introduction

The main mechanisms for the 'loss' of injected fresh water are dispersion (hydrodynamic mixing and molecular diffusion), density stratification (gravitational segregation) and lateral movement down hydraulic gradient. Mixing occurs at the interface of injected and native waters, and a dispersion or buffer zone develops. The degree of mixing is partly dependent on the type of flow in the aquifer. Harpaz (1971) showed that sandstones are likely to have higher recovery efficiencies than limestones due to the relatively slow groundwater movement in sandstones. The recharging water follows a radial expansion pattern and tends to retain the shape of a coherent water body, except in highly stratified formations.

The amount of mixing between native and injected water in an ASR-scheme, and the quality changes that occur as a consequence of this mixing, will largely depend on the physical properties of the aquifer in which the ASR-scheme is carried out. Building up a bubble of injected water in the aquifer in which little or no mixing with the native water occurs is one of the key aims of a successful ASR-scheme. If extensive mixing occurs, the recovered water will be influenced by the native water quality, which can be undesirable.

In order to assess the suitability of the main aquifers in Britain for ASR in terms of mixing, a sensitivity analysis has been carried out. The aquifers considered are the Chalk, Lincolnshire Limestone, Lower Greensand and Sherwood Sandstone, these being the aquifers most likely to be used for ASR (Figure. 2.1).

For each aquifer, a range in values of the major parameters (e.g. porosity, permeability, thickness) was defined based on the known properties of the aquifer. The impact of this variation on the amount of mixing between native and injected water was then assessed. using a 3D-dual porosity model, SWIFT (see Box). The impacts of operational and test cycles on the recovered water quality were also modelled. No chemical reactions between the injected water and the native groundwater and the aquifer material were included. The changes therefore solely reflect mixing processes and are what would be expected of a non-reactive solute such as chloride. The results (represented by the concentrations measured in the well) show the possible ranges in recovered water qualities and the differences between the four main aquifer types.

The SWIFT Model

SWIFT is a fully transient three-dimensional model, which simulates the flow and transport of fluids (brines), heat (energy) and radionuclides in fractured geologic media. It is particularly appropriate for modelling ASR in fractured media because of its ability to model dual porosity aquifers. Such aquifers are widespread in the UK (Chalk and Lincolnshire Limestone) and where present are likely to be important in controlling the recovered water quality in an ASR-scheme. When a dual porosity medium is modelled in SWIFT, the modelled system is described in two parts: the fractures and the porous blocks. Both parts have their own properties and must be fully defined.

4.2 Impacts of the main British aquifers on mixing during ASR

The Chalk and the Lincolnshire Limestone are both best described as dual porosity aquifers. The main difference between them is the matrix porosity (2 to 40 times greater in the Chalk). In dual porosity aquifers, the bulk of the flow takes place in the fractures while storage is provided by the matrix. The important parameters in this type of aquifer, as far as solute transport is concerned, are the fracture and matrix porosity, the spacing between fractures and the diffusion coefficient. This is a measure of the rate at which solutes can penetrate the matrix blocks as a result of concentration gradients. Of these parameters, only matrix porosity is readily measured, although estimates of fracture porosity and fracture spacing can be made from pumping tests and from geophysical logging. The diffusion coefficient of some solutes into clean chalk samples have been measured and so estimates (order of magnitude) for this parameter are available. However the relevance of laboratory measurements on clean uniform surfaces to processes occurring at natural fracture surfaces is still poorly understood.

In contrast to the Chalk and the Lincolnshire Limestone, the Lower Greensand behaves as a single porosity medium. This means that the same void spaces (as reflected by the porosity) control both the permeability and the storage. In this case, the parameters that are of most relevance to transport of solutes, are the porosity and dispersivity. Dispersivity is a measure of how much a plume of solute will spread as it moves and is controlled by the heterogeneity of the aquifer. Dispersivity can be measured in the laboratory under controlled conditions but the values obtained are often found to be much smaller than those estimated from field data. This is a because of the large-scale heterogeneities present in the aquifer but not represented in the small blocks of aquifer material that can be tested in the laboratory. The dispersivity is therefore usually derived during model calibration with field data.

The behaviour of the Sherwood Sandstone lies somewhere between the dual-porosity and single-porosity ideals and is probably best described as a dual-permeability medium. This is because the matrix is permeable enough to transmit water at the low rates which are relevant in regional flow systems, but probably not in the near-well situation where fracture flow is likely to dominate. The SWIFT model cannot simulate this type of aquifer, and in the work reported here, the Sherwood Sandstone has been modelled as a dual-porosity medium.

4.3 The dual-porosity issue

4.3.1 Conceptual model

In some cases, the effects of molecular diffusion may be highly significant and this is considered to be the dominant mixing process in the Chalk aquifer in the UK (Jones et al., 1998). The Chalk is unusual in that it has a high porosity (up to 40%) and may contain saline or brackish water in the pore spaces. Due to the small pore throat diameters, groundwater flow is dominantly through fractures (1-2% porosity) and not through the pores. The ratio of matrix water to fracture water is high and so diffusion of solutes from the matrix water can therefore have a strong influence on the chemistry of the mobile fracture water.

If a Chalk aquifer contains poor quality water then injection of potable water will mix with and displace water from the fractures. However, diffusive mixing will be the

dominant process between the fracture and the matrix waters. The rate at which this occurs depends on the surface area of contact between the two waters, their relative volumes and the concentrations and ionic species under consideration. The scale and rate of this process is therefore a key to the success of ASR schemes in aquifers that contain non-potable native groundwater.

It is therefore worthwhile examining the processes that occur during an injection-recovery cycle in some detail. This has been modelled by considering a cylinder of fractured aquifer centered around a well. The numerical grid used for these calculations extended to a radius of 2000 m about the well and has a variable mesh spacing beginning at 0.25 m close to the borehole and increasing logarithmically with distance away from the well. Initially, the aquifer was assumed to be full of water, both in the fractures and the matrix, with a nominal solute concentration ('salinity') of 1.0 representing native groundwater. The injected water was assumed to have a concentration of 0.0. Therefore the relative concentration in the recovered water lies between 0 and 1 and is a direct measure of the fraction of the native water found in the recovered water – this is one measure of the efficiency (or inefficiency) of an ASR scheme. The response of the model to a typical annual cycle is shown in Figure 4.1. The relative concentration plotted is that found at the well.

During the injection phase (Figure 4.1A), the concentration at the well is 0.0, that is, the injected water concentration. If the well is left standing after injection stops (Figure 4.1B), the concentration in the well gradually increases due to diffusive exchange between the injection water in the fractures and the native groundwater in the matrix. When the recovery (pumping) phase starts (Figure 4.1C), the concentration in the well increases further as higher salinity water from greater distances in the aquifer is drawn into the well along fractures. This is the key phase of the cycle as predictions can be compared directly with measured concentrations in the recovered water. When the recovery stops, the now relatively fresh water in the matrix close to the well causes a dilution of the fracture water by diffusive mixing. As soon as injection starts again, the salinity in the well drops to 0.0, i.e. back to the concentration in the injected water. If the volume of injected water is greater than that taken out during recovery, such a cycle builds up a 'bubble' or buffer zone of injected water in the aquifer, albeit with considerable mixing with native groundwater at the interface.

It is the moderately slow rate of exchange between matrix and fracture water that is the problem with dual porosity aquifers such as the Chalk. If this exchange were either very fast or very slow then the ideal for ASR – a distinct bubble of injected water close to the well – could be established. When significant exchange takes place within a few months or years, the timescale of a typical ASR scheme, this ideal is prevented.

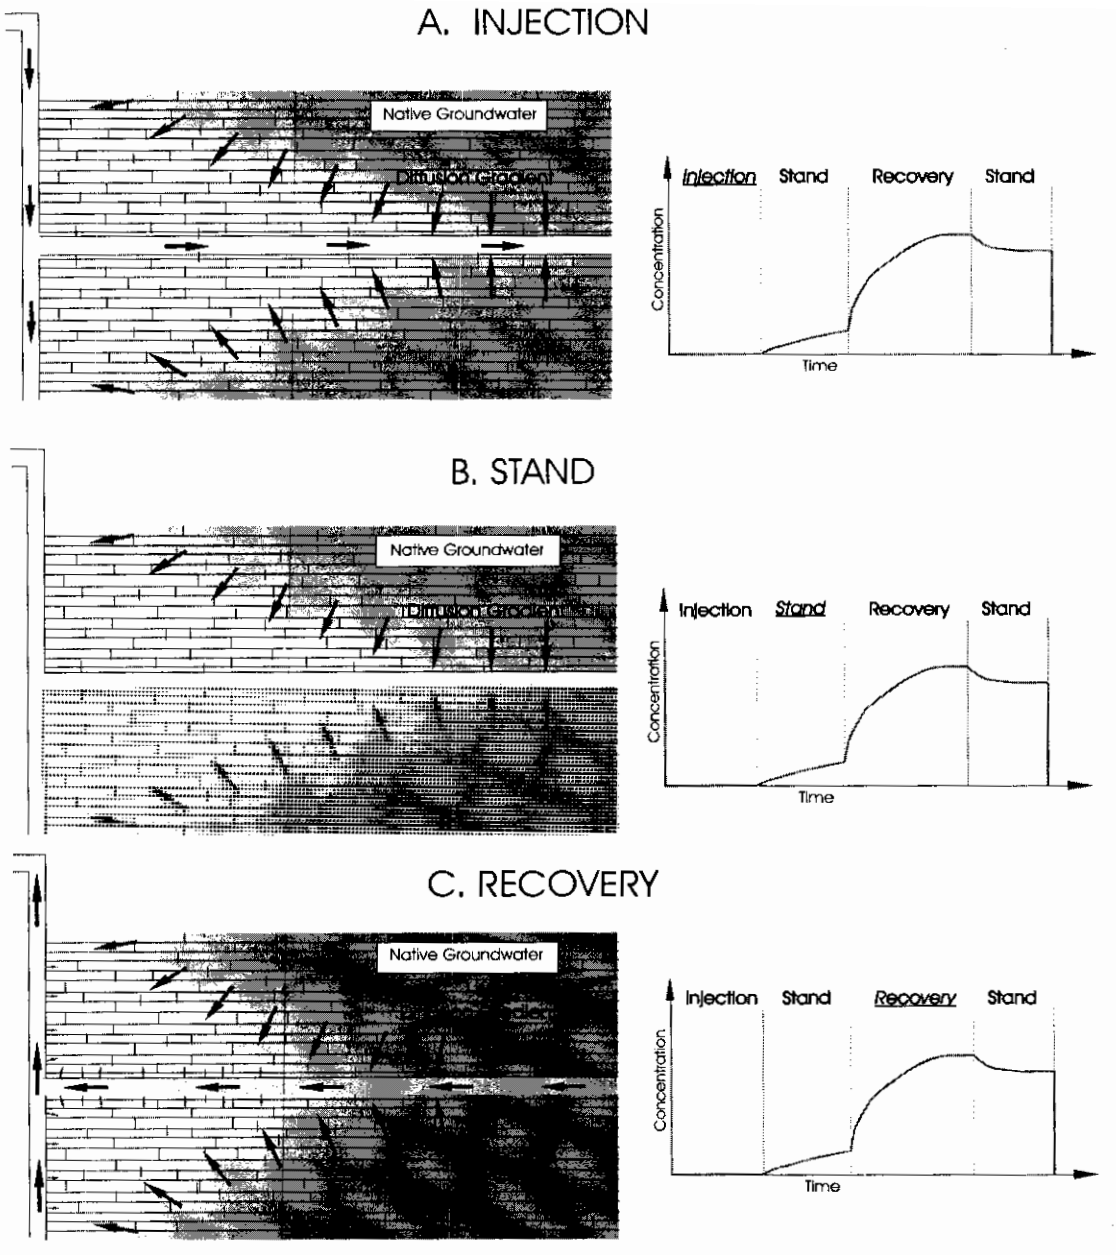

Figure 4.1 Modelled response of a dual-porosity aquifer to a typical injection-stand-recovery cycle. The relative concentration plotted is a measure of the fraction of the native water in the recovered water

4.3.2 Calibration of a dual porosity model against field data collected from a trial in the Chalk aquifer

The modelled results were calibrated against data collected during an extensive cycle-testing programme undertaken by Wessex Water Services at their site in the confined Chalk aquifer at Lytchett Minster in Dorset. Water from a supply main was injected at a constant rate of 2 to 3.2 Ml/d in cycles ranging in duration from a few days initially and increasing to over four months in Cycle 9. Apart from the first cycle, less water was

recovered than was injected in order to build up a buffer zone. The water injected over nine cycles totaled about 980 Ml of which 360 Ml was recovered. Using a fracture porosity of 0.01, the maximum radius of the residual 'bubble' in the fractures is estimated to be about 700 m.

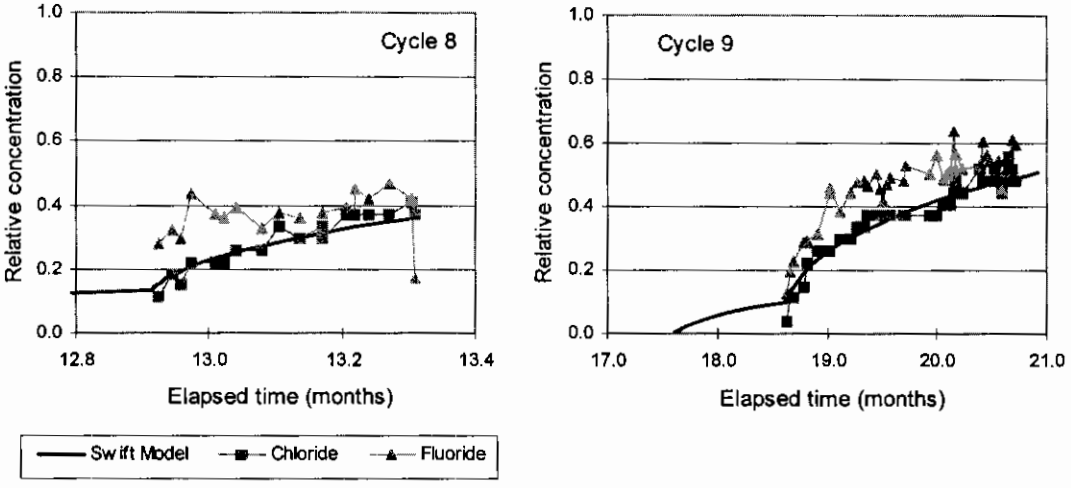

Figure 4.2. Results of dual porosity modelling from Cycles 8 and 9 of the testing programme in the Chalk aquifer at Lytchett Minster. Data for the observed variation in chloride and fluoride concentrations are also shown

The model was matched to the non-reactive solute, chloride. The match between the modelled and observed concentrations is good for Cycle 8 and 9 (Figure 4.2). A good match was also found for the preceding seven cycles. Also shown in Figure 4.2 are the relative concentrations for what proved to be a reactive solute, fluoride. The measured relative concentration of fluoride is greater than the modelled concentration indicating that some fluoride must be dissolving from the aquifer. The impacts of geochemical reactions on the recovered water quality are discussed further in Chapter 5.

4.4 Impact of mixing in British aquifers

In order to assess the impact of ASR-schemes on the recovered water quality in British aquifers, a sensitivity analysis was carried out using the SWIFT-model. The impact of operational and test cycles on the recovered water quality were modelled assuming a plausible range of aquifer parameters (Table 4.1). No chemical reactions between the injected water and the native groundwater and the aquifer material were included in the model. The changes therefore solely reflect mixing processes, both advective and diffusive.

For the sensitivity analysis, two ASR regimes were tested. One regime represents a typical series of test cycles (short cycles), while the second represents a typical series of operational cycles, i.e. long cycles. This was done to determine whether the timescale was important or not.

Table 4.1 Estimated values or ranges of values for some physical properties of the main aquifers in the UK

Aquifer	Permeability (m/d)		Porosity (%)		Storativity (m^{-1})	Thickness (m)
	Matrix	Fracture	Matrix	Fracture		
Lincolnshire Limestone (Jurassic)	10^{-3}	10 to100	1-10	0.5 to 5	10^{-6}	10-40
Chalk (Cretaceous)	10^{-3}	1 to100	20-40	0.5 to 2	10^{-6}	50-200
Sherwood Sandstone (Triassic)	1 to 50	10 to 500	10-25	1	10^{-5}	50-300
Lower Greensand (Cretaceous)	1 to 100		10-25		10^{-5}	10-40

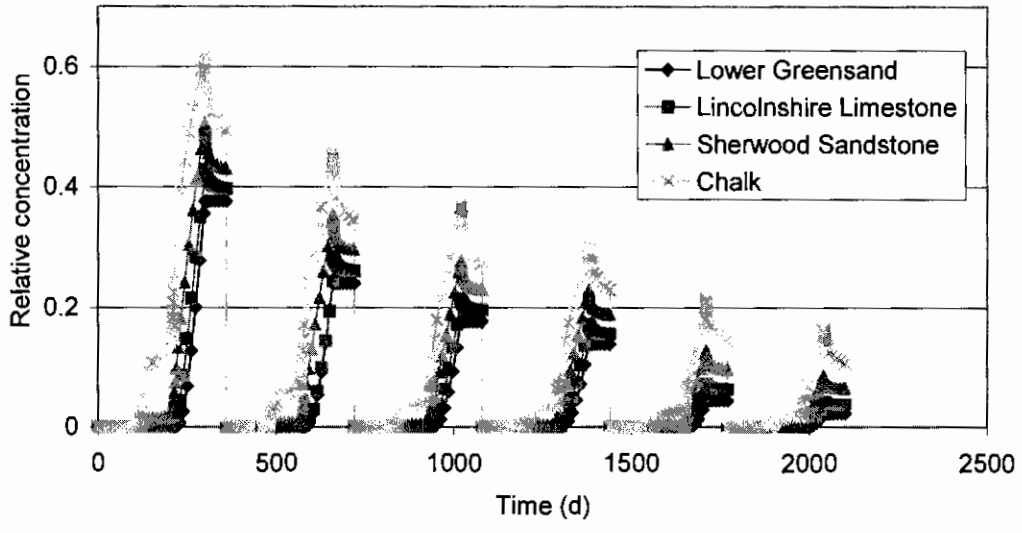

Figure 4.3 Predicted responses of the four major aquifers in the UK to ASR over six annual cycles. Each trace represents a series of injection-stand-recovery cycles of the type illustrated in Figure 4.1

For each aquifer a base case was modelled. The selected parameter values were chosen to be in the middle of the estimated parameter range (if a range was indicated). The base case was calculated for each aquifer over six annual cycles (Figure 4.3). The peak concentration declines with successive cycles because of the gradual increase in the size of the freshwater bubble close to the well. The relative concentration in a given cycle increases in the sequence: Lower Greensand < Lincolnshire Limestone < Sherwood Sandstone < Chalk, reflecting the increasing influence of fracture flow in drawing in native groundwater and reducing the compactness of the freshwater bubble around the well.

As an example of the sensitivity of the results to variations in aquifer properties, a detailed analysis of the Chalk aquifer was undertaken (Figure 4.4). These analyses were

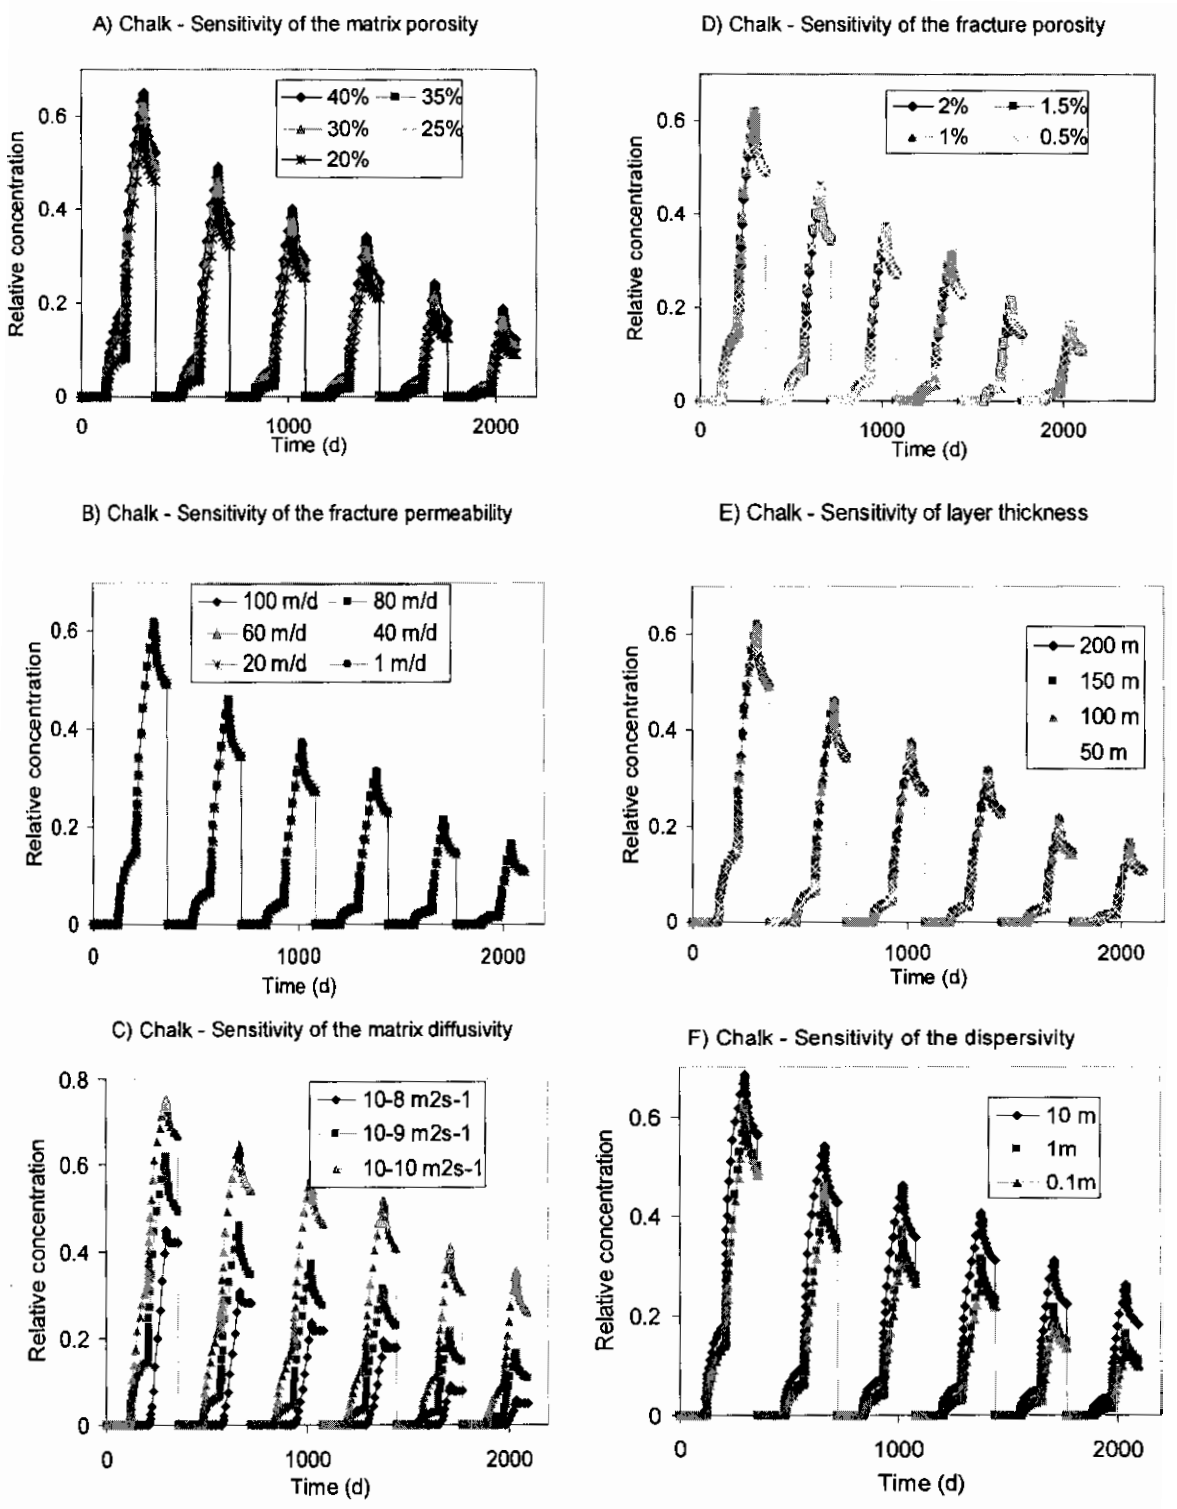

Figure 4.4 Sensitivity analysis of ASR-cycle testing in the Chalk to various aquifer properties: matrix porosity, fracture permeability, fracture porosity and layer thickness, matrix diffusivity and dispersivity

also carried out for the other aquifers except for the influence of matrix diffusivity and dispersivity, which were only evaluated in the case of the Chalk aquifer. These two parameters were assumed to be constant for the Sherwood Sandstone, the Lincolnshire

Limestone and the Lower Greensand because their dependency on the other parameters was unknown. It is, in general, difficult to measure the matrix diffusivity and dispersivity of aquifers.

Varying the parameter values over the plausible ranges expected for the dual-porosity Chalk aquifer, the Sherwood Sandstone and the Lincolnshire Limestone aquifers showed that the effect on the relative concentration of a non-reactive solute was small. Because of these low sensitivities, the conclusions drawn from the short-term test cycles can reasonably be extrapolated to longer-term operational cycles. Of the parameters examined, the matrix porosity had the greatest influence on the modelled relative concentrations. Variations in the other parameters (fracture permeability, fracture porosity and thickness of the aquifer) were negligible and variations in the matrix diffusivity and aquifer dispersivity were small.

However, the sensitivity to the parameters that are difficult to measure (matrix diffusivity, dispersivity) might be greater than shown in Figure 4.4. For example, it cannot necessarily be concluded from these calculations that these parameters never influence the modelled concentrations since they also depend on the values of other parameters such as fracture permeability, rock porosity and matrix porosity. A matrix diffusivity of 10^{-9} m^2/s and a fracture dispersivity of 10 m were found to be appropriate for all of the aquifers modelled.

The lack of sensitivity of the mixing to the aquifer thickness and permeability is not unexpected since the same volume of water had been injected in each of the model runs. This, of course, leads to very different imposed heads on the aquifer, some of which would be unlikely in reality. However the volume of the aquifer (and thus the volume of the native groundwater), which comes into contact with the injected water is the same in all cases in which only the permeability or the thickness were changed. For dual-porosity aquifers, the matrix permeability has little effect on predicted concentrations because it has been assumed that there is no flow in the matrix except perpendicular to the fractures. This is a reasonable assumption for the Chalk and the Lincolnshire Limestone, but for the Sherwood Sandstone this assumption might not hold and therefore the results for the Sherwood Sandstone aquifer should be viewed with caution.

Based on the parameter estimates given in Table 4.1 and the calculations described above, the Chalk seems to be the least suitable aquifer for ASR in terms of recovered water quality. This is due to its high matrix porosity in comparison to the other aquifers, leading to a high degree of mixing between injected and native water. Due to the low matrix porosity of the Lincolnshire Limestone, matrix effects are less important. Because of the combination of good matrix porosity and fracture permeability in the Sherwood Sandstone (a dual-permeability aquifer), the response largely depends on the presence or absence of fractures in the target aquifer. If fractures are present, the response tends towards that of a Chalk aquifer, whereas if fractures are absent, then the response tends towards that of the Lower Greensand aquifer.

The absence of dual-porosity effects in the Lower Greensand aquifer means that the quality of the native groundwater has a minimal influence on the quality of the recovered water as it is simply displaced by the injected water with little mixing.

If the quality of the native groundwater in an aquifer is already good, then the extent of mixing is not important and other quality issues and the efficiency of the scheme in terms of recovery of injected water will determine the likely overall benefits.

The main conclusion of this modelling is that where an ASR scheme is to be used in an aquifer with poor quality native groundwater then, all other things being equal, dual-porosity aquifers will need more conditioning (injection of non-recoverable water to build up a buffer zone of mixed waters) than single porosity aquifers. However the suitability of any particular aquifer depends on its physical (dispersive and diffusive parameters) and chemical characteristics (native groundwater and injected water quality) Local variations can be great and will need to be determined on a site-by-site basis from field trials.

5 Water – groundwater – rock interactions

5.1 Introduction

The geochemical processes involved in an ASR scheme involve a range of chemical reactions between the injection waters, the native groundwater and the aquifer (Figure 5.1). Therefore the chemical changes that occur are determined by three end-members:

- chemical composition of the injected water;
- chemical composition of the native groundwater;
- chemical (mineralogical) characteristics of the aquifer.

There are large potential variations in the chemical compositions of both the injection and the native waters, as well as the rock matrix. The source of the injected water can include drinking water, untreated or treated surface water, untreated or treated groundwater or reclaimed water. Native groundwater quality can vary from fresh through brackish water to saline water. The major element chemistry is often dominated by reactions involving carbonate or silicate mineral phases. The redox status may be either oxidising or reducing. In addition, large regional differences exist in native groundwater quality related to land use, residence time and differences in aquifer mineralogy.

The simplest estimate of recovered water quality is that it will lie somewhere between that of the injection water and that of the native groundwater. If there are no chemical reactions, then the recovered water quality will merely reflect the mixing ratio. This would be true of an ion such as chloride and is what has been modelled in Chapter 4. Most solutes do react to some extent with the aquifer – the solid/solution ratio is extremely high in aquifers so that even a small amount of dissolution, for example, can have a major effect on groundwater quality. In most cases, native groundwater will have equilibrated with the host aquifer and so this should give an indication of the presence of relatively soluble minerals such as halite (NaCl), gypsum ($CaSO_4.2H_2O$), calcite (CaCO3), dolomite ($CaMg(CO_3)_2$) and fluorite (CaF_2). Geochemical modelling can help to establish which of these minerals is present in the aquifer.

Occasionally, the injection of water may cause 'new' reactions to take place, which could lead to the quality of the recovered water quality being outside the range of quality spanned by the injection and native water. For example, if oxidising water is put into a reducing aquifer containing pyrite (FeS_2) then this could lead to pyrite oxidation with the release of sulphate, and probably more significantly, dissolved iron. Other minor elements could also be released. The extent of this oxidation is controlled by both the amount of dissolved oxygen and nitrate in the injection water. Injecting reducing water into an oxidising aquifer could also lead to the release of iron and manganese by dissolving iron and manganese oxides. There can also be some surprising effects when mixing two waters – for example, the mixing of two calcite-saturated waters can lead to a calcite-unsaturated water and thereby lead to further calcite dissolution from the

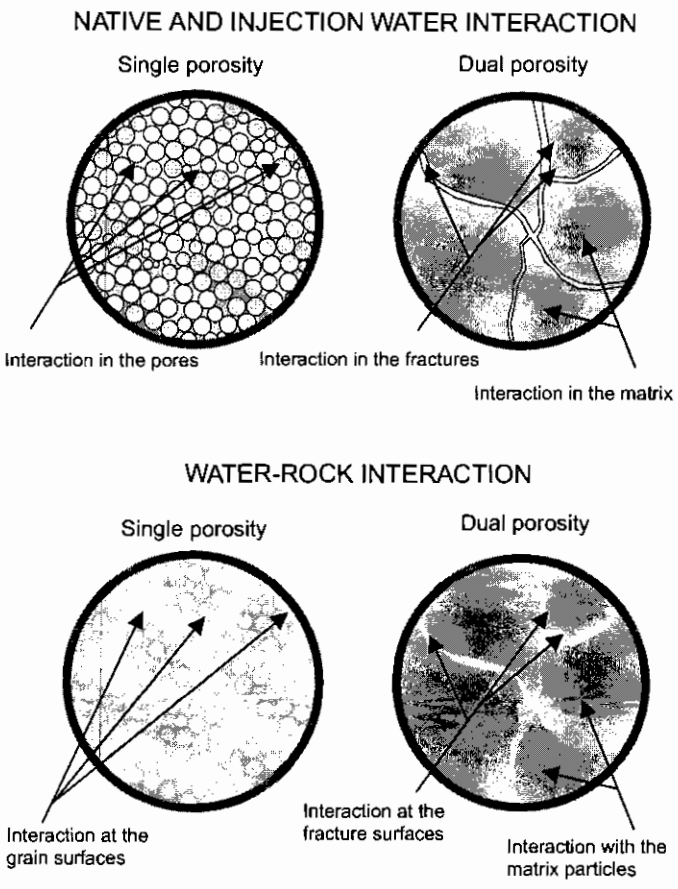

Figure 5.1 Situations in which chemical interactions between groundwater and aquifer can take place during ASR

Aquifer material. Similar effects can occur with other minerals. The danger with these additional reactions is that they may put the recovered waters outside the acceptable range for drinking water or may lead to the development of precipitates that may clog the well. Geochemical modelling can provide estimates of these effects but the rate of most of these dissolution/precipitation reactions in British aquifers is poorly understood and so these estimates are likely to be only approximate.

The PHREEQC Model (originally developed by the USGS)

PHREEQC is based on an ion-association aqueous model and has capabilities for (1) speciation and saturation-index calculations; (2) reaction-path and 1D-transport calculations involving reversible reactions, which include aqueous, mineral, gas, solid-solution, surface-complexation, and ion-exchange equilibria, and irreversible reactions, which include specified mole transfers of reactants, kinetically controlled reactions, mixing of solutions and temperature changes and (3) inverse modelling, which finds sets of mineral and gas mole transfers that account for differences in composition between given waters, i.e. how the water quality may have evolved from one place to another (Parkhurst and Appelo, 1999).

Modelling of the likely major impacts of ASR on the recovered water quality in the four main aquifers in Britain was carried out using various plausible combinations of

injection water quality, aquifer type and native water quality. The aquifers investigated were the Chalk, the Lower Greensand, the Sherwood Sandstone and the Jurassic Limestone. The PHREEQC geochemical speciation and transport model (see Box) was used for these calculations. The objective of this modelling was to provide guidance on possible water quality issues that should be considered when investigating the development of new ASR-schemes. More detailed modelling based on site-specific data is necessary to assess any probable water quality problems in specific situations since conditions are likely to vary greatly from site to site.

Table 5.1 The range of injection and native water combinations tested during the geochemical modelling for various British aquifers

Chalk	Lincolnshire Limestone
• Injection of treated Upper Chalk water into the confined Upper Chalk at Lytchett Minster • Injection of treated Upper Chalk water into the confined Upper Chalk at Holton Heath • Injection of treated Blashford Lakes surface water into the confined Upper Chalk at Lytchett Minster • Injection of treated Blashford Lakes surface water into the confined Upper Chalk at Holton Heath	• Injection of River Trent water into the Lincolnshire Limestone at Spalding Bulb Company • Injection of River Trent water into the Lincolnshire Limestone at Lenton PS
Sherwood Sandstone	**Lower Greensand**
• Injection of River Derwent water into the Sherwood Sandstone aquifer at Budby. • Injection of River Derwent water into the Sherwood Sandstone aquifer at Gainsborough B.P. • Injection of Magnesian Limestone water into the Sherwood Sandstone aquifer at Gainsborough B.P. • Injection of Magnesian Limestone water into the Sherwood Sandstone aquifer at Budby.	• Injection of treated Upper Chalk water into the Lower Greensand at Stockbury • Injection of River Medway water into the Lower Greensand at Stockbury

The main geochemical processes relevant to ASR include mixing, adsorption-desorption, ion-exchange, oxidation-reduction and dissolution-precipitation reactions

(Jones et al., 1999). In addition, microbially-mediated reactions (not modelled here) may occur, particularly related to the degradation of organic chemicals and the reduction of nitrate. An overview of the different types of injection and native waters used for the exploratory modelling is given in Table 5.1. The end members were selected to be representative of scenarios that have been, or are likely to be utilised. Details of the water chemistries used are given in Gaus (2001).

Major chemical changes to the quality of the injected water during recovery are to be expected when one or more of the following conditions are met:

- there is a large difference in chemical quality between the injected and the native water; this can cause large differences in pH or redox status.
- the native water or the sediment do not possess a sufficient pH buffering capacity (e.g. in the case of acidic waters where no calcite or dolomite is present for dissolution)
- there is a large difference in elemental concentrations between the injection and the native water (e.g. fluoride) and significant mixing occurs (e.g. in dual porosity aquifers)
- a change in chemical condition of the water having contact with the sediment is able to trigger major (e.g. dissolution of gypsum) or minor (e.g. dissolution of heavy metals) reactions.

5.2 Geochemical assessment for the different aquifers

Depending on the flow regime in the aquifer, different types of chemical interactions are likely to dominate and determine the quality of the recovered water.

In cases where the aquifer has a dual porosity character (as is the case for the Chalk and the Lincolnshire Limestone), the following factors might influence the quality of the recovered water:

- during ASR, the native water in the fractures will be replaced quickly with injected water. However, diffusional interchange between the matrix and fractures is relatively slow with the matrix retaining the native water signature for a long time. This diffusional mixing might lead to additional geochemical reactions.
- the water quality in the matrix pores may differ significantly from that of the water in the fractures. Such differences may have significant effects.

When the aquifer is a single porosity aquifer (e.g. the Lower Greensand) in which intergranular flow predominates, then it is more likely that a 'bubble' of injected water will form around the ASR-injection well. This bubble, of almost 100 % injected water, will be surrounded by a mixing zone of native and injected water. The creation of such a bubble (reservoir) of injected water in the aquifer has two major consequences:

- simple mixing between the injected water and the native water will be restricted to the mixing zone, as will the impact of geochemical reactions between the waters, leaving the injected water in the bubble relatively unaffected.

- largely unmixed injected water in the bubble will be able to trigger more intense geochemical reactions with the sediment when there is a large difference in quality between injected and native waters.

Although the behaviour of the Sherwood Sandstone lies somewhere between dual-porosity (the bulk of the flow takes place in the fractures and storage is provided by the matrix) and single-porosity (flow takes place in the matrix), it is probably best described as a dual-permeability medium. The matrix is permeable enough to transmit water at the low rates relevant to regional flow systems, but is probably not permeable enough to affect water flow in some near-well situations where rapid fracture flow is likely to be dominant. Because the extent of mixing will be even greater in the dual porosity case, this is seen as the worst case and was therefore assumed in the modelling.

The main chemical reactions for each aquifer have been classified into issues related to the native water quality, issues related to the injected water quality and issues related to the chemical reactions within the aquifer. Interactions with the sediment are based on the anticipated major components from geochemical descriptions for the different aquifers. The results of the modelling study are discussed in detail, and tabulated in Gaus (2001) and are summarised here in Table 5.2

These conclusions are based on the modelled cases only, and highlight the main chemical reactions likely to occur when implementing an ASR-scheme. Other chemical interactions may determine the quality of the recovered water when other injection waters are used, when the native water has a different quality, or when the geochemistry of the aquifers is different from that assumed here. Also reactions involving some minor elements such as cadmium, nickel and arsenic have not been considered.

In general the changes in the quality of injected water which may occur following recovery will depend strongly on the injected water quality and the native groundwater quality as well as the physical (transport) and chemical properties of the aquifer concerned. Recovered water quality will usually lie somewhere between the two end-members and for reactive solutes, may be closer to the native groundwater quality. Rarely, there may be interactions between injected groundwater and the aquifer that give rise to poorer recovered water quality than found in either of the two end-members. The most likely example of this is where aerated, high-nitrate groundwater is injected into a reducing aquifer containing pyrite (FeS_2). This can lead to the release of significant quantities of iron, sulphate and other minor elements.

Geochemical modelling can be used at different levels when planning and developing an ASR-scheme. During the initial desk study, it can be used to provide an initial assessment of the chemical viability of the scheme. During the trial and implementation stages of an ASR scheme as additional water quality data become available, geochemical modelling can be used to assess the impact of specific geochemical reactions. This is illustrated for the case of fluoride, which was monitored during an ASR trial in the Chalk in southern England (see Section 5.3).

Table 5.2. Possible impacts of ASR on recovered water quality in the UK

Inorganic chemical parameter	Possible groundwater reactions which may change the injected water quality
pH	In aquifers containing free calcium carbonate (all Chalk limestone aquifers and usually the Sherwood Sandstone and Lower Greensand), the pH of the recovered water is likely to be close to that of the native groundwater.
Chloride (Cl)	Expect injected water to mix with native groundwater and the final Cl concentration will reflect the extent of this mixing and the two concentrations, i.e. conservative mixing. This should be relatively rapid in well-mixed aquifers but will be slow (months to years) in dual porosity aquifers such as the Chalk.
Sodium and potassium (Na and K)	As for Cl but some cation exchange will occur on clays, which will tend to buffer concentrations to be closer to those in the aquifer. The effect will be greatest where the clay content is greatest, e.g. Lower Chalk and parts of the Lower Greensand.
Calcium and magnesium (Ca and Mg)	In the presence of free calcium carbonates, these concentrations are likely to be controlled by carbonate equilibria but cation exchange may also be important where the clay content is high. Generally concentrations will tend to approach those of the native groundwater.
Iron, manganese, ammonium and nitrite (Fe, Mn, NH_4 and NO_2)	Most injected waters will be aerobic and therefore low in these constituents but may be injected into a reducing aquifer where they are elevated (in the UK, most confined aquifers are reducing). This will increase their concentration in the recovered water but it should not be greater than in the native groundwater and will tend to be less if the injected water contains dissolved oxygen.
Sulphate (SO_4)	Similar to Fe and Mn but injection of aerated or high nitrate water into a reducing aquifer containing pyrite could lead to release of sulphate and acidity (which could lead to enhanced release of CO_2 when it reacts with carbonates).
Fluoride (F)	Similar to Cl but there can be an additional slow release from fluoride-containing minerals, especially where Ca concentrations are low. High native concentrations of fluoride are occasionally found in carbonate aquifers in the UK, but not in the sandstone aquifers.
Trace constituents	Most metals (Zn, Cd, Pb, Al etc) which are present as cations or carbonate complexes tend to be present at low concentrations at the near-neutral pH's of most UK groundwaters. Exceptions can arise in slightly acidic (some shallow Sherwood Sandstone and Lower Greensand groundwaters) and strongly reducing waters but such instances are relatively rare. Arsenic can be enhanced near mineralised areas and close to the redox boundary in semi-confined aquifers, both in the Chalk and Sherwood Sandstone. Boron can be high particularly in areas associated with residual salinity.
Nitrate (NO_3)	Likely to be reduced if high nitrate, aerobic water is injected into a reducing aquifer due to denitrification.

Although beyond the scope of the modelling undertaken, the potential improvements in water quality, resulting from ASR, are considerable. Reduction of nitrate, when injected into a reducing aquifer may be microbially mediated, as may many other reactions involving organic chemicals. Attenuation of these chemicals during artificial recharge, is poorly understood and is the topic of much current research. Examples of attenuation of disinfection-by-products (DBP) (Pyne et al., 1996) and the capacity of aquifers for adsorbtion and biodegradation of organic carbon (Dillon and Pavelic, 1996) have been documented. However the sustainable treatment processes occurring in aquifers need further investigation, particularly in relation to pathogens, natural and synthetic organic chemicals, including endocrine disruptors.

5.3 Case Study: fluoride modelling of the ASR trial in Lytchett Minster

The SWIFT model, applied to the ASR trial in the Chalk aquifer at Lytchett Minster, Dorset, (see Section 4.3.2) demonstrated that the increase in fluoride concentration in the recovered water could not be attributed solely to dual-porosity mixing. An additional chemical reaction must have taken place to give the observed increase of about 10 % above that predicted for mixing alone. Geochemical modelling was used to help to identify the geochemical processes leading to this additional increase in fluoride in the recovered water. A full description of the fluoride modelling at Lytchett Minster can be found in Gaus,et al. (2001).

An example of the excess fluoride in the recovered water is shown in Figure 5.2 (right) for Cycle 9. Data from other cycles showed the same pattern. Chloride (which shows conservative behaviour) was used to calculate the amount of mixing between injection and native water and is shown on the x-axis. The ratio between mixing based on fluoride to that based on chloride is plotted on the y-axis. If fluoride also behaved conservatively, the fitted line would be horizontal; intersecting the y-axis at 1.0. The fact that this ratio is much greater than 1 at the beginning of each recovery cycle, and reduces during the recovery phase, indicates that processes other than simple mixing control the fluoride concentration. Where the main component of the recovered water is injection water, the fluoride concentration is much greater than would be expected from simple mixing alone. With an increasing fraction of native water in the mixture, excess fluoride due to geochemical reactions will influence the fluoride mixing ratio to a lesser degree because of the high fluoride concentration in the native groundwater.

Three mechanisms that could cause the observed increase in fluoride concentrations were postulated and the results expected from each mechanism was modelled and then compared with the field observations. The three mechanisms are:

1. the fluoride concentration in the matrix water is higher than in the fracture water: the recovered water will reflect the difference between the fracture water and the matrix water in the Chalk even with no geochemical reactions

2. the mineral fluorite (CaF_2) is available for dissolution in the matrix and in the fractures, but only a limited amount is present: the concentration of fluoride in the recovered water will be limited by the amount of fluorite in the sediment that is available for dissolution

3. fluorite is available in sufficient quantities for the fluoride concentration to reach saturation but the dissolution kinetics are slow: the rate of fluorite dissolution therefore determines the fluoride concentration in the recovered water (a simple kinetic equation was used to describe the dissolution kinetics).

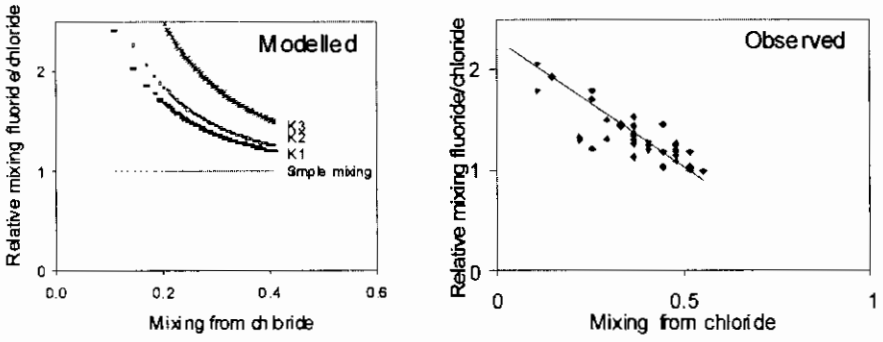

Figure 5.2 Comparison of modelled and observed relative mixing ratios for fluoride and chloride versus the amount of mixing between injection and native groundwater. Left: modelled ratios based on fluorite dissolution kinetics (mechanism 3) for three parameter sets (K1, K2 and K3); Right: optimal fit (line) through observed ratios (crosses) from Cycle 9.

The modelling results according to mechanism 3 are shown in Figure 5.2 (right). Modelling showed that the mechanisms 1 and 2 were not able to fit the observed data. Therefore, it is concluded that the increase in fluoride is probably controlled by the dissolution kinetics of a mineral, probably fluorite, which is present in excess in the Chalk sediments.

If this is the case, a significant decrease in fluoride concentration in subsequent cycles is unlikely to occur until the available fluorite is exhausted and mechanism 2 becomes the dominant process. However, the amount of fluoride dissolved and removed during ASR-cycles is likely to be small compared with that present within the solid phases in the aquifer. No data are available for the amount of fluorite present in the Chalk sediment at the site.

This case study demonstrated the broader view that must be taken when including an ASR scheme as part of a water resources strategy. The cost implications of the additional treatment, or blending, need to be compared to alternative sources of supply, remembering to include the environmental benefits (Eastwood and Stanfield, 2001). The Chalk and Lincolnshire Limestone are known to contain occasional high-fluoride groundwaters (Edmunds et al., 1989). The Sherwood Sandstone aquifer is normally low in fluoride (<0.1 mg/l). Fluorapatite, another F-containing mineral, is known to be present in some Chalk sediments and could provide an additional source of fluoride but it is likely to be released at a much slower rate than from fluorite.

6 Regulatory considerations

6.1 Regulations affecting Artificial Recharges to groundwater

Under the Groundwater Regulations, 1998 (GWR) an authorisation is required for discharges of listed substances to groundwater (the saturated zone). Regulation 6 of the GWR makes provision for the authorisation of artificial recharges, subject to there being no risk of pollution of groundwater. (Note: under the GWR it is not just actual pollution but the risk of such pollution that has to be considered). Direct discharges to groundwater (directly to the water table) may be consented under the Water Resources Act, 1991- these consents also act as authorisations under the GWR.

The GWR, which reflect the EU Groundwater Directive, require that there should be no entry of List I substances into groundwater and no pollution by List II substances. Listed substances (List I and List II) are given in the Schedule attached to the GWR. There is a formal process by which the Environment Agency, as the responsible body in England & Wales, determines whether a substance is listed. The Ecotox Centre should be consulted regarding the status of any particular substance.

Under Regulation 2, the Environment Agency can determine whether a discharge can be excluded from the GWR by virtue of the quantity and concentration of listed substances in the discharge. This is a case-specific assessment, which must be undertaken with no prior investigation of the hydrogeology of the site (following a European Court decision several years ago) it must be obvious from the nature of the source material that it could not cause entry into groundwater of List I substances or pollution by List II substances. The DETR guidance on the GWR makes it clear that although there are no specific concentration limits for pollutants, the drinking water and other similar standards may be used as a benchmark for such assessments.

If a discharge is found to be outside the remit of the Groundwater Regulations by virtue of the ***de minimis*** provision above, it is unlikely to require any other form of consent under water quality legislation. If the discharge contains only non-listed but nevertheless potentially polluting matter (e.g. bacteriological contamination), it may still possibly require a discharge consent under the Water Resources Act, 1991.

List I substances can be allowed to enter groundwater if the groundwater body can be declared as being "permanently unsuitable for other uses". There is a detailed procedure that describes this within the Agency's Groundwater Regulations Process Manual. This is publicly accessible but is not a published procedure. It can be obtained via Environment Agency offices.

6.2 Guidance on dealing with authorisations for artificial recharge and recovery (ARR) schemes

As part of a project assessing the potential for ASR in England and Wales, the regulatory issues associated with development of schemes were reviewed in the context of the existing guidance. The conclusions of this review are given in Appendix J of the project report (Jones et al. 1998), the main points of which are summarised below.

The purpose of Appendix J was to provide guidance on the licensing and consenting requirements associated with Artificial Recharge and Recovery (ARR) schemes. These can range between:

- Aquifer Storage and Recovery (ASR) schemes as developed in the USA, involving recharge of water into relatively deep, possibly poor quality and little-used aquifers to create a bubble of fresh groundwater for subsequent re-abstraction, and

- Artificial recharge schemes involving injection of water into good quality, generally well-utilised, aquifers to enable better or increased use of water resources (e.g. to store excess winter resources for re-abstraction to meet summer demand, or to support use of an aquifer with limited or heavily-utilised natural resources, etc).

The guidance covers a range of situations encompassed by such schemes, all of which will require authorisations from the Environment Agency.

Nothing in the guidelines modifies the abstraction licensing best practice set out in the Environment Agency's National Abstraction Licensing Manual, to which reference should be made for detailed explanation of Agency requirements, policy and procedures. Unless otherwise stated, references to sections in the legislation relate to the Water Resources Act 1991 ("WRA1991").

The phased and individual nature of ARR scheme development (which can extend over several years) makes it difficult to produce guidelines which will cover every eventuality but in general, the developer should ensure that :

a) Abstraction of water from any aquifer or surface water source is authorised either by an existing licence or by a Section 32 consent, as appropriate, having been discussed with the Agency beforehand.

b) The recharge of any water to the receiving aquifer is authorised in accordance with legislative and Agency requirements.

c) The discharge of any water to controlled waters (either surface or groundwater) is authorised in accordance with legislative and Agency requirements.

Discharge consenting requirements for b) and c) above will depend upon whether or not the discharge is classed as trade effluent. Where in doubt, Agency staff should consult their Regional legal departments.

The Agency will seek to control all recharge and subsequent re-abstraction to ensure effective development of water resources whilst protecting the environment and other abstractors. In particular, it will expect schemes to be sustainable in terms of quantities recharged and re-abstracted and may wish to apply water level or water quality conditions to any authorisations issued.

The developer should be aware that, for most schemes, the Agency will issue separate authorisations relating to each main phase of development/implementation, since the monitoring, abstraction and discharge requirements for the initial testing, operational

testing and final scheme implementation phases will differ. It is therefore important that the developer continues to keep in close contact with the Agency as each phase progresses.

Whilst the Agency appreciates that developers will want to know at the outset about the likelihood of obtaining all necessary authorisations for all phases, it is unlikely to be able to give firm indications at that stage. Much will depend upon the findings of investigations as each phase of the scheme progresses. It is possible that later phases will not be able to go ahead if, for example:

- earlier phases show there are insufficient resources to provide the donor water, or
- there are incompatibilities in quality between the donor and receiving waters that cannot be resolved, or
- there are adverse effects on lawful abstractions, or
- the Agency believes that the recharge of water will be environmentally damaging.

6.3 Phased development/authorisations

The phased and individual nature of ARR scheme development (which can extend over several years) makes it difficult to produce guidelines that will cover every eventuality. In general, the developer should obtain the necessary authorisations throughout the six phases of development and ensure that the required Environmental Impact Appraisals (EAPs) are carried out.

Phased development of Artificial Recharge and Recovery Schemes	
Phase 1	preliminary discussions
Phase 2	development/construction of donor source(s)
Phase 3	construction/initial development of recharge borehole(s)
Phase 4	operational testing of recharge borehole(s) and re-abstraction source(s)
Phase 5	applications for authorisations for operational scheme
Phase 6	determination and issue of licences and consent

6.4 Environmental Impact Appraisals (EAPs)

The Agency will require that the effects of the proposed development on the environment are considered. The scope of the impact appraisal will be affected by the nature of the aquifer, the two extremes of which are shown below.

Aquifer Type	Nature of the Aquifer	Type of EAP
Shallow Unconfined (Traditional Artificial Recharge Schemes)	Good quality water present Probability that surface water may be affected Probable impact on existing abstraction rights Limited spread of level changes	Full EAP probably required
Deep Confined (Aquifer Storage and Recovery Schemes)	Poor quality water No direct connection with surface water Existing abstractors likely to be absent Level changes can be widespread	Relatively restricted EAP probably sufficient

In addition to the normal requirements necessary for abstraction licences, environmental impact appraisals for ARR schemes should include consideration of, amongst others, the following effects as appropriate. Some of these issues have been considered further in the ASR-UK project. Discussion of the possible environmental impacts is in Chapter 3 of this report. A series of models are described that can be used to assess and quantify the likely impacts. These models are of varying complexity so they can be applied at appropriate phases of development.

Feature	Possible effects	Possible problems
Existing abstraction boreholes	Increase or decrease in rest water level in the borehole	Existing installation becomes inappropriate
Existing abstraction boreholes where rest water level is close to surface	Increase in level to give artesian conditions	Flooded pump chambers Electrical problems Flooding of nearby farmland
Low lying areas	Increase in groundwater level	Water logged ground Flooding Increased flow of land drains (loss of recharged water)
Springs	Increase in spring flow; Changes in quality of groundwater discharged	Insufficient overflow capacity for new flows Flooding of chamber and pumping equipment Flooding of receiving water course

		Loss of recharge water
		Change in habitats
Streams	Increase in streamflow/flow in ditches;	Flooding
		Increase in depth of cattle watering areas
	Changes in quality of groundwater discharged	Loss of recharge water
		Change in habitats
Water bodies	Change in level	Change in habitats
		Changes in overflow quantities
		Loss of recharge water
Change in groundwater quality	Deterioration in quality	Loss of potability or suitability of water for use
		Corrosion or encrustation on water system - pumps and household systems
		Quality effects on habitats
Ground instabilities	Wetting of Clays;	Subsidence as clays swell
	Lubrication of strata boundaries	Instability of slopes

ANNEX J3 – The Potential for Aquifer Storage and Recovery in England and Wales. (from Jones et al. 1998)

✓ = Normally required × = Normally not required (but subject also to note where indicated)

Notes:

1. A Section 32 Consent should be issued at the operational testing stage if initial testing has failed to provide sufficient information to enable a formal licence application to be properly assessed. Otherwise, issue a time-limited licence or variation as appropriate (time limit may need to be shorter than policy would normally indicate).

2. Either new licence or licence variation, depending on type of approval given for operational testing. If licence was issued at that stage, a variation may be needed.

3. If characteristics of source or understanding of impact not properly known (e.g. current licence was determined as a Licence of Right or source was never properly tested), or it is necessary to control the testing to be carried out/specify special monitoring, it would be best to persuade potential operator to accept a Section 32 Consent, otherwise the Agency's requirements should be defined in a formal agreement (either under Section 20 (for water companies), or Section 158 of WRA, 1991).

4. If characteristics of source or understanding of impact still not properly known, you will need to persuade potential operator to accept a further Section 32 Consent, or define the Agency's requirements in another formal agreement (either under Section 20 or Section 158 of WRA, 1991).

5. The ARR operator will need to apply for a variation if it wishes to take advantage of reduced charges associated with any transfer of water or if earlier testing reveals current licence is inappropriate for the operational scheme.

6. New or varied licence will usually need to be for a shorter time limit than normal policy dictates, since the conditions included are likely to be test-specific.

7. Where a licence has been issued/varied for testing purposes, it may need varying for subsequent phases of development/operational use.

8. If it is necessary to control the testing to be carried out /specify special monitoring in such a way that is not covered by any existing licence, the Agency's requirements should be defined in a formal agreement (either under Section 20 or Section 158 of the WRA, 1991).

9. If it is necessary to further control testing/specify monitoring, the Agency's requirements will need to be defined in another formal agreement as for Note 8 above.

10. "Surface water" source of supply refers to those sources for which abstraction must be licensed (i.e. those that are non-exempt). The Water Resources Act 1991 defines those that are exempt (see 3.2.2.1(a) in guidance notes).

11. ✓= Normally required, ×=Normally not required (subject also to note where indicated).

7 Summary and conclusions

1. Aquifer Storage Recovery (ASR) is viable water management technique that has the potential to resolve a wide variety of supply issues in an environmentally sustainable manner. The main advantages are:

   - Net abstraction is zero or negative so minimal impact on the surface water environment.
   - Small land area required to store relatively large quantities of water at the point where it is available for injection and needed for supply.
   - Staged development possible to spread costs and at the same time keep up with demand.
   - Improvements in water quality can occur during storage and, once understood, water quality problems can be addressed, on recovery, through treatment or dilution. Cost implications need to be assessed in relation to alternative schemes

2. Several aquifers in the UK are suitable for ASR schemes, their advantages and disadvantages are summarised below. These comments are generic and because the scale of schemes can be of the order of a few hundred metres, local geological conditions may be different. Minor aquifers, or blocks of major aquifers may prove to be ideal for ASR at particular localities even where they are not generally considered to have a high potential.

   - The **Sherwood Sandstone and some Permian sandstone** aquifers appears to have the greatest potential due to their wide geographical distribution, great thickness and high inter-granular porosity. Care is needed to select a section of the aquifer with high porosity and few fractures in order to constrain the bubble of injected water, displace indigenous groundwater and thus obtain a high recovery efficiency
   - **Lower Greensand** aquifer is limited in areal extent and thickness but, in suitable locations, this high matrix porosity aquifer will be a good ASR target. Injected bubbles will displace the native groundwater thus minimising the zone of mixing and hence geochemical problems
   - The **Chalk** aquifer has been demonstrated to be an effective hydraulic target for ASR but if the native groundwater quality is non-potable then diffusion from the matrix will be a long-term problem. This does not preclude the use of these parts of the aquifer where environmental impact considerations may still make the scheme attractive. However, the economic implications of additional treatment or dilution will need to be factored in. Where the Chalk is in hydraulic contact with overlying **Palaeogene** or **Quaternary** arenaceous deposits or the underlying **Upper Greensand**, then the storage in these aquifers can make an ASR scheme potentially more viable.
   - The variability of the **Jurassic limestones** will make their suitability for ASR equally variable. However, the aquifer may be able to provide a

reservoir for ASR where the local hydrogeological conditions are suitable. The high diffusivity of these aquifers means that the environmental impacts need to be evaluated at distances of several kilometres.

- Other **minor aquifers** should be considered on an individual basis. ASR schemes require areas of aquifers of the order of only tens of hectares so suitable, local geological settings can be adequate. Aquifers identified as having some potential include the **Fell Sandstone, Millstone Grit, Kellaways Rock** and some **Upper Lias Sands.** When considering these aquifers their potential can by reviewed in respect of the "aquifer continuum" described in this report. This continuum ranges from unconsolidated arenaceous deposits with high matrix porosity (Lower Greensand), through consolidated sandstone aquifer with high matrix porosity and some fracture flow (Sherwood Sandstone), fracture flow dominated, high diffusivity aquifers (Jurassic Limestone) to fracture flow dominated aquifers with dual porosity mixing being the dominant process (Chalk).

3. The environmental impacts of schemes will be crucial in determining their success or failure and should be assessed at the earliest stages of a scheme. Key issues are the impacts on water levels in overlying aquifers and in the unconfined part of the target aquifer, even at distances of several kilometres. Of particular concern are the impacts on stream-flow and wetlands and these need to be assessed in relation to the time delay of response of the aquifer at outcrop in relation to injection or recovery at the ASR well. Simple models have been developed to address some of these issues and to act as tools to assist decision-making on how to proceed and what additional information is required throughout the review, field trial and implementation phases of a scheme. Optimisation of the operational cycle can be demonstrated to minimise the impacts.

4. The recovery efficiencies of ASR schemes will be determined by the amount of mixing between the native groundwater and the injected water and this is controlled by the physical properties of the aquifers. In addition to physical mixing, both advective and diffusive, geochemical reactions between different waters and the rock matrix will determine the quality of the recovered water. The physical aspects have been modelled using the SWIFT/486 modelling package to test the sensitivity of the systems to ranges of aquifer properties as well as testing and operational cycles. Within the limitations and assumptions inherent in the model, the main conclusion is that dual-porosity aquifers will need more conditioning (injection of non-recoverable water to build up a buffer zone of mixed waters) than single porosity aquifers before they are suitable for use for ASR. However the suitability of any aquifer depends on the site-specific dispersive and diffusive parameters, which can generally only be obtained from field trials.

5. Geochemical models have been used to predict likely impacts of injecting a variety of waters into different aquifers containing different groundwaters. The selection of the different components was constrained by the most likely scenarios in the four major aquifers. The PHREEQC model was used and it was

found that, depending on the flow regime in different aquifers (matrix flow or fracture flow dominated), different chemical reactions dominate

- In dual porosity aquifers the injected water in the fissures will continue to react with the matrix water as well as the rock matrix whereas in a single porosity aquifer the pore water is displaced and reactions are restricted to the peripheral mixing zone, the bulk of the injected water being unaffected. However, in the latter case, the reactions, if any, between the injected water and the rock matrix will dominate.

- Geochemical reactions can be expected to be significant if there are:

    i. Large differences in pH and redox potential between the native and injected water

    ii. Little buffering capacity in the native water and/or the sediment

    iii. Large differences in concentrations between native and injected waters, combined with intensive mixing

    iv. The water mixture triggers dissolution reactions leading to the sediment releasing significant quantities of major or minor elements.

Descriptions of Anisotropy and Heterogeneity and Their Effect on Ground-Water Flow and Areas of Contribution to Public Supply Wells in a Karst Carbonate Aquifer System

By Lari A. Knochenmus *and* James L. Robinson

Abstract

Delineation of areas of contribution to wells tapping a karst carbonate aquifer system can be extremely difficult using conventional approaches designed for isotropic and homogeneous aquifers, because ground-water flow tends to be through solution-enhanced conduits. Nonradial flow along preferential zones can result in inaccurate estimates of flow paths and traveltimes. Because of the large variability in factors affecting contributing areas and an imperfect understanding of how these factors can vary, the estimation of contributing areas is an approximation at best.

To better understand the effects of aquifer anisotropy and heterogeneity on areas of contribution, an exploratory modeling approach was used. MODFLOW, a numerical flow model, and MODPATH, a particle tracking program, were used to generate time-related areas of contribution for six hypothetical carbonate aquifer system types. The six types were conceptualized to approximate different types of aquifer anisotropy and heterogeneity. These include: (1) an isotropic and homogeneous single-layer system; (2) an anisotropic in a horizontal plane single-layer system; (3) a discrete vertically fractured single-layer system; (4) a multilayered system; (5) a doubly porous single-layer system; and (6) a vertically and horizontally interconnected heterogeneous system. The simulated aquifer anisotropy was 5:1 (K_{xx}/K_{yy}) determined from TENSOR2D results. The simulated discrete vertical fracture network represents locations inferred from mapped photolineaments. The simulated enhanced flow zones were determined from borehole video and geophysical logs. Areas of contribution were simulated for two prototype regions. The two prototypes were selected to be representative of the hydrologic diversity within the study area and were designated the Central Swamp and Lake Terrace regions.

Localized conditions in pumping, production well distribution, and aquifer transmissivity affect the size, shape, and orientation of areas of contribution to public supply wells. The simulated areas of contribution are 60 percent larger in the Central Swamp region where pumpage is more than double and transmissivity is about half that of the Lake Terrace region. Although these factors are important, this study focused on the effects from hydrogeologic factors common to karst carbonate aquifer systems.

This study indicates that the distribution and type of aquifer anisotropy and heterogeneity will affect the size, shape, and orientation of areas of contribution in a karst carbonate aquifer system. The size of the 50-year time-related areas of contribution ranged from 8.2 to 39.1 square miles in the Central Swamp region and from 4.0 to 18.3 square miles in the Lake Terrace region. Simulations showed that the size of areas of contribution is primarily affected by simulated withdrawal rates, effective porosity of the carbonate rock, and transmissivity. The shape and orientation of the simulated areas of contribution primarily result from aquifer anisotropy, well distribution, flow along solution-enhanced zones, and short-circuiting of flow through fracture networks.

Comparisons also were made between protection zones delineated using analytical models and areas of contribution delineated using numerical models. The size of the 5-year time-related protection zone in the Central Swamp region using an analytical model was almost twice as large as the numerically simulated area of contribution, and more than eight times larger than the numerically simulated area of contribution in the Lake Terrace region. The differences in size are primarily the result of how the flow field is approximated. The analytical method assumes only lateral flow to wells but numerical methods allow particles to move laterally and vertically. Additionally, multiple-well-interference effects resulting from the close proximity of several pumping wells cause individual capture zones to converge or diverge, depending on the difference in pumping rates and orientation among the wells. Such an interpretation is not available from analytical methods. The simulated distributions of aquifer anisotropy and heterogeneity, in this study, were highly conceptualized, but were based on plausible occurrences of anisotropy and heterogeneity inherent in carbonate aquifer systems.

INTRODUCTION

The 1986 Safe Drinking Water Act Amendments require States to establish wellhead protection programs to delineate protective areas (areas of contribution) around existing and future public supply wells and well fields. The contributing area includes the geographical extent from which ground-water flow is diverted to the pumping well (Morrissey, 1989, p. 7-8). Traditional strategies to protect ground-water resources have been through land-use regulation within a prescribed radial area around each well. At times, little regard has been given to localized hydrogeologic factors common to karstic aquifers that can affect the size, shape, and orientation of areas of contribution to supply wells. Public supply wells in karst carbonate aquifers are particularly vulnerable to contamination. This is because permeability in carbonate aquifers is enhanced by circulation of water and dissolution of rock, creating higher permeability along preferred flow paths.

Historically, carbonate aquifers have been treated as diffuse-flow aquifers, in that ground-water movement virtually follows Darcy's law. This assumption, although adequate for defining flow in regional ground-water studies, is inadequate for local studies based on the inaccuracies inherent in the conceptual model. For example, the effects of nonradial, non-Darcian flow due to preferential flow paths through enhanced secondary-porosity zones, such as fractures, is a complicating aspect for developing useful strategies for ground-water protection in carbonate terranes. Therefore, a better understanding of the effects of aquifer heterogeneity on the size, shape, and orientation of contributing areas to supply wells is needed to understand ground-water flow to pumped wells. In 1990, the U.S. Geological Survey, in cooperation with the Florida Department of Environmental Protection (FDEP), began a study to illustrate the effects of aquifer anisotropy and heterogeneity, inherent to karst carbonate aquifers, on the size, shape, and orientation of contributing areas around public supply wells and well fields.

Purpose and Scope

This report describes aquifer anisotropy and heterogeneity in a karst carbonate aquifer, how these heterogeneities affect ground-water flow, and their effect on the size, shape, and orientation of contributing areas to well fields. To evaluate how areas of contribution might be affected by aquifer anisotropy and heterogeneity, a study area in west-central Florida (fig. 1) underlain by the Floridan aquifer system was selected because adequate existing data were available. Within the study area, two prototype carbonate aquifer systems were defined for detailed study. The specific purposes of the report are to:

1. Describe the anisotropy and heterogeneity typical of a karst carbonate aquifer system.
2. Present effects of aquifer anisotropy and heterogeneity on ground-water flow.
3. Show the effects of aquifer anisotropy and heterogeneity on areas of contribution to supply wells.
4. Compare delineation of protection zones determined using analytical methods and areas of contribution determined using numerical methods.

Spatial distributions of aquifer anisotropy and heterogeneity, examined in this report, were based on the results of previous studies. Historical aquifer test data were used as input to a computer program, TENSOR2D (Maslia and Randolph, 1986), to identify the possible range in magnitude and direction of anisotropy (K_{xx}/K_{yy}) in a horizontal plane. Results of a photolineament study (Culbreath, 1988) were used to

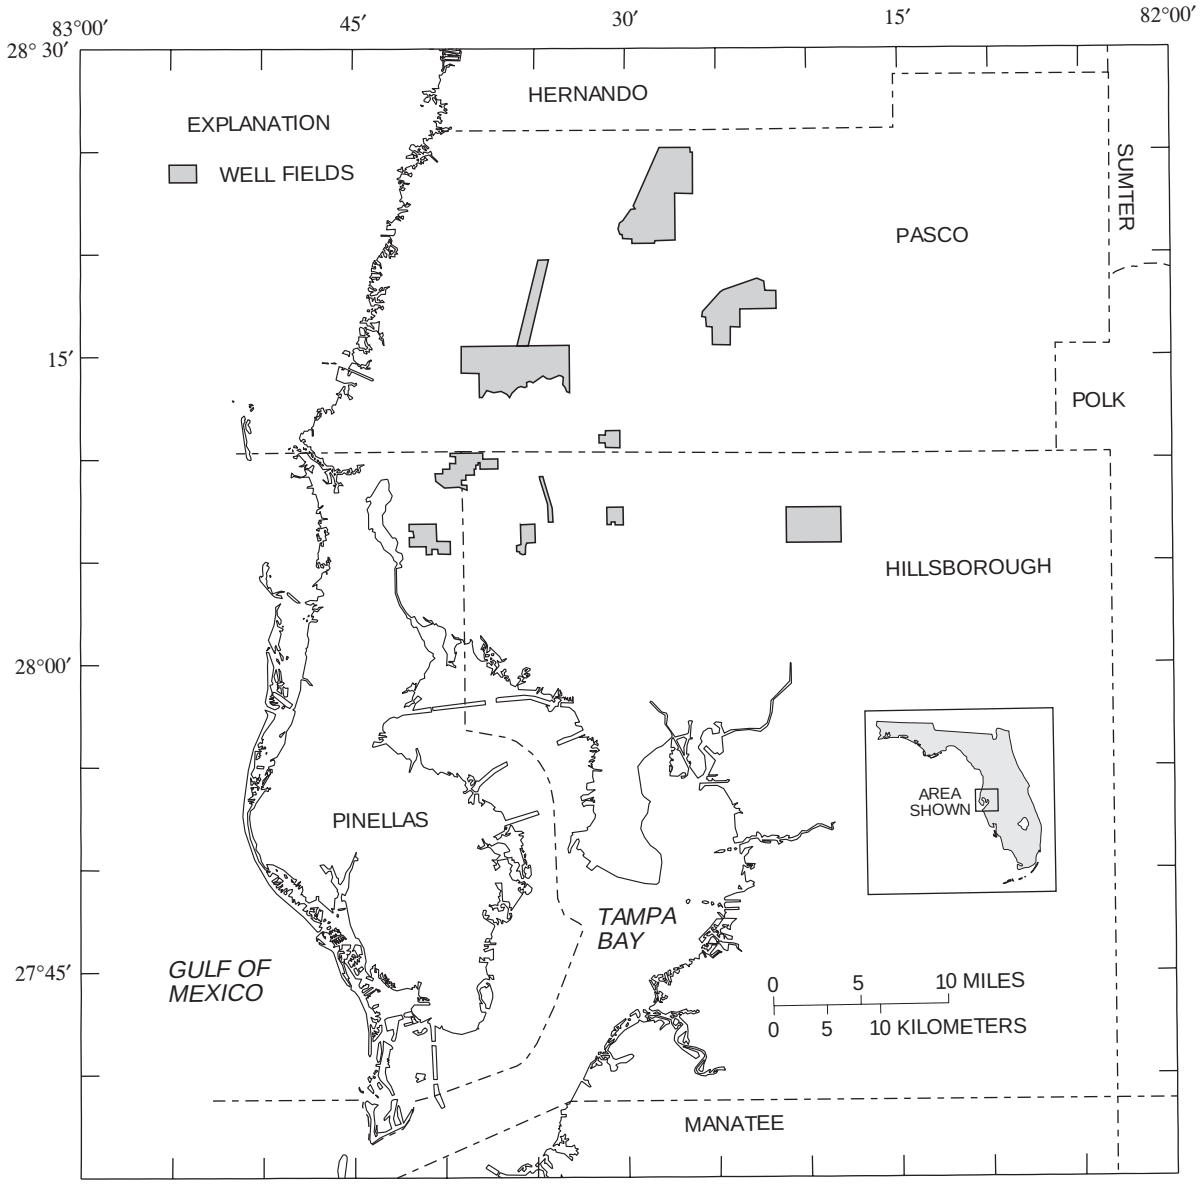

Figure 1. Location of the study area and well fields.

estimate locations of vertical fracture zones. Borehole video and geophysical logs were used to estimate locations of enhanced flow zones (Safko and Hickey, 1992). The data were then used to construct various hypothetical carbonate aquifer system types to be tested at two prototype regions, using the U.S. Geological Survey modular ground-water flow model (MODFLOW) and particle tracking program (MODPATH). This report is based on work done in west-central Florida, but the investigative techniques presented are applicable to similar hydrogeologic settings elsewhere.

Hydrogeology of the Upper Floridan Aquifer, a Typical Karst Carbonate Aquifer System

The most productive carbonate sequence in Florida and the southeastern Coastal Plain is the Floridan aquifer system, composed of limestones and dolomites with enhanced permeability caused by tectonic fracturing and karstification. These processes created secondary porosity, resulting in significant aquifer heterogeneity. Secondary porosity is defined in the Dictionary of Geologic Terms (Bates and Jackson, 1984) as porosity

developed in rock after its deposition or emplacement through such processes as solution or fracturing. The mechanisms for secondary porosity development in the Upper Floridan aquifer system are mechanical fracturing and chemical dissolution.

Vertical fracturing in a carbonate aquifer system can occur from propagation of basement structures through the overlying carbonates in response to crustal flexing caused by earth tides (Blanchet, 1957). Surface lineaments have long been recognized as surface manifestations of underlying vertical to near-vertical zones of fracture concentrations (Lattman and Parizek, 1964). Previous investigators recognized the occurrence of fracture traces and surface lineaments in west-central Florida as systematic patterns and correlated these patterns to fractures observed in limestone outcrops (Vernon, 1951, p. 47-52). Culbreath (1988) investigated the correlation between surface lineaments and major faults in the crystalline basement rocks using gravity surface geophysical methods. The surface lineaments that had corresponding gravity anomalies were orthogonally and bimodally distributed, and their preferred orientation is between 45 and 55 degrees east and west of north (fig. 2). Culbreath (1988) hypothesized that geologic structures occurring in this preferred orientation are more likely to be manifested at the surface as lineaments because they parallel the stress fields associated with earth tides.

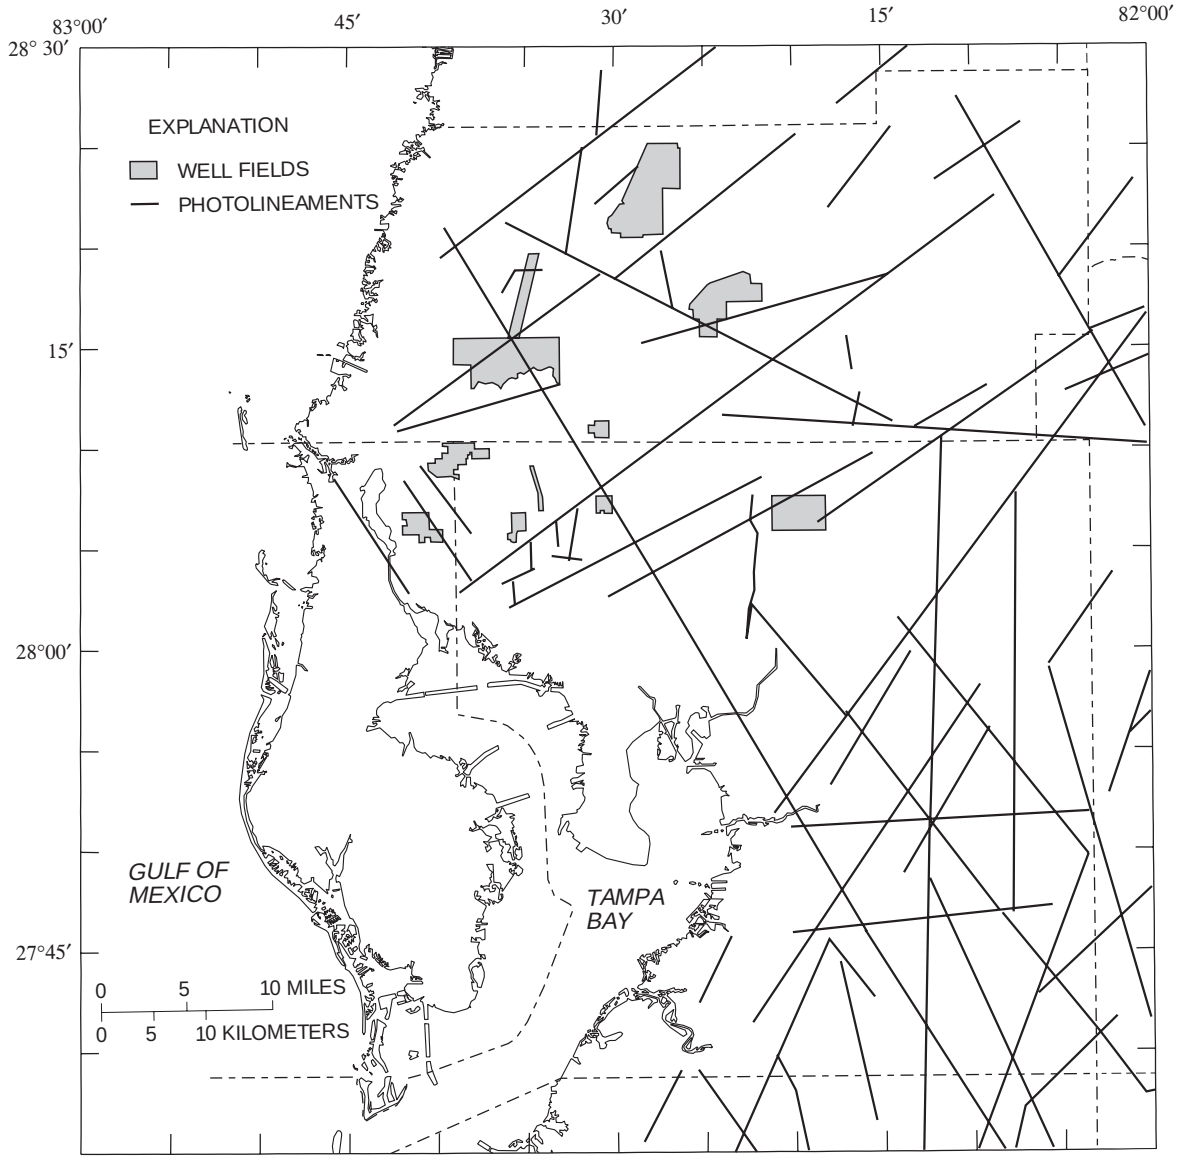

Figure 2. Location of photolineaments that have corresponding gravity anomalies. (Modified from Culbreath, 1988.)

In karst carbonate aquifer systems, fracture zones can be enlarged by chemical dissolution. Fractures channel ground-water flow along discrete paths, resulting in increased solution activity. Lattman and Parizek (1964) observed that karst features and associated highly transmissive zones are related to differential dissolution of the carbonate rock along linear fractures, faults, and joints in the rocks. Within the surface expressions of vertical to near-vertical fractures, narrow zones have been detected where porosity can be 10 to 100 times that of the intergranular matrix (Stewart and Wood, 1984). These narrow zones are highly heterogeneous discrete zones of increased vertical permeability within the carbonate aquifer system.

One mechanism for development of the heterogeneous layering of higher permeability zones in carbonate aquifer systems is chemical dissolution in response to changes in sea level. As water levels in the ocean rise and fall, base-levels change and subaerial karstification is cyclically renewed, creating various horizons of extensive secondary porosity development throughout the carbonate sequence. Chemical dissolution is most aggressive along zones of weakness in carbonate sequences. Horizontal zones of weakness tend to be at lithologic interfaces of differing types, at a specific lithologic boundary where a concentration of impurities such as sand, silt, and shell exists, and where cyclic changes such as laminations occur within a lithology. The lithologic heterogeneity within the Floridan aquifer system resulted from deposition in warm shallow seas over periods of geologic time where even slight changes in depositional conditions and diagenetic alterations resulted in textural and mineralogical changes described above. Vertical fracturing and heterogeneous layering of the carbonate rocks have resulted in variable horizontal and vertical permeabilities in the Upper Floridan aquifer (Williams, 1985). Subtle variations can affect porosity and permeability, resulting in a highly heterogeneous carbonate aquifer system.

Hydrogeologic Setting

The hydrogeologic framework in the study area comprises two aquifers, the clastic surficial aquifer system and the carbonate Floridan aquifer system that are separated by the intermediate confining unit (fig. 3). The Floridan aquifer system consists of the Upper and Lower Floridan aquifers that are separated by a middle confining unit (Miller, 1986). The middle confining unit and Lower Floridan aquifer generally contain saltwater in the study area. The Upper Floridan aquifer contains all or parts of the Avon Park Formation, the Ocala Group, the Suwannee Limestone, and the Tampa Member of the Arcadia Formation of the Hawthorn Group. In this report, the Tampa Member will be used to designate the Tampa Member of the Arcadia Formation of the Hawthorn Group. The formation names used in this report are based upon the geologic definitions of Scott (1988) and are the usage of the Florida Geological Survey.

Transmissivity

In general, the majority of water supplied to municipal wells open to the entire Upper Floridan aquifer is from two 50- to 100-ft thick, areally persistent, highly fractured zones in the dolomitic section of the Avon Park Formation (Ryder, 1978; Ryder and others, 1980; CH2M Hill, 1990a,b). The overlying Ocala Group, Suwannee Limestone, and the Tampa Member, where present, also are characterized by discrete producing zones that occur locally and less predictably near formational contacts. Although most of the water is derived from discrete producing zones, the intergranular matrix of the Upper Floridan aquifer also is a source of ground water.

Transmissivity of the Upper Floridan aquifer is highly variable and ranges from 29,400 to 130,000 ft^2/d within the study area. This is a direct result of the anisotropic and heterogeneous nature of the aquifer. Transmissivities determined from aquifer tests for the Upper Floridan aquifer vary widely because: (1) some wells do not penetrate the highly permeable (fractured) dolomites in the Avon Park Formation, (2) the wells may or may not intersect locally occurring permeability zones related to secondary porosity, and (3) the highly heterogeneous and anisotropic nature of the carbonate aquifer system makes the application of standard methods of aquifer test analysis uncertain and the results questionable (Wolansky and Corral, 1985, p. 28). Table 1 lists the ranges in transmissivity in the study area as reported by other investigators and compiled by Bengtsson (1987).

Porosity

The following definitions, of different porosity types, are the terminology used in this report. The porosity classification in based on the size, shape, distribution, and volume of voids compared to the overall volume of rock. Porosity may be microscopic or macroscopic.

Figure 3. Hydrogeologic framework.

Microscopic porosity includes intercrystalline porosity, interstitial porosity, and microfissure porosity. Intercrystalline porosity is defined as the voids between mineral crystals. Interstitial porosity is defined as the voids between loose or poorly cemented granular material. Microfissure porosity is defined as the voids formed by microjoints, microfissures, and bedding and schistosity planes. Macroscopic or channel porosity is the porosity occurring as large fissures, conduits, and channels. In carbonate sequences, porosity is often a combination of microscopic and macroscopic porosity and therefore, two additional porosity types are defined. Rock porosity is defined as the porosity of unfissured blocks or volumes of rock. Massive or formation/aquifer scale porosity is defined as the combined porosity from both interstitial pores (rock porosity) and fissures (channel porosity) (LaMoreaux and others, 1984, p. 47). Effective porosity is defined as the amount of interconnected pore space available for fluid transmission (Lohman and others, 1972, p. 10).

Table 1. Ranges in transmissivity values by well field from aquifer test analyses

[ft^2/d, feet squared per day. Modified from Bengtsson (1987)]

Well Field	Transmissivity (ft^2/d)
Cross Bar Ranch	47,500 to 115,000
Cypress Creek	31,500 to 53,600 78,610
Starkey	[1]40,000 60,700
South Pasco	53,600 47,000 51,000 to 71,000
Eldridge Wilde	[1]33,000 34,400 to 58,800 35,500
East Lake	40,000
Cosme-Odessa	[1]53,500
Section 21	29,400 to 87,000 60,000 71,000
Morris Bridge	53,000 to 130,000 35,000 to 56,000

[1]Wells do not penetrate the major producing zones in the Avon Park Formation.

Some aquifers can be characterized by diffuse-flow where water moves more or less uniformly through the interconnected pore space of the rocks (rock porosity). Unconsolidated clastic aquifers are in this category. Karst carbonate aquifers can be characterized by conduit flow along irregularly distributed, solution-enlarged fissures (channel porosity) in combination with diffuse flow through the more uniformly distributed, interconnected pores (rock porosity). The Floridan aquifer system of west-central Florida is in this category (Vecchioli and others, 1989, p. 33)

Twenty-two core samples from four wells were selected for laboratory analysis of effective porosity to characterize the matrix properties of the Upper Floridan aquifer. The core samples were supplied by the Florida Geological Survey. Samples were selected as representative of a specific hydrogeologic unit within the study area. Laboratory analyses for effective porosity were completed by a commercial laboratory. The four wells from which cores were selected are ROMP 99 (Regional Observation Monitoring Well Program), ROMP TR12-3, ROMP TR14-2, and Brantley #1 (fig. 4). The effective porosity values, corresponding lithologic unit, and sample depths are listed in table 2. The average effective porosity values for the Tampa Member, Suwannee Limestone, and Ocala Group are 29, 36, and 38 percent, respectively. Cores were not selected for evaluating the effective porosity of the Avon Park Formation because of its highly fractured nature. A well-indurated core selected to be representative of the Avon Park Formation would disproportionately represent the least permeable zones. Additional effective porosity values, determined from cores from selected wells (fig. 4), in the proximity of the study area are listed in table 2.

Effective porosities typical of clastic aquifers reflect the interstitial porosity, which can be measured at the rock-core scale, whereas effective porosities typical of karst carbonate aquifers are massive porosities and reflect both rock porosity and channel porosity that cannot be satisfactorily measured at the rock-core scale. Generally, the effective porosity associated with fractured aquifers is much less than that of porous media aquifers. Therefore, the range of effective porosity values presented in this study include values associated with channel and interstitial porosity and represent the massive porosity of a karst carbonate aquifer system.

DESCRIPTIONS OF ANISOTROPY AND HETEROGENEITY IN THE STUDY AREA

Field data collected from wells in the study area indicate the presence of aquifer anisotropy and heterogeneity. Anisotropy and heterogeneity in carbonate aquifer systems is largely attributed to aquifer stratification, localized solution channeling, and discontinuous confining beds.

Anisotropy

Anisotropy is defined as the condition of having different properties in different directions (Bates and Jackson, 1984, p. 21). A fractured carbonate aquifer system can often be modeled as an anisotropic aquifer, because the permeability inherent in a carbonate aquifer can result from preferential dissolution of rock along fractures producing directional dependent aquifer properties. Experiments by Hushey and Crawford (1967) indicated that the overall permeability is greater when fractures are aligned with the predominant flow direction. Analytical solutions were developed for use in conjunction with aquifer test data to determine aquifer anisotropy and components of the anisotropic transmissivity tensor. These components define the principal directions of anisotropy corresponding to the

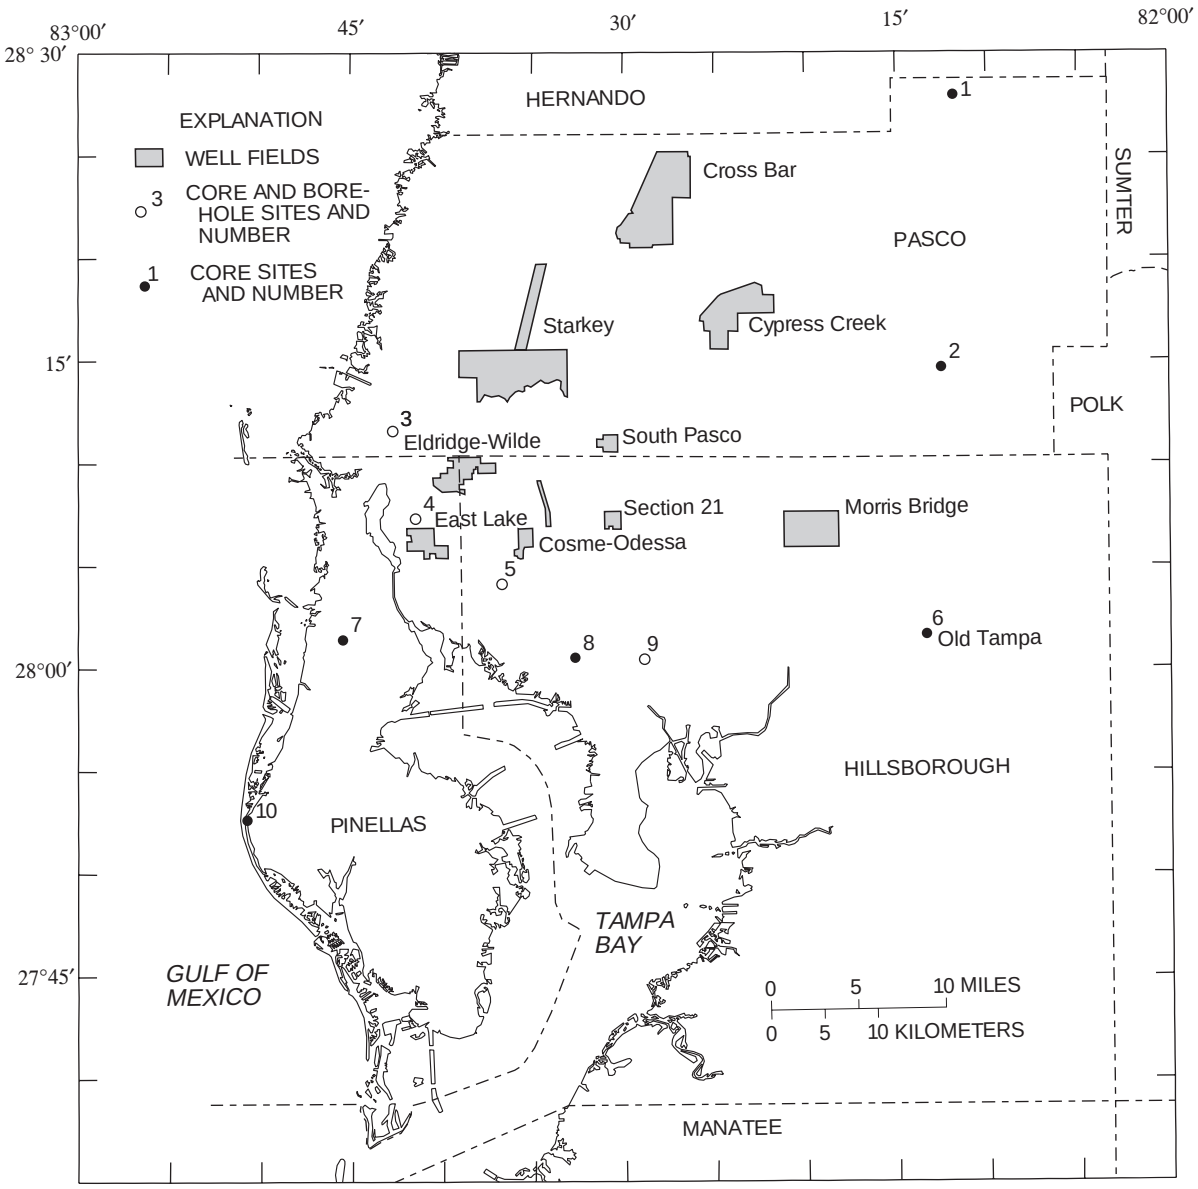

Figure 4. Location of the study area, well fields, and selected wells.

directions in space at which transmissivity (or hydraulic conductivity) attains its maximum and minimum values. The value of the ratio of the maximum and minimum transmissivities defines the magnitude of anisotropy. Based on indications of nonisotropic and nonhomogeneous porous-media ground-water flow, the TENSOR2D computer program (Maslia and Randolph, 1986) was used to evaluate the magnitude and direction of aquifer anisotropy. The TENSOR2D program automates the solution of hydraulic parameters and tensor components for an anisotropic aquifer using the Papadopulos method (1965). The rigorous application of the Papadopulos method requires data from a pumping well and a minimum of three observation wells. Transmissivities are determined for both the major ($T_{\varepsilon\varepsilon}$) and minor ($T_{\eta\eta}$) components of the anisotropic transmissivity tensor. Aquifer test data from wells, shown in figure 4, that tap a karst carbonate aquifer system were used as input to the program.

Aquifer test data sets for seven well fields within the study area were analyzed by using the TENSOR2D program. The results were highly variable within and among the well fields. In several instances, multiple wells were tested within the same well field, and TENSOR2D results did not indicate the same magnitude or direction of aquifer anisotropy; therefore, even at a local scale, the aquifer is not homogeneous, and the results were considered qualitative. Sometimes, the

components of transmissivity could not be determined by using TENSOR2D analysis because of one or a combination of several possible factors: (1) the observation well distribution was insufficient to characterize the transmissivity tensor; (2) the assumptions of Papadopulos were violated because observation wells were too close together, too near the pumping well, or too far from the pumping well; and (3) the horizontal anisotropy did not adequately account for all of the variability in aquifer properties. The magnitude of aquifer anisotropy from the aquifer test data sets ranged from 2.5:1 to 25:1. Aquifer anisotropy for well fields increased toward the north, coinciding with a thinning of the confining materials. The average aquifer anisotropy from all TENSOR2D results was 5:1. The directions of apparent anisotropy ranged from 40 to 130 degrees and generally coincided with the orientation of the photolineaments. If the anisotropy is due to persistent fracture sets of relatively consistent orientation, it could be inferred that the principal directions are a result of fracture orientation. However, there is no guarantee that regional scale fractures would be indicative of density, persistence, and orientation of fractures at a local scale.

Layered Heterogeneity

Although the Floridan aquifer system is basically a vertically continuous sequence of generally permeable carbonates, extremely high permeabilities occur as discrete zones within the aquifer. Geophysical logs and borehole television surveys from regionally dispersed wells indicate that the aquifer system contains several highly permeable zones. These zones, which contribute most of the water to wells, generally conform to bedding planes and commonly contain enhanced secondary porosity caused by solution or fracturing and are separated by rocks of lower permeability that display relatively few secondary porosity features. Borehole television surveys have demonstrated that, in places, the Floridan aquifer system contains thin to moderately thick horizontal openings connected by nearly vertical fractures, some of which have been enlarged by chemical dissolution.

An approach that uses borehole data for characterizing secondary porosity of carbonate rocks was applied to this study. A detailed description of the methodology can be found in a report by Safko and Hickey (1992). Generally, the distribution of effective secondary porosity is determined from concurrent interpretation of lithologic logs, drillers' comments, borehole geophysical logs, and television surveys. The term "effective secondary porosity" is defined as observed secondary porosity from the borehole television surveys supported by interpretations of the caliper, pumping flowmeter, and pumping temperature logs, which indicates that the observed secondary porosity extends beyond the immediate vicinity of the borehole. Such secondary porosity features would be principally related to geologic processes rather than drilling activities (Safko and Hickey, 1992, p. 1).

Effective secondary porosity distributions in the study area were characterized in a general way from four test wells in northwest Hillsborough, northeast Pinellas, and southern Pasco Counties (fig. 4). The wells were constructed and tested under supervision of CH2M Hill as part of the Northwest Hillsborough Water Resources Assessment Project (NWHWRAP). The wells penetrate the entire thickness of the Upper Floridan aquifer. Figure 5 shows the lithologic, apparent secondary porosity, driller comments, caliper, pumping flowmeter, pumping temperature, and effective secondary porosity logs for each of the four wells. All logs, except the effective secondary porosity logs, were constructed from observed data. The apparent secondary porosity log was constructed from the television survey by classifying observed secondary porosity types for 10-ft segments of the borehole. Secondary porosity was classified into three types—vugs, cavities, and fractures—based on definitions proposed by Safko and Hickey, (1992). Cavity porosity designation was further restricted only to those zones in which the driller comment logs specified a bit drop. No bit drops were reported during the drilling of the NWHWRAP test holes; therefore, all observed cavities from the borehole television surveys (fig. 5, col. B) were interpreted as resulting from borehole collapse during the drilling process. The term "dredging" (fig. 5, col. B) refers to the removal of rock fragments from a borehole before drilling can continue. Dredging is required as a consequence of the collapse of poorly indurated lithologies during drilling and often results in enlargement of the borehole diameter. Miller (1986) states that the fractured nature of dolomite commonly causes chunks of dolomite to be dislodged during the drilling process. Corroborative data from pumping flowmeter and temperature logs were used to verify flow zones. Where appreciable flow enters the well, as indicated from flowmeter and temperature log response, apparent secondary porosity was considered to be effective secondary porosity.

Effective secondary porosity for each of the NWHWRAP wells are described below. Effective secondary porosity for NWHWRAP site 1-D (fig. 5) is characterized by vug porosity from 425 to 485 ft and by large vugs intersected by high angle fractures from 585 to 675 ft and at 816 ft. Because borehole television survey data were not available for the bottom 379 ft of the borehole, the secondary porosity could not be characterized for the flow zone from 1,085 to 1,187 ft. Effective secondary porosity for NWHWRAP site 2-D (fig. 5) is characterized by fracture porosity from 262 to 272 ft and from 312 to 332 ft and by large vugs intersected by high angle fractures from 700 to 822 ft, from 942 to 982 ft, and from 992 to 1,072 ft. Effective secondary porosity for NWHWRAP site 3-D (fig. 5) is characterized by fracture porosity from 198 to 218 ft, from 558 to 638 ft, and from 828 to 878 ft and by large vugs intersected by high angle fractures from 638 to 768 ft and from 890 to 1,018 ft. Because borehole television survey data were not available for the interval from 258 to 558 ft, secondary porosity could not be characterized for the flow zone from 290 to 320 ft and from 405 to 455 ft. Effective secondary porosity for NWHWRAP site 4-D (fig. 5) is characterized by vug and fracture porosity from 309 to 405 ft. Because borehole television survey data were not available for the bottom 389 ft, the secondary porosity could not be characterized for the flow zone from 990 to 1,120 ft. The effective secondary porosity interpretations are shown in figure 5, column G, and are interpreted to be distributed spatially and interconnected beyond the vicinity of the borehole and to be the result of geologic processes. The secondary porosity types associated with the prominent flow zones are probably intersections of near vertical fractures with horizontal planes of weakness that have been enlarged by solution.

Analysis of the distribution of the effective secondary porosity indicates that the Upper Floridan aquifer is a layered aquifer system. In general, the producing zones occur near lithologic contacts where horizontal zones of weakness tend to occur. The majority of water enters the borehole from the fractured dolomitic units of the Avon Park Formation. Dolomite beds tend to be severely fractured along zones of weakness. The types of secondary porosity are different in the limestone and dolomite sequences (fig. 5, col. B), possibly the result of the response of different lithologies to stress. Limestone is ductile and the apparent secondary porosity types tends to be vugs and cavities. Because of less induration in the limestone, drilling processes can create cavities from washouts. Dolomite is harder and more brittle and the apparent secondary porosity type tends to be fractures.

Prototype Regions

Within the study area, two prototype carbonate aquifer systems were characterized for detailed analysis. The hydrogeologic framework of these two prototypes represent the end-members of the hydrologic diversity in the study area and were designated the Central Swamp and Lake Terrace regions. The names of these regions were derived from the physiographic units where they are located. The physiographic units north of Tampa Bay are shown in figure 6. Each physiographic unit encompasses one or more well fields. The hydrogeologic framework and aquifer characteristics for the Central Swamp and Lake Terrace regions are those for the Cypress Creek and Cosme-Odessa well fields, respectively.

Descriptions of the hydrogeologic framework and aquifer characteristics of the prototype regions are based on existing data compiled from previous studies by the U.S. Geological Survey, the Southwest Florida Water Management District, the Florida Geological Survey, and private consulting firms. The hydrogeologic framework is composed of two aquifer systems separated by the intermediate confining unit. Aquifer heterogeneity, including vertical fracture zones and horizontal enhanced flow zones, has been observed in both the Central Swamp and Lake Terrace regions. The vertical fracture network is based on the actual locations identified by Culbreath (1988). Horizontal layering of the Upper Floridan aquifer in the Central Swamp and Lake Terrace regions is supported by drillers' logs, specific-capacity data, and borehole geophysical logs for selected wells in the regions. Locations of selected wells (fig. 7) and generalized hydrogeologic sections constructed from well data (figs. 8 and 9) show the observed distribution of aquifer heterogeneity.

There are several hydrologic differences between the two prototype regions. Topography in the Central Swamp region is flat and swampy, and land surface ranges from 60 to 70 ft above sea level. In the Lake Terrace region, land surface ranges from 10 to 70 ft above sea level. The surficial aquifer system is 25 ft thick or less in the Central Swamp region and ranges from 50 to 100 ft in the Lake Terrace region. In the Central Swamp and Lake Terrace region, the intermediate confining unit ranges from 25 to 50 ft thick and 25 ft or less, respectively. The Upper Floridan aquifer is about 900 and 1,125 ft thick, respectively. The Central

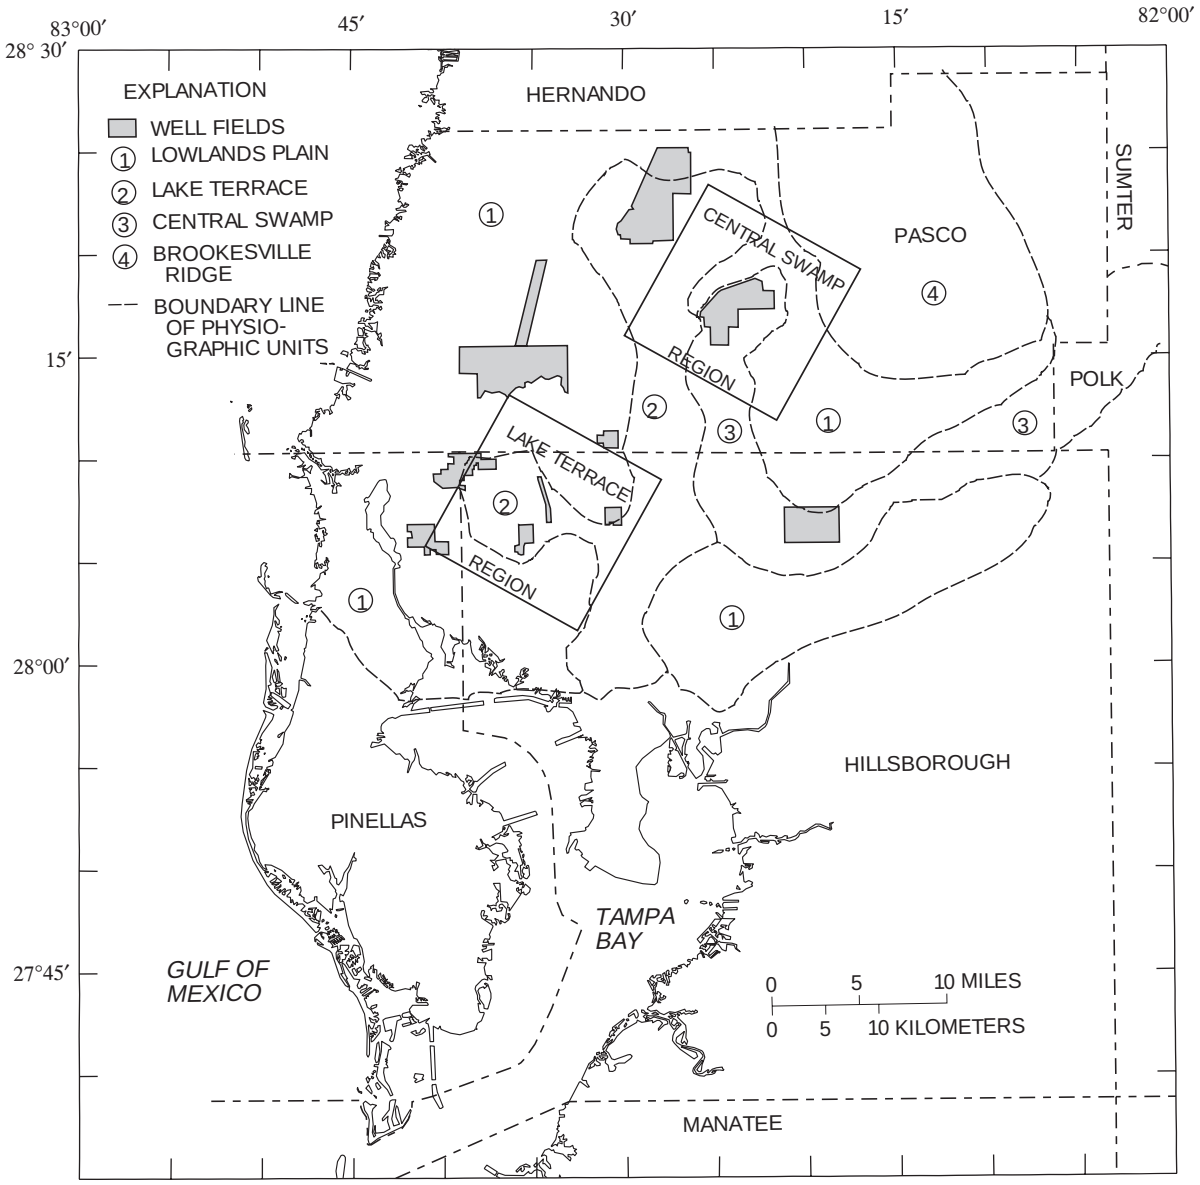

Figure 6. Physiographic units and regions.

Swamp and Lake Terrace regions are in zone 2 and zone 4 of sinkhole types classified by Sinclair and others (1985). Zone 2 is characterized by bare or thinly covered limestone where sinkhole development is rare. Zone 4 is characterized by a 25- to 100-ft thick clastic cover where sinkholes are numerous. Layering of the secondary porosity zones in the Central Swamp region is highly variable (fig. 8). Ryder (1978) states that, in the vicinity of Cypress Creek well field, movement of ground water is primarily along solution-enhanced joints and fractures, and water enters the well from discrete flow intervals.

Two major water-bearing zones occur in the dolomitic zone of the Avon Park Formation. The Tampa Member, Suwannee Limestone, and Ocala Group can contain solution-enhanced permeable zones that generally occur near formational contacts. In the Lake Terrace region, specific-capacity data from wells in the vicinity of the Cosme-Odessa well field, indicate the existence of three flow zones. These enhanced flow zones are at depths from 360 to 420 ft, from 780 to 840 ft, and from 1,000 to 1,155 ft below sea level. Borehole interpretation methods indicate an effective secondary porosity zone from 290 to 390 ft (fig. 9).

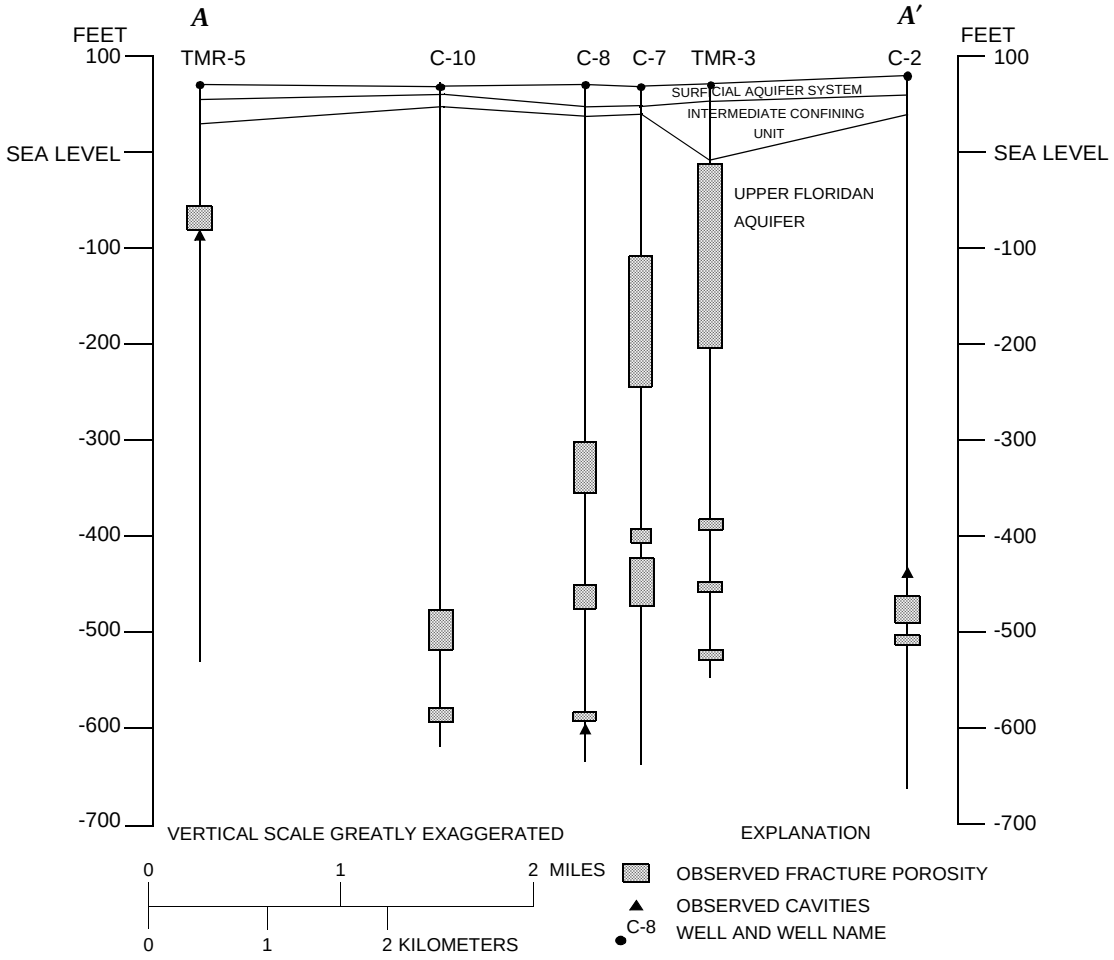

Figure 8. Generalized hydrogeologic section *A-A′*, showing vertical distribution of observed secondary porosity across the Cypress Creek well field.

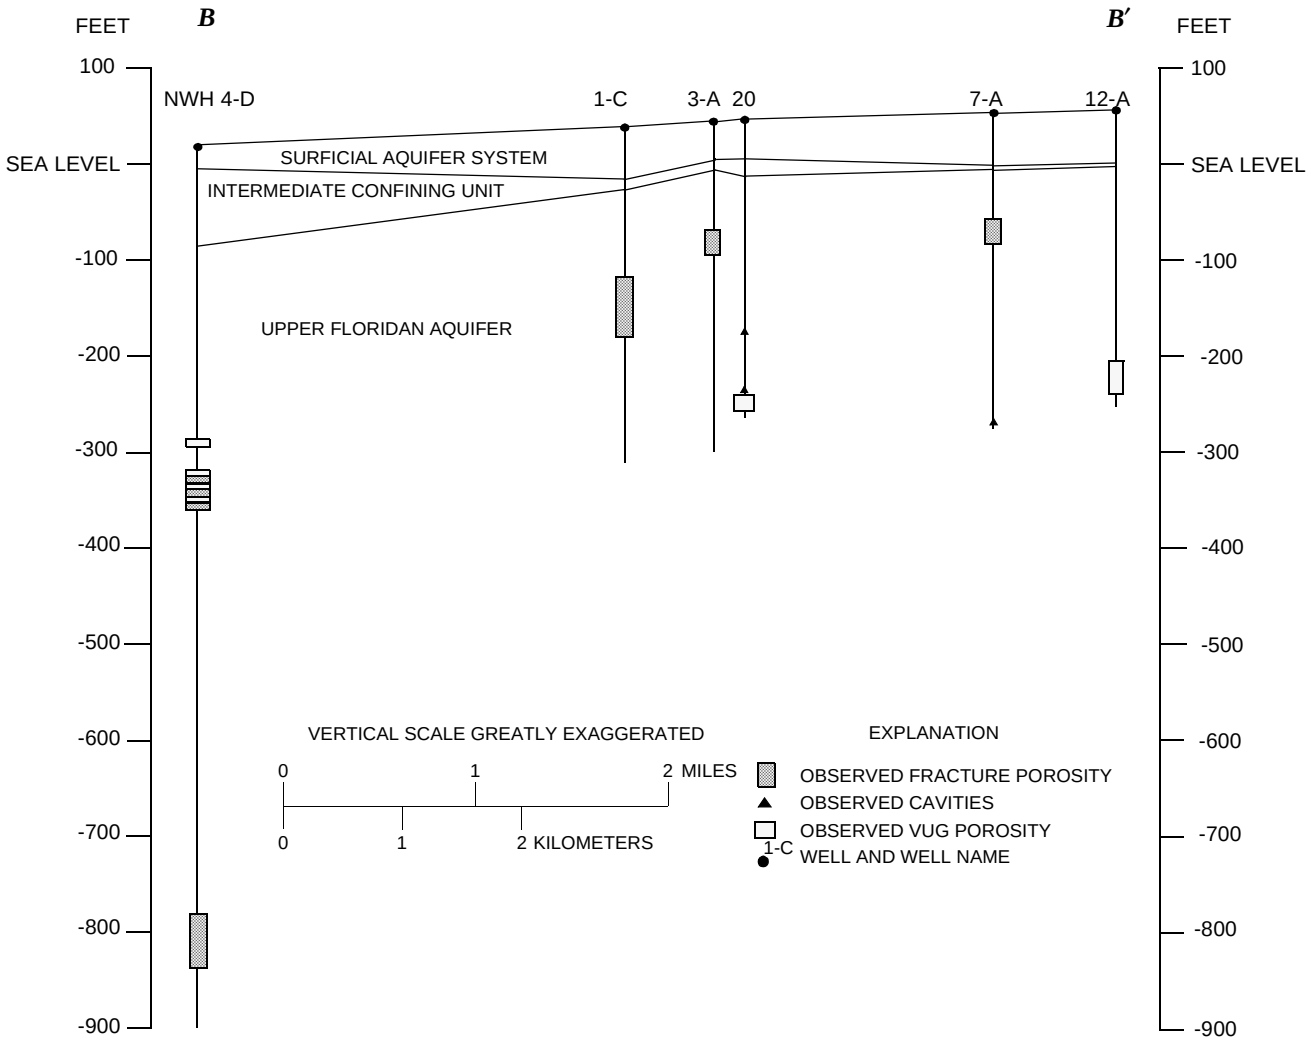

Figure 9. Generalized hydrogeologic section *B-B′*, showing vertical distribution of observed secondary porosity across the Cosme-Odessa well field.

A highly fractured zone from 980 to 1,130 ft is indicated by the caliper log. Pumping temperature logs indicate borehole flow from 1,000 to 1,030 ft (CH2M Hill, 1990a,b).

Generally, the depth interval from 425 to 780 feet within the Ocala Group has lower permeability and acts as a semiconfining unit within the Upper Floridan aquifer. Permeable zones overlie and underlie this zone. As shown in figures 8 and 9, the sources of water to wells, in both the Central Swamp and Lake Terrace regions, are derived from multiple, vertically spaced, and discrete permeable zones.

HYPOTHETICAL CARBONATE AQUIFER SYSTEMS

Observations of anisotropy and heterogeneity, based on field data, in the Central Swamp and Lake Terrace regions led to the development of six hypothetical carbonate aquifer systems. These systems were conceptualized to illustrate generalized types of carbonate aquifer systems. The systems were developed to incorporate increasingly complex representations of aquifer anisotropy and heterogeneity. In addition, an isotropic and homogeneous carbonate aquifer system was developed for comparison with the more complex carbonate aquifer systems.

The first carbonate aquifer system is that of a single isotropic and homogeneous unit, where aquifer properties are uniform (fig. 10, case 1).

The second carbonate aquifer system incorporates horizontal anisotropy (fig. 10, case 2) where aquifer properties differ by direction. The anisotropy was found to vary from site to site. This is most likely caused by the orthogonal distribution of the fracture network.

The third carbonate aquifer system includes a fully penetrating vertical fracture network in a single layer carbonate unit (fig. 10, case 3). The fracture network is based on the work of Culbreath (1988). Fractures in carbonate aquifer systems can behave as impermeable barriers to flow or as highly permeable conduits for flow (Stewart and Wood, 1984). Both impermeable and highly permeable fractures are known to occur in the Upper Floridan aquifer system.

The fourth carbonate aquifer system includes heterogeneous layering of hydraulic properties as a result of carbonate dissolution, thereby creating enhanced flow zones (fig. 10, cases 4a and 4b). Case 4a shows the layering of the carbonate aquifer system by using lithostratigraphic boundaries. Field data indicates that these units have different hydraulic properties. Case 4b shows the redistribution of layers by further defining the relatively thin flow zones found within specific lithostratigraphic units. Enhanced flow zones in carbonate terranes are indicated from specific-capacity data, borehole geophysical logs, and drillers' logs.

The fifth carbonate aquifer system was that of a doubly porous system (fig. 10, case 5). In a double porous system, the aquifer porosity consists of two types, the postdepositional secondary porosity, such as fractures and solution channels and the syndepositional primary porosity of the intergranular matrix, both having distinctive characteristics. Two coexisting porosities and hydraulic conductivities are recognized: those of lower storage capacity (low porosity) and higher hydraulic conductivity (permeability) of the fracture dominated rock volumes, and those of higher storage capacity (high porosity) and lower hydraulic conductivity (permeability) of the unfractured rock volumes. Field evidence supports this double porosity behavior. The core data suggests that primary porosity is significant; however, borehole geophysical log and television survey interpretations indicate that appreciable flow enters the well along discrete zones characterized by secondary porosity features. Transmissivity values determined from aquifer test analysis within a single well field vary significantly. The highest calculated transmissivities are probably from areas where the pumped well intersected fractured (secondary porosity) zones. Both secondary and primary porosity contribute to the total porosity in the aquifer; however, if movement of water within pores isolated from solution channels were insignificant relative to movement within the solution channels, then transmissivity and effective porosity values would be ascribed to the flow properties and channel porosity volume of the solution conduits. Channel porosity volume relative to the total rock volume is typically much less than the measured 30 percent from core samples.

The sixth carbonate aquifer system (fig. 10, case 6) combines the effects of both the enhanced vertical interconnection between hydrogeologic layer and the horizontal, solution-enhanced flow zones.

EFFECTS OF AQUIFER ANISOTROPY AND HETEROGENEITY ON GROUND-WATER FLOW

Aquifer anisotropy and heterogeneity, inherent in carbonate aquifer systems, can affect both the direction and velocity of ground-water flow. Fluid flow in karst carbonate aquifers can be highly variable and difficult to measure or predict with a reasonable degree of certainty, because flow regimes can range from almost entirely diffuse to predominantly conduit flow. Over brief periods of time, where small volumes of the aquifer are tested, such as during aquifer testing, a carbonate aquifer system might be dominated by flow in fractures. Yet, with longer periods of time, a larger volume of the aquifer is tested and the overall flow might tend to behave as if it were an equivalent porous medium. A karst carbonate aquifer system might behave as an equivalent porous medium when the secondary porosity features are numerous and spatially interconnected such that the aquifer effectively assumes hydraulic characteristics of a porous medium. Additionally, the volume of aquifer material tested or scale of the problem determines how heterogeneities must be taken into account in evaluating the flow system. Although Darcian flow assumptions might be acceptable for estimating the general head gradient, the average linear velocities might be inaccurate due to the directional dependence and strong discontinuity of fractures.

The influence of aquifer anisotropy and heterogeneity on the movement of ground water often can be inferred from aquifer and tracer test data and from

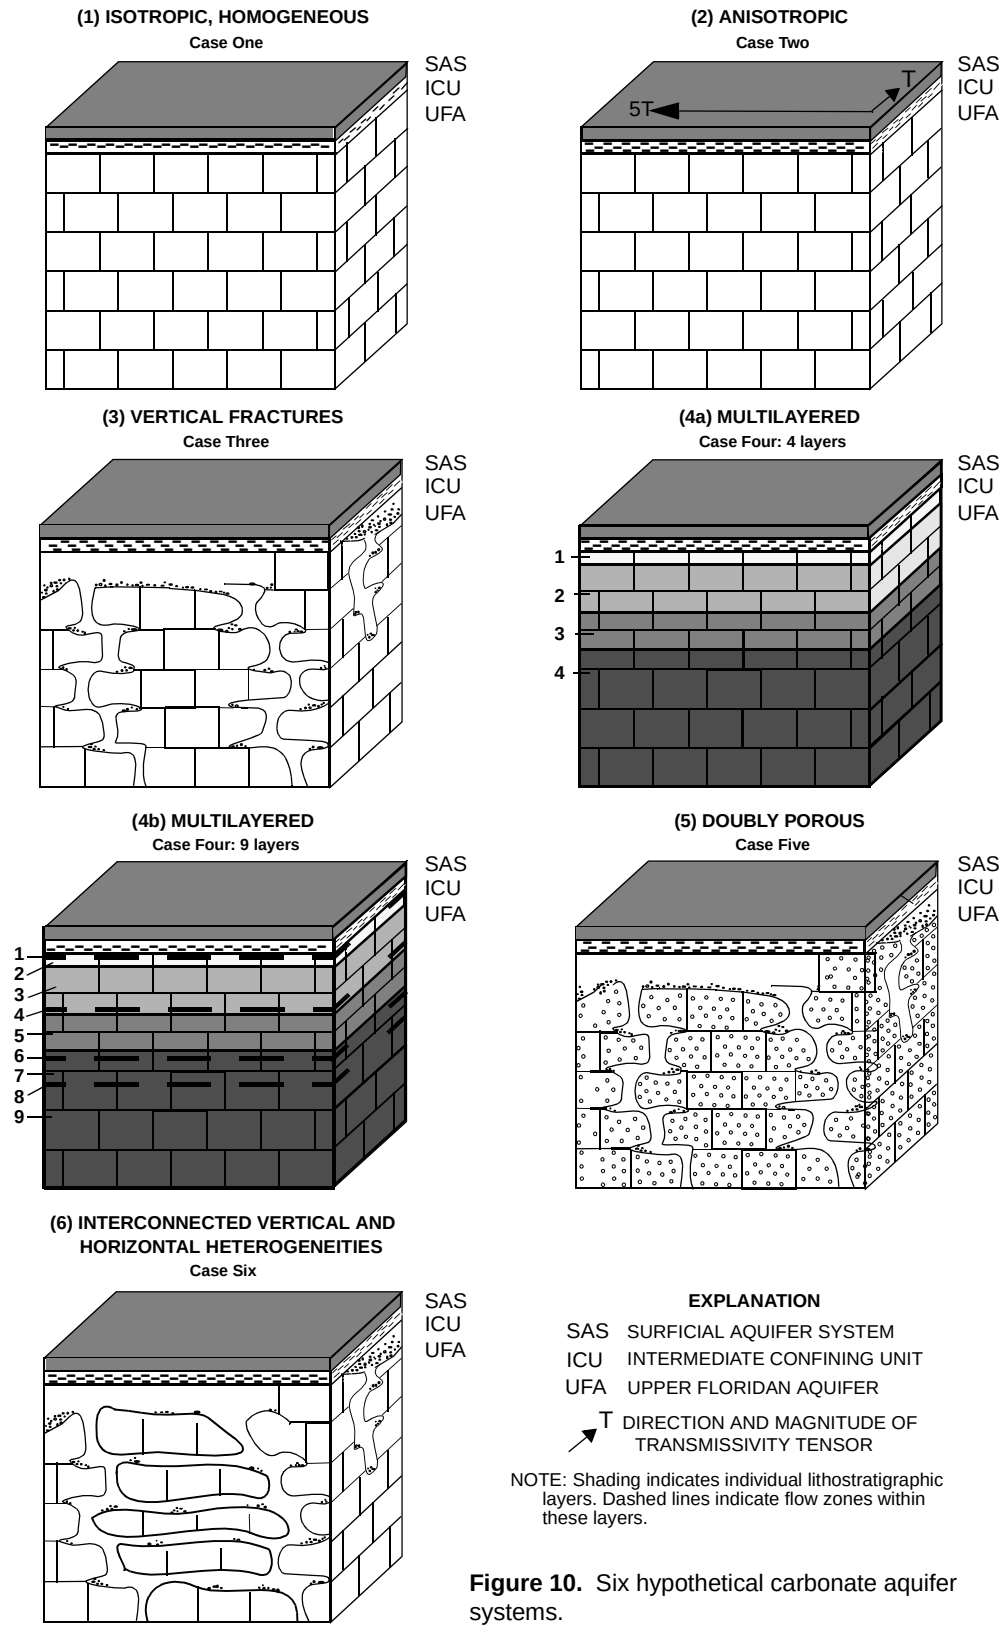

Figure 10. Six hypothetical carbonate aquifer systems.

borehole geophysical logs. Aquifer test data for the Upper Floridan aquifer have been collected by the U.S. Geological Survey, local and State agencies, and private consultants. Selected aquifer tests conducted from 1952 to 1976 were analyzed and presented in a report by Wolansky and Corral (1985). The purpose of that study was to obtain a probable range of values of transmissivity, storage coefficient or specific yield, and leakance for the surficial aquifer system, the intermediate confining unit, and the Upper Floridan aquifer. In several instances, analyses of aquifer test data from the Upper Floridan aquifer system provided ambiguous results and were excluded from the report. These aquifer tests, which indicated a wide variation in hydraulic properties at a site, as determined by inconsistent responses in several observation wells, indicated that the basic assumptions of the analytical solutions were not entirely met. The authors surmise that heterogeneity, anisotropy, and hydrologic boundaries may be responsible for the apparent variation in aquifer properties (Wolansky and Corral, 1985, p. 27).

Tracer tests were performed at the Old Tampa well field in 1992 (fig. 4). Rapid fluid flow between widely separated wells was observed, indicating that flow is through conduits rather than through porous media (Robinson, 1995). Prior to tracer test initiation, tracer arrival time of 46 days was calculated based on porous media flow assumptions, a distance between wells of 200 ft and a porosity of 25 percent. Initial tracer arrival occurred after 4 hours, a second arrival occurred after 36 days, and a peak concentration occurred after 48 days. The bimodal distribution of tracer arrival suggests that the porous media assumptions are not strictly obeyed in the aquifer. Conclusions from the reports by Wolansky and Corral (1985) and Robinson (1995) are that aquifer and tracer test data indicate that the hydraulic response of the carbonate aquifer system to stresses in west-central Florida deviates from isotropic and homogeneous porous media behavior. These assumptions are used for most area of contribution calculations.

MODEL DESIGN AND SIMULATION OF THE PROTOTYPE CENTRAL SWAMP AND LAKE TERRACE REGIONS

A finite-difference flow model was used to evaluate the effects of simulated aquifer anisotropy and heterogeneity on areas of contribution to supply wells in the Central Swamp and Lake Terrace regions. The models are highly conceptual and were not calibrated because of the hypothetical nature of the simulation and because no data exists for comparison with the model results. The analysis implemented an exploratory modeling approach where models are constructed to simulate a wide range of possible solutions. It is used to better understand a system filled with hydrologic uncertainties. This modeling approach permitted many combinations of aquifer anisotropy and heterogeneity types to be simulated. To compare the effects of aquifer anisotropy and heterogeneity on contributing areas, particle tracking was used to delineate the size, shape and orientation of these areas. Contributing area analysis delineates the two-dimensional surface area that corresponds to the area of influence of a pumping well. The area of influence of a pumping well is the area around a well where captured water balances well discharge. The carbonate aquifer system types were simulated by emphasizing anisotropy and heterogeneity typical of karst carbonate terranes.

The models selected to analyze ground-water flow in the study area are the U.S. Geological Survey MODFLOW program (McDonald and Harbaugh, 1984) and MODPATH program (Pollock, 1988). MODFLOW is a three-dimensional, finite-difference flow model. The flow fields generated by MODFLOW are used as input to MODPATH. The MODPATH program is a post-processing, particle-tracking program designed for use with output from flow simulations obtained using MODFLOW. MODPATH is used to delineate pathlines and position of particles at specific time intervals within the simulated flow system. Pathlines and particles can be tracked forward (in the direction of future locations) or backward (in the direction of past locations) from specified model cells.

MODFLOW and MODPATH numerical models were used to generate time-related areas of contribution in the Central Swamp and Lake Terrace regions and were each simulated as the six hypothetical carbonate aquifer system discussed in a previous section of the report. Particles were backtracked from simulated well locations toward the recharge areas to delineate pathlines along which ground-water would flow toward the well. The areal extent of the simulated pathlines defines the approximate area of capture from which the well field draws its water. If the hydrologic system is at equilibrium, the resulting particle paths delineate the total capture zone. Lengths of pathlines are proportional to ground-water flow velocity. Velocities increase as particles approach the simulated wells and is indicated by progressively longer spacing between positions of particles plotted along pathlines.

Boundary Conditions and Grid Design

The two prototype regions were assigned identical boundary conditions and model size so that comparisons between the regions were similarly constrained. Although the boundary conditions do not correspond to natural hydrologic boundaries, if the model area were sufficiently large such that effects of simulated well field pumping would not cause measurable head changes at the boundaries, constant-head boundaries could then be used (Bush, 1978). This criterion was used to define the location of the lateral, hypothetical boundaries for the Central Swamp and Lake Terrace regions. The procedure used to determine this area was to utilize the MODPATH program to evaluate the configuration of particle paths delineating sources of water to well fields. MODPATH was used in conjunction with a calibrated flow model (Fretwell, 1988), that coincides with the study area of this project. The area around each well field encompassed by the pathlines was used as general guidelines for locating the lateral boundaries beyond which well field pumping effects are minimized. An adequate model extent of 100-mi^2 was selected and the lateral boundaries were specified as constant-head boundaries. The upper boundary condition, the water table, was also assigned a specified head. The lower boundary condition was designated a no-flow boundary and represents the hydrologic boundary between the Upper Floridan aquifer and the middle confining unit. Discretization of the 100-mi^2 model area created 1,600, 1/16-mi^2 uniform grid blocks per layer. Both the Central Swamp and Lake Terrace regions were assigned equivalent boundary condition types and discretizations (fig. 11) and these conditions were not changed during simulation. The main objective of the digital simulation was to illustrate how the incorporation of conceptualized distributions of aquifer anisotropy and heterogeneity effect the size, shape, and orientation of areas of contribution to supply wells. The areas of contribution for this study are based on a "traveltime" distance, not on a capture zone defined by a potentiometric surface; therefore, a gradient for neither the water table nor pumped aquifer was simulated.

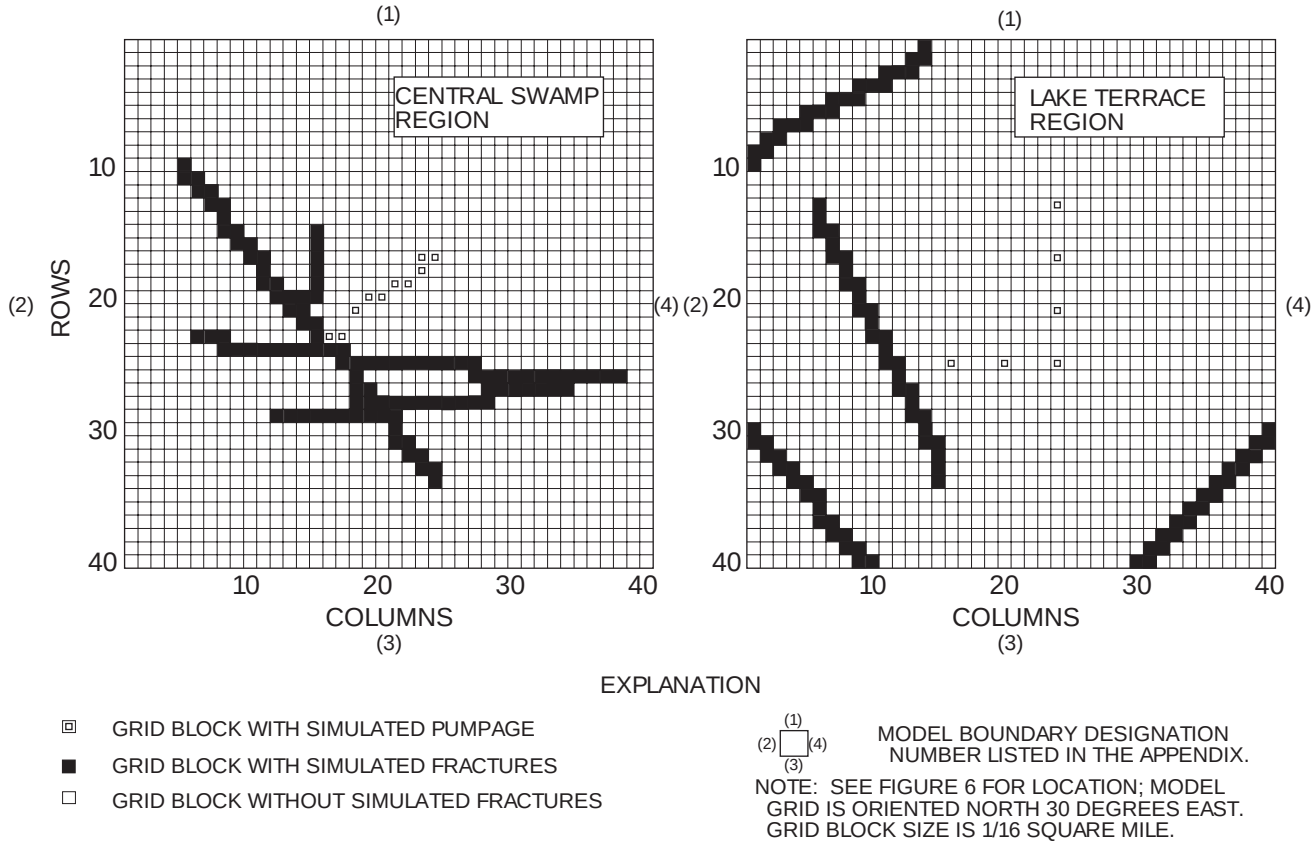

Figure 11. Model grid of 40 rows and 40 columns per layer, showing grid blocks, simulated fractures, and wells in the Central Swamp and Lake Terrace regions.

Model Input Parameters

The quasi-three-dimensional flow systems of the Central Swamp and Lake Terrace regions were constructed to include an unconfined aquifer system (surficial aquifer system) and a confined aquifer system (Upper Floridan aquifer) separated by a confining unit (intermediate confining unit). Model input parameters were compiled from data gathered during previous investigations and are defined for each of the hypothetical carbonate aquifer system types in the following sections of the report. The input parameters were derived from specific capacity tests, aquifer tests, laboratory core analyses, surface and borehole geophysical log data, and calibrated model information (Hutchinson, 1984; Bengtsson, 1987; Fretwell, 1988). Input data for the regions for each of the carbonate aquifer system types are shown in figures 12 and 13.

Simulated pumpage are 30 and 13 Mgal/d, which are the withdrawals used in previously calibrated models for the Cypress Creek and Cosme-Odessa well fields, respectively (Hutchinson, 1984; Fretwell, 1988). Well locations and grid distributed pumpage approximates the configuration of the Cypress Creek and Cosme-Odessa production wells (fig. 11).

Case 1: Isotropic and Homogeneous Single-Layer System

The input data selected for simulating an isotropic, homogeneous, single-layer, carbonate aquifer system for the Central Swamp and Lake Terrace regions are described below. The transmissivity values selected for simulation of the Central Swamp and Lake Terrace regions are 30,000 and 57,000 ft^2/d, respectively. Reported transmissivities in the vicinity of these regions are listed in table 1.

The thickness of the aquifer penetrated by test wells in the Central Swamp region for which transmissivity values are reported is 700 ft. Even though these wells are not fully penetrating, the major water-bearing zones designated by Ryder (1978) have been penetrated. Therefore, the reported transmissivity values should be considered representative of the Upper Floridan aquifer in the region. Reported transmissivity values from published calibrated models for the Cypress Creek well field ranged from 26,000 to 41,000 ft^2/d (Fretwell, 1988) and from 31,500 to 53,600 ft^2/d (Ryder, 1978).

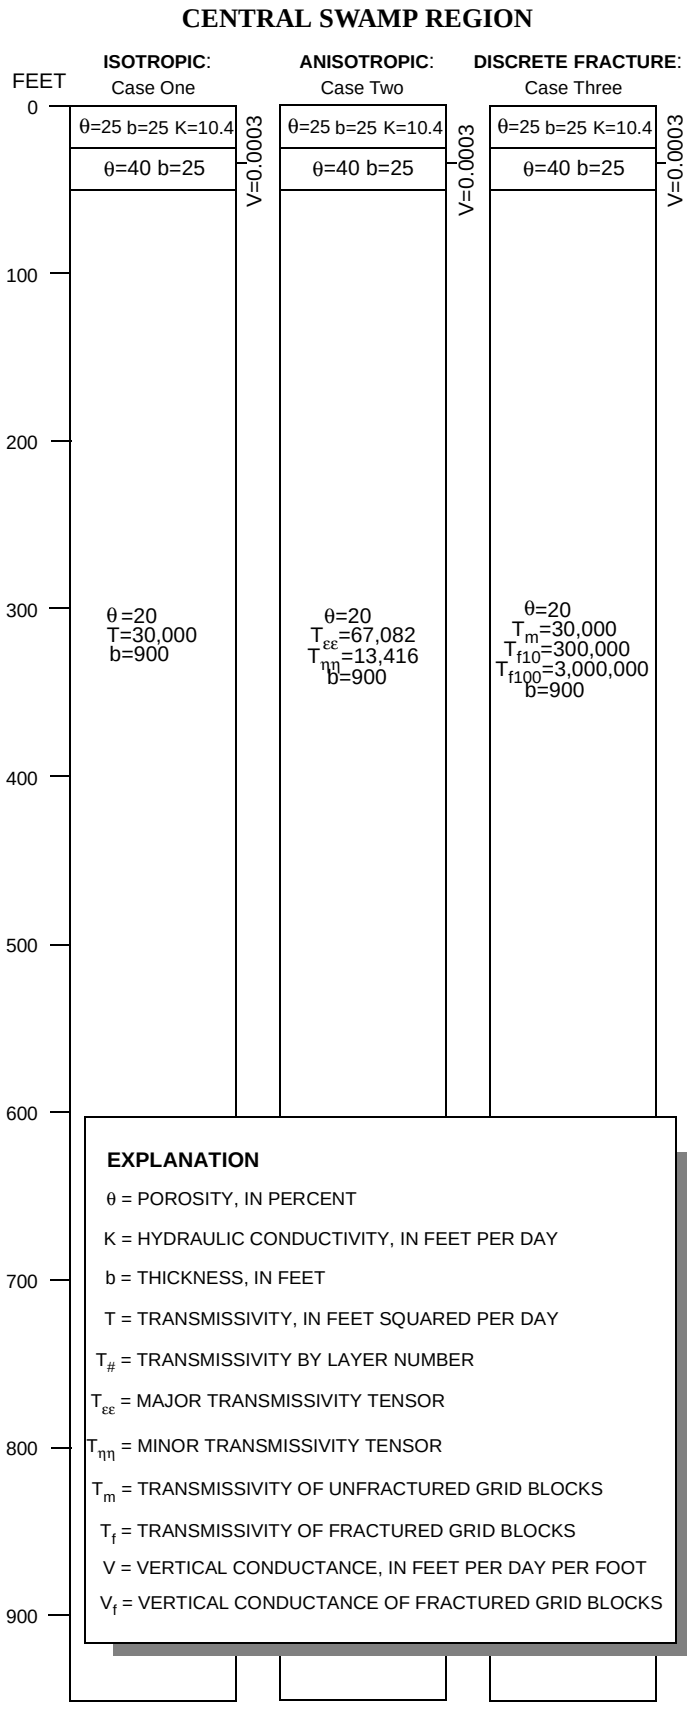

Figure 12. Distribution of input data for the Central Swamp region for the hypothetical carbonate aquifer systems.

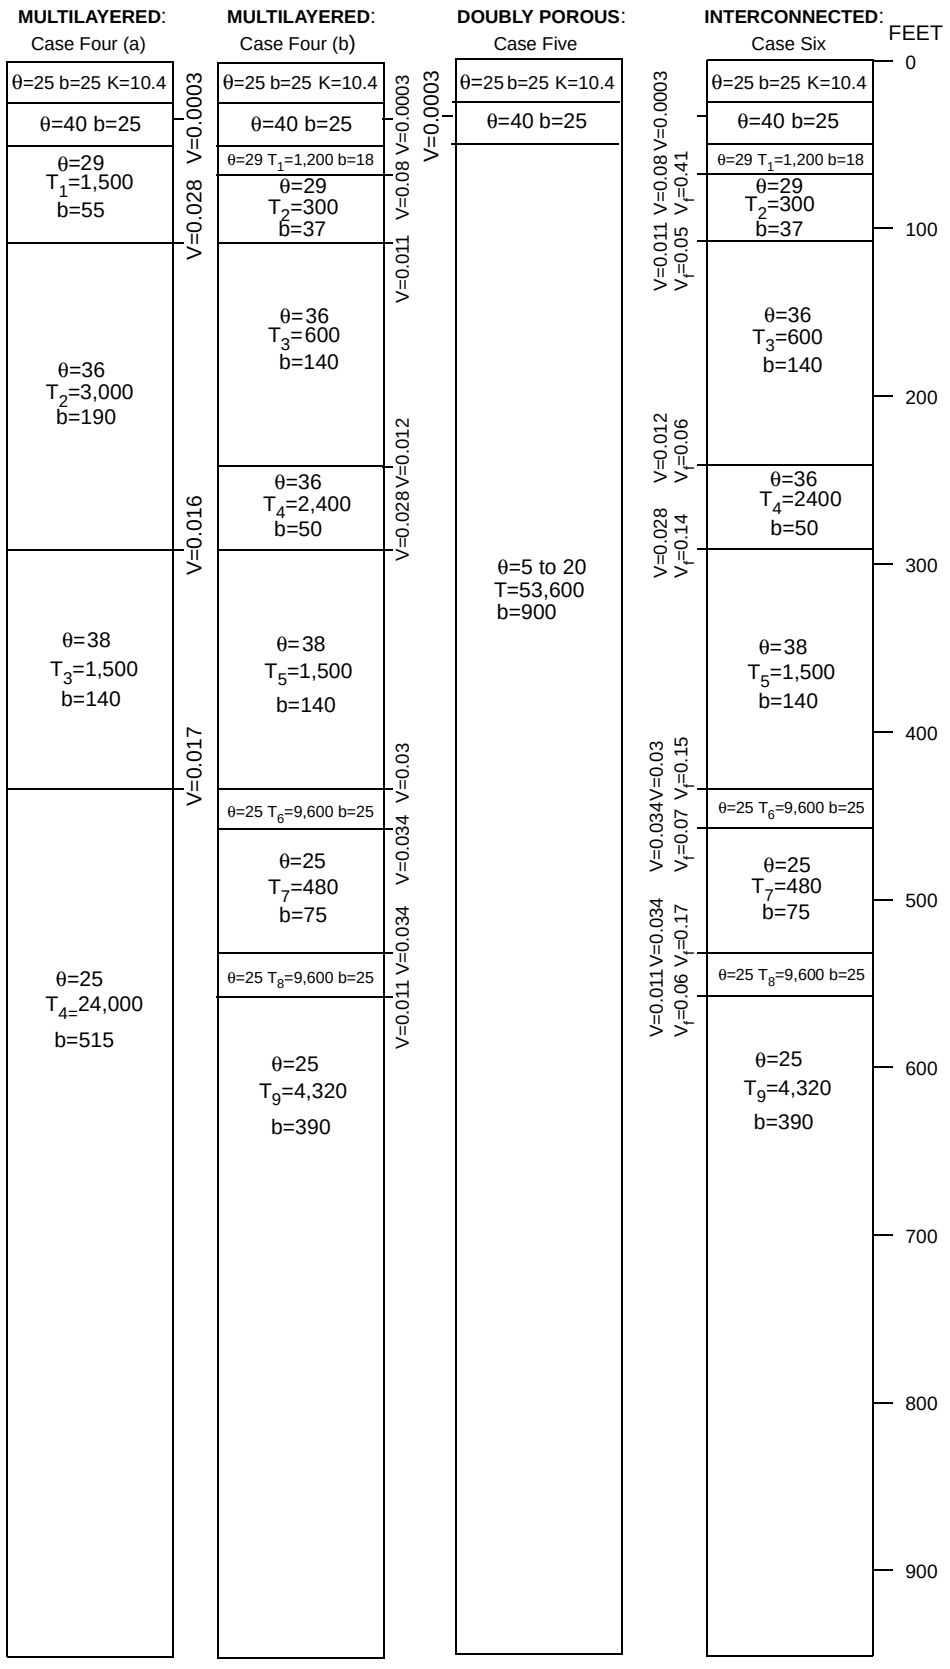

Figure 12. (Continued) Distribution of input data for the Central Swamp region for the hypothetical carbonate aquifer systems.

LAKE TERRACE REGION

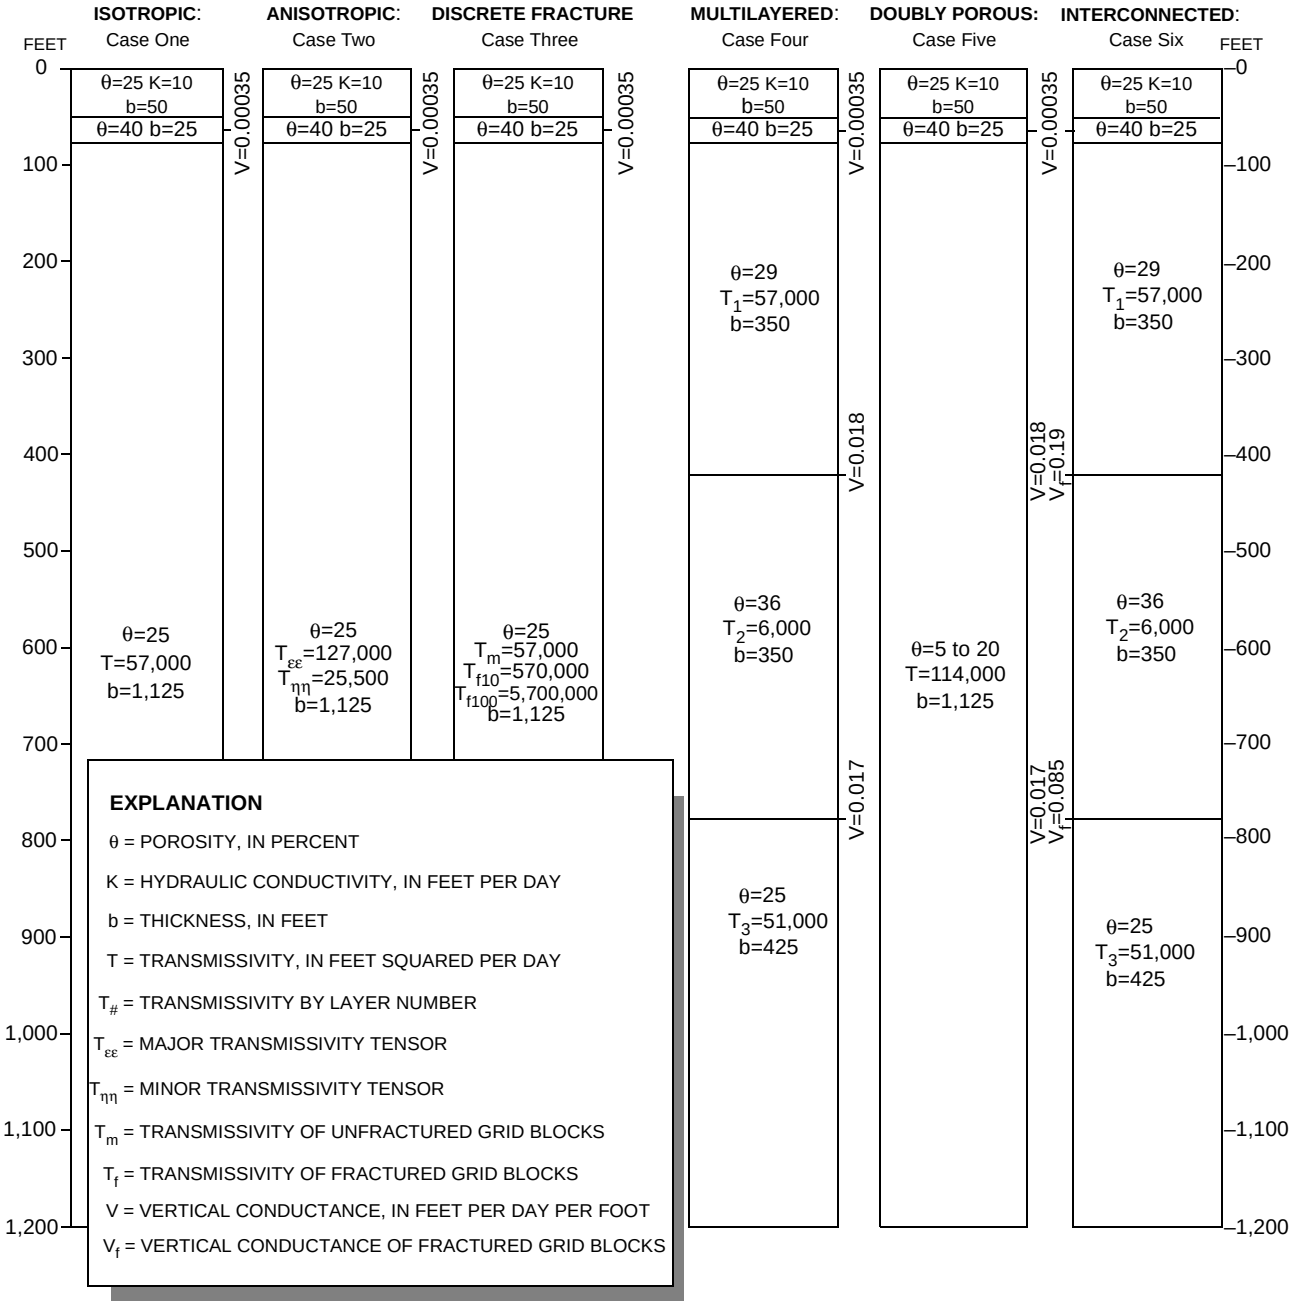

Figure 13. Distribution of input data for the Lake Terrace region for the hypothetical carbonate aquifer systems.

Reported transmissivities from published calibrated models for the Cosme-Odessa well field are 57,000 ft^2/d (Hutchinson, 1984; Bengtsson, 1987) and 66,000 ft^2/d (Fretwell, 1988). However, the aquifer thickness penetrated by the test wells in the Lake Terrace region for which transmissivity values are reported ranges from 200 to 600 ft and represents only 18 to 53 percent of the estimated 1,125-ft total thickness of the Upper Floridan aquifer in the region. Reported transmissivity values should be considered a minimum for the Upper Floridan aquifer in the Lake Terrace region.

The effective porosity values selected for simulation in the Central Swamp and Lake Terrace regions are 20 and 25 percent, respectively. These values are representative of the rock or primary porosity of the Upper Floridan aquifer system.

Case 2: Anisotropy in a Horizontal Plane for a Single-Layer System

The transmissivity values for an anisotropic carbonate aquifer system in the Central Swamp and Lake Terrace regions were computed by assuming an anisotropy ratio of 5:1 and effective transmissivities (T_e) of 30,000 and 57,000 ft^2/d, respectively. The term "effective transmissivity" is defined as the average of the transmissivities in the two principal directions corresponding to the greatest and least preferred flow directions. These directions defined the principal transmissivity tensors. The selected anisotropy ratio is the average of the TENSOR2D results from aquifer tests in west-central Florida. Anisotropy was simulated by using the MODFLOW program with two transmissivity tensors designated $T_{\varepsilon\varepsilon}$ and $T_{\eta\eta}$, which are the maximum and minimum transmissivities, respectively. The equation used to compute the transmissivity tensors is:

$$T_e = (T_{\varepsilon\varepsilon} \times T_{\eta\eta})^{1/2}.$$

Maximum transmissivities probably coincide with fracture locations. Because the fractures are orthogonally distributed, two possible orientations of maximum transmissivity are possible. Therefore, the maximum transmissivity tensor was independently simulated, first along rows and then along columns. The input values for the maximum and minimum transmissivities are about 67,000 and 13,400 ft^2/d in the Central Swamp region and 127,500 and 25,500 ft^2/d in the Lake Terrace region.

Case 3: Discrete, Vertically Fractured, Single-Layer System

Simulation of a carbonate aquifer system with discrete, fully penetrating, permeable vertical fractures was approximated by incorporating differing permeabilities for the fractured and unfractured grid blocks. The influence of permeable vertical fractures in a carbonate aquifer system can be grossly approximated by enhancing the transmissive properties of the fractures. Studies have indicated that fracture permeability may be 10 to 100 times greater than unfractured rock permeability (Stewart and Wood, 1984). Fractures can act as conduits for flow as well as barriers to flow. Both types, conduits and barriers, have been observed in the Upper Floridan aquifer in west-central Florida (Wood and Stewart, 1985). Fractures that are barriers to flow have been recrystallized or filled in with clastic material and are simulated as no-flow grid blocks. Fractures that are conduits for flow are simulated by increasing the transmissivity in the fractures grid blocks relative to the unfractured blocks. The fracture locations in the Central Swamp and Lake Terrace regions, based on the work of Culbreath (1988), are shown in figure 11. The simulated fracture-influenced transmissivity values for the Central Swamp and Lake Terrace regions range from 300,000 to 3,000,000 ft^2/d and 570,000 to 5,700,000 ft^2/d, and the simulated porosities are 20 and 25 percent, respectively. The transmissivity and porosity selected for simulation of the unfractured part of the aquifer in the Central Swamp and Lake Terrace regions are 30,000 ft^2/d and 20 percent and 57,000 ft^2/d and 25 percent, respectively. These transmissivity values fall within the range of published data for west-central Florida. The porosity values are average values from core samples from this study and published reports in west-central Florida.

Case 4: Multilayered System

Carbonate aquifer systems with multiple layers of differing hydraulic properties was simulated by subdividing the single layer aquifer into separate lithostratigraphic units. In addition, discrete flow zones occur within these lithostratigraphic units. Data indicate that, in the study area, the Upper Floridan aquifer contains multiple, thin, flow zones that supply most of the water to wells. The occurrence of flow zones are at varying depths but are generally associated with locations of lithologic contacts. The layered carbonate aquifer system in the Central Swamp region was simulated, both as a four- and nine-layer system on the basis of specific-capacity data and the work of Ryder (1978). The layered carbonate aquifer system in the Lake Terrace region was simulated as a three-layer system.

The four-layer aquifer system in the Central Swamp region was simulated by redistributing aquifer properties by lithostratigraphic unit based on the assumption, supported by physical data, that the lithostratigraphic units do not equally supply water to wells. The four layers of the carbonate aquifer system represent the lithostratigraphic units of the Tampa Member, Suwannee Limestone, Ocala Group, and Avon Park Formation. These lithostratigraphic units are 55, 190, 140, and 515 ft thick and contribute 5, 10, 5, and 80 percent of the flow, respectively. Multilayered models of differing hydraulic characteristics require vertical-conductance data (VCONT) that define the interaction between layers. VCONT is a calculated input parameter and is defined as the vertical hydraulic conductivity divided by the thickness from one layer to the next

lower layer (McDonald and Harbaugh, 1984, p. 155). The simulated ratio of horizontal to vertical hydraulic conductivity is 5:1. This ratio falls within the range of published values determined from core analyses. Porosities were assigned to each layer based on effective porosities determined from core analyses for specific lithostratigraphic units of the carbonate aquifer system. Input values are shown in figure 12.

A nine-layer aquifer system in the Central Swamp region was simulated also because, within these distinct lithostratigraphic units, discrete flow zones occur that supply most of the water to wells. Aquifer properties were redistributed by assuming that 80 percent of the flow in each lithostratigraphic unit, with the exception of the Ocala Group, was derived from the discrete flow zones. The Ocala Group tends to behave as a semiconfining unit within the study area. The lithostratigraphic units were relayered to incorporate the discrete flow zones. The location and thickness of the flow zones in the Tampa Member, Suwannee Limestone, and Avon Park Formation generally conform to descriptions by Ryder (1978). The Tampa Member has an 18-ft-thick flow zone that supplies 80 percent of the flow from the unit. The flow zone occurs near the contact with the intermediate confining unit. The remaining 37 ft of the Tampa Member supplies the remaining 20 percent of the flow from the unit. The Suwannee Limestone has a 50-ft thick flow zone that supplies 80 percent of the flow from the unit. The flow zone occurs near the contact with the underlying Ocala Group. The remaining 150 ft of the Suwannee Limestone supplies 20 percent of the flow from the unit. The Ocala Group was simulated without a discrete flow zone and the entire 140-ft thickness supplies 5 percent of the total water to the well. Two discrete flow zones, each with a thickness of 25 ft, were simulated in the Avon Park Formation. The combined flow supplied from the Avon Park Formation to wells from the two zones is equivalent to 80 percent of the flow from the unit. The flow was equally divided between them. The remaining 20 percent of flow from the unit was attributed to the two less permeable, unfractured units separating the producing zones. Input values are shown in figure 12.

The VCONT values simulated for the nine-layer carbonate aquifer system are a calculated parameter (McDonald and Harbaugh, 1984, p. 155). The porosities were assigned by lithostratigraphic unit as described for the four-layer model. Although the nine-layer model is highly conceptualized, many authors have alluded to the heterogeneous layering observed.

A three-layer aquifer system in the Lake Terrace region was simulated. Specific-capacity data and borehole geophysical log interpretations for the NWHWRAP test well 4-D (CH2M Hill, 1990b) indicate that, in the vicinity of the Lake Terrace region, the Upper Floridan aquifer contains two units of high permeability that are separated by a unit of low permeability. Pumping flowmeter logs from the test well indicate that slightly more than half of the flow enters the well from the upper 300 ft of the carbonate aquifer, and most of the remaining flow enters the well from the lower 300 ft. Based on the discussion of well penetration depth, published transmissivity values of 57,000 and 51,000 ft^2/d were used to characterize the upper and lower producing zones, respectively. The selected horizontal to vertical hydraulic conductivity ratio is 5:1. The input values for VCONT are a calculated parameter. Porosities were assigned to each layer based on average effective porosities determined by core analysis for specific lithostratigraphic units. Input values are shown in figure 13.

Case 5: Doubly Porous, Single-Layer System

Doubly porous systems consist of two media: the high porosity, low permeability of the unfractured parts of the aquifer; and the low porosity, and high permeability of the fractured parts of the aquifer. Generally, fluid transmission occurs through the fractures; therefore, a doubly porous aquifer system can be approximated by using porous media models and by increasing the effective transmissivity (permeability) and by decreasing the effective porosity (Gordon, 1986). The rationale of increasing the overall transmissivity in the simulation is because fractures transmit the water and typically have higher transmissivities than unfractured parts of the aquifer. The rationale for decreasing the porosity in the simulation is because, in an aquifer system consisting of both primary and secondary porosity, fluid flow tends to be through the secondary porosity solution features which make up only a small part of the total aquifer porosity. Therefore, the rate of fluid movement can be more accurately estimated by using a porosity value only associated with the conduits. The doubly porous carbonate aquifer system was approximated by simulating the aquifer as a single layer with a higher transmissivity and lower porosity value for both the Central Swamp and Lake Terrace regions. The transmissivity value selected for the Central Swamp region is the largest transmissivity value determined from aquifer test analyses. The transmissivity value selected for the Lake Terrace region is

equivalent to the total transmissivity of the multilayered model. The wide range of effective porosities is measured in carbonate aquifer systems, and the effective porosity that is solely related to the volume of the fractures is unknown. Therefore, a range of porosities was tested. Input values are shown in figures 12 and 13.

Case 6: Vertically and Horizontally Interconnected Heterogeneous System

The carbonate aquifer system incorporating vertical fracture zones and horizontal, solution-enhanced conduits, was simulated to investigate the effects of a hypothetically distributed, three-dimensional heterogeneity. The distribution of transmissivity values for the Central Swamp and Lake Terrace regions is identical to the distribution used to simulated the multilayered aquifer system, thereby incorporating horizontal, solution-enhanced flow zones. Vertical fractures were simulated by increasing the vertical hydraulic conductivity in fractured blocks relative to the unfractured blocks to simulate the enhanced connectivity between layers. The calculated VCONT values used in the layered model were used to simulate the unfractured blocks. The calculated VCONT values for the fractured blocks were simulated as being five times as permeable as the unfractured blocks, thereby short-circuiting the porous media flow. The term "short-circuiting" is used to describe the interconnection between fractures enhancing fluid movement. This short circuiting was observed at the Old Tampa well field (Robinson, 1995). The effective porosity values are those used for the layered model. Input values are shown in figures 12 and 13.

Simulated Areas of Contribution to Supply Wells, Using Particle Tracking Techniques

Ground-water flow was modeled by using particle tracking techniques to derive the area contributing water to supply wells. The area around each well encompassed by pathlines defines the approximate area of contribution that supplies water to pumping wells. Areas of contribution were delineated for the hypothetical carbonate aquifer systems by placing particles within the grid block containing wells and by running the MODPATH program in the backward-tracking mode. Particle locations were plotted at 10-year intervals and terminated after 50 years. Particle locations were also plotted for a 5-year delineation of the area of contribution. The particle paths were plotted in plane and cross-sectional view. Plane view particle paths were used to estimate time-related areas of contribution to supply wells for the Central Swamp and Lake Terrace regions. Plane views were created by projecting all of the particle paths onto a two-dimensional slice and, therefore, represents the composite area of contribution for the entire thickness of the simulated regions. The extent of the particle paths represents the maximum area from which water is supplied to the wells. Cross-sectional view particle paths are presented to show the effects of aquifer heterogeneity on the vertical flow fields. Cross-sectional views were created by projecting particle paths for supply wells located along a specified row onto that particular row. Therefore, particle paths in the cross section and in the plane view cannot be readily correlated. The sizes of the simulated areas of contribution are those for 50- and 5-year time-related areas.

The Central Swamp Region

The size, shape, and orientation of the areas of contribution in the Central Swamp region for the hypothetical carbonate aquifer systems were delineated by seeding cells containing production wells with particles and by analyzing the flow path patterns in plane view (fig. 14). In addition, boundary fluxes were calculated using the computer program ZONEBUDGET. ZONEBUDGET can be used to calculate the subregional water budgets using results from MODFLOW (Harbaugh, 1990). The appendix contains a list of inflow percentages from each of the constant-head boundaries. Inflow from the constant-head water table ranged from 58 to 81 percent. A brief discussion of the ZONEBUDGET results is included in the discussion of the individual cases.

Case 1.—The isotropic, homogeneous single-layer carbonate aquifer system has a 12.7-mi^2 area of contribution in the shape of an elongated oval. The orientation is slightly northeast-southwest, roughly following the supply well orientation. The ZONEBUDGET results for Case 1 indicates that about 75 percent of the boundary inflow is derived from the water table. The lateral boundaries contribute varying percentages ranging from 5.5 to 7 percent. The differences among percentages derived from the individual lateral boundaries is probably the result of well locations relative to the boundaries.

Cases 2A and 2B.—The simulated areas of contribution are approximately 12.4 mi^2 for the anisotropic, single-layer, carbonate aquifer system. The shape and orientation are elliptical and elongated in the direction of the maximum transmissivity tensor. The ZONEBUDGET results for Cases 2A and 2B indicate that about 63 percent of the boundary inflow is derived from the water table. This is 12 percent less than in the isotropic case (Case 1) and is probably the result of enhanced direction-dependent lateral transmissivity in the pumped aquifer. The combined inflow from the lateral boundaries normal to the maximum transmissivity tensor contribute about 35 percent.

Case 3A.—The simulated area of contribution is approximately 8.2 mi^2 for the impermeable, discrete, fractured, carbonate aquifer system. The shape is roughly circular and without apparent orientation. The shift to a more circular area of contribution is probably due to the flow field attenuation at the fracture network and greater velocities of the particles not intersecting fractures. The ZONEBUDGET results for Case 3A indicates that about 81 percent of the boundary inflow is derived from the water table. This is 6 percent more than in the isotropic case and is probably the result of the flow field attenuation by the simulated impermeable fractures in the pumped aquifer. Lateral inflow is contributed almost exclusively from lateral boundaries 1 and 4, which are located away from the impermeable fracture blocks.

Cases 3B and 3C.—The simulated areas of contribution for the permeable, discrete, fractured, carbonate aquifer system ranged from 10.7 to 12.1 mi^2. The size of the area of contribution for various values of fracture-influenced transmissivity is not greatly affected; but, as the ratio of transmissivities in the fractured and unfractured blocks increases, particle paths deviate from radial flow. Particles travel two to three times farther in the simulated fractured blocks than in the unfractured blocks. The ZONEBUDGET results for Cases 3B and 3C indicate that about 69 and 63 percent of the boundary inflow is derived from the water table, respectively. This is 6 and 12 percent less than in the isotropic case and is probably the result of enhanced transmissivity of the simulated permeable fractures. The lateral boundaries closest to the fractured blocks contribute a greater percentage, and this percentage increases as the ratio of transmissivities in the fractured to unfractured blocks is increased.

Case 4A.—The simulated area of contribution for the four-layer carbonate aquifer system is the same size (12.7 mi^2), shape, and orientation as the simulated area of contribution for the Case 1 model. This indicates that the distribution of transmissivity values by layer does not affect the composite area of contribution to supply wells. However, these alterations do affect the individual particle paths. The vertical component of flow is enhanced by simulating a layered aquifer system with variable hydraulic properties. The ZONEBUDGET results for Case 4A indicates that about 72.5 percent of the boundary inflow is derived from the water table. The lateral boundaries contribute varying percentages ranging between 5.6 and 7.5 percent.

Case 4B.—The simulated area of contribution for the nine-layer carbonate aquifer system is 23.0 mi^2. The shape is irregular, but roughly circular. There appears to be no preferred orientation. This hypothetical carbonate aquifer system incorporated discrete producing zones of higher permeability. The particle paths are horizontal in the permeable zones and more vertical in the lower permeability layers. The particles travel four times farther in these zones, generating a larger composite area of contribution. The ZONEBUDGET results for Case 4B indicates that about 75 percent of the boundary inflow is derived from the water table and is nearly equivalent to the isotropic case. The lack of preferred orientation of the composite area of contribution is supported by the budget results because nearly equivalent percentages are contributed from each of the lateral boundaries.

Case 5.—The simulated area of contribution for the doubly porous, carbonate aquifer system are 12.7, 16.0, and 39.1 mi^2 for porosities of 20, 10, and 5 percent, respectively. The area of contribution for the doubly porous model with an effective porosity of 20 percent is not shown in figure 14 because it is identical to Case 1. The doubly porous model with an effective porosity of 5 percent is almost circular in shape. No orientation was evident. The ZONEBUDGET results for Case 5 when using a 5 percent porosity indicates that about 57 percent of the boundary inflow is derived from the water table. This is 18 percent less than in the isotropic case and is probably the result of the higher simulated transmissivity in the pumped aquifer. The lack of preferred orientation of the area of contribution is supported by the budget results because nearly equivalent percentages are contributed from each of the lateral boundaries.

Case 6.—The simulated area of contribution for the vertically and horizontally interconnected heterogeneous carbonate aquifer system is 23.6 mi^2.

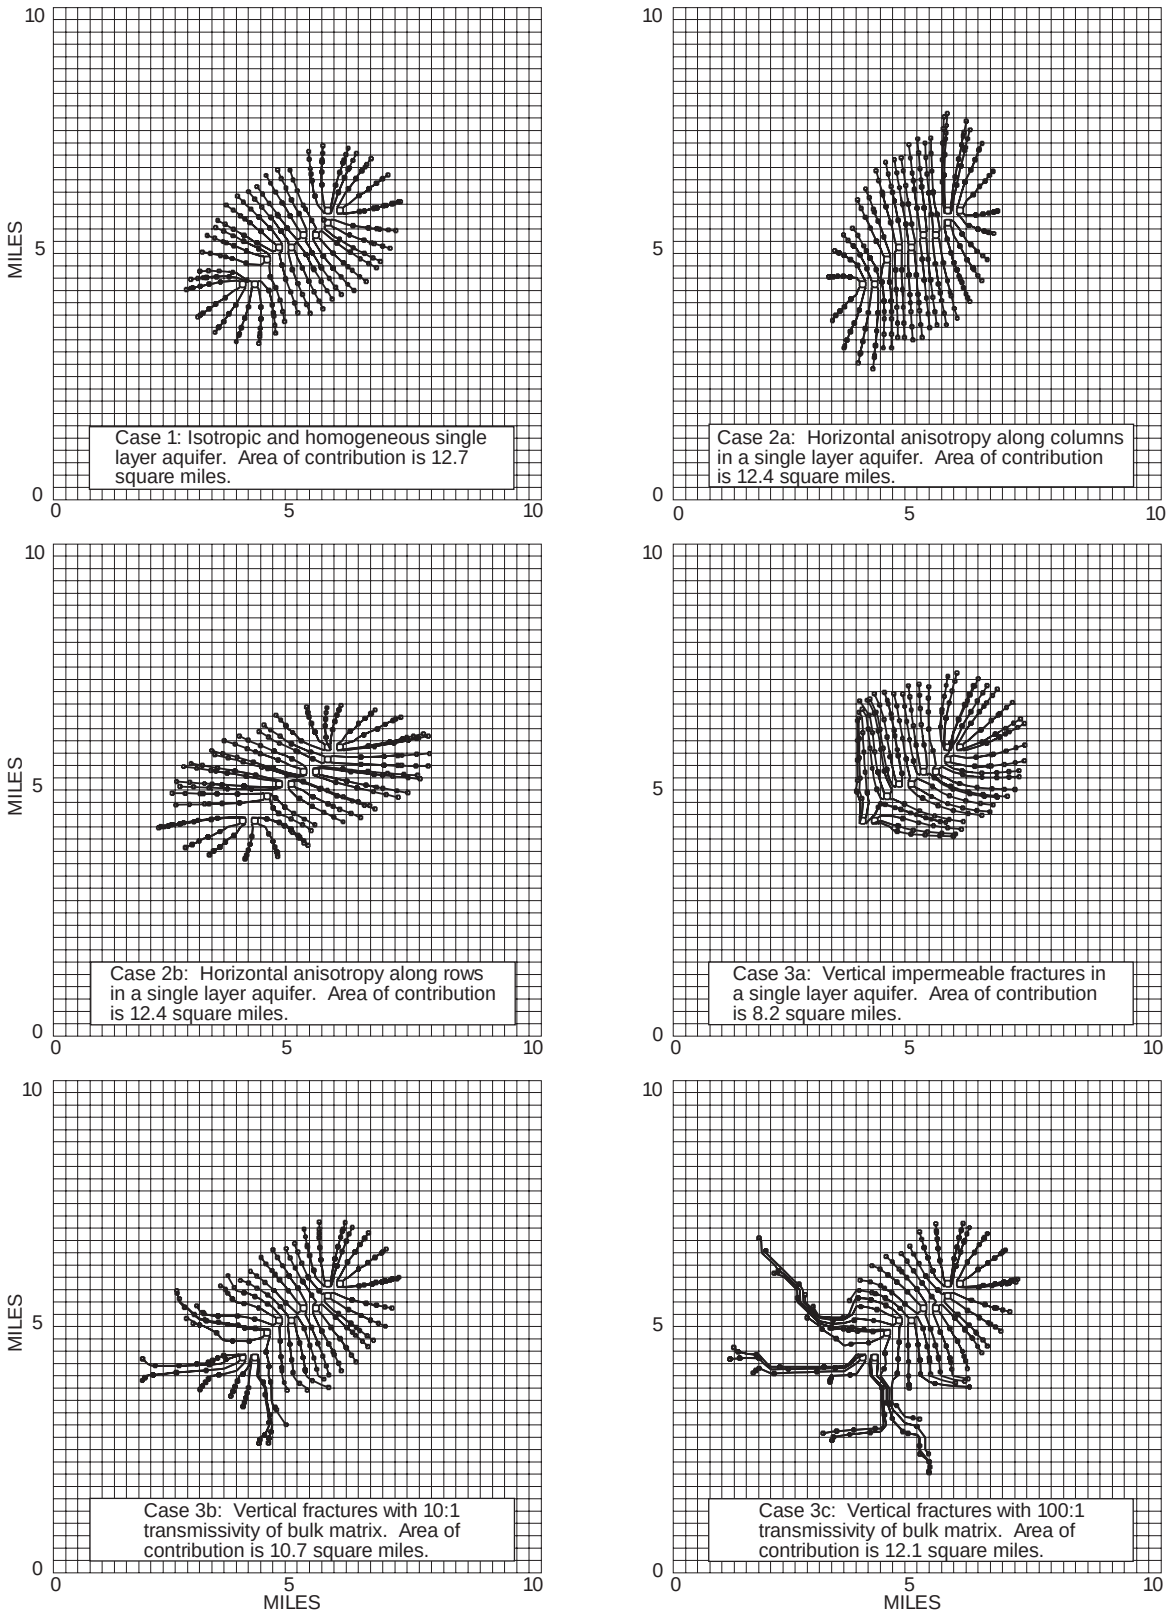

Figure 14. Fifty-year time-related area of contribution for the hypothetical carbonate aquifer systems in the Central Swamp region.

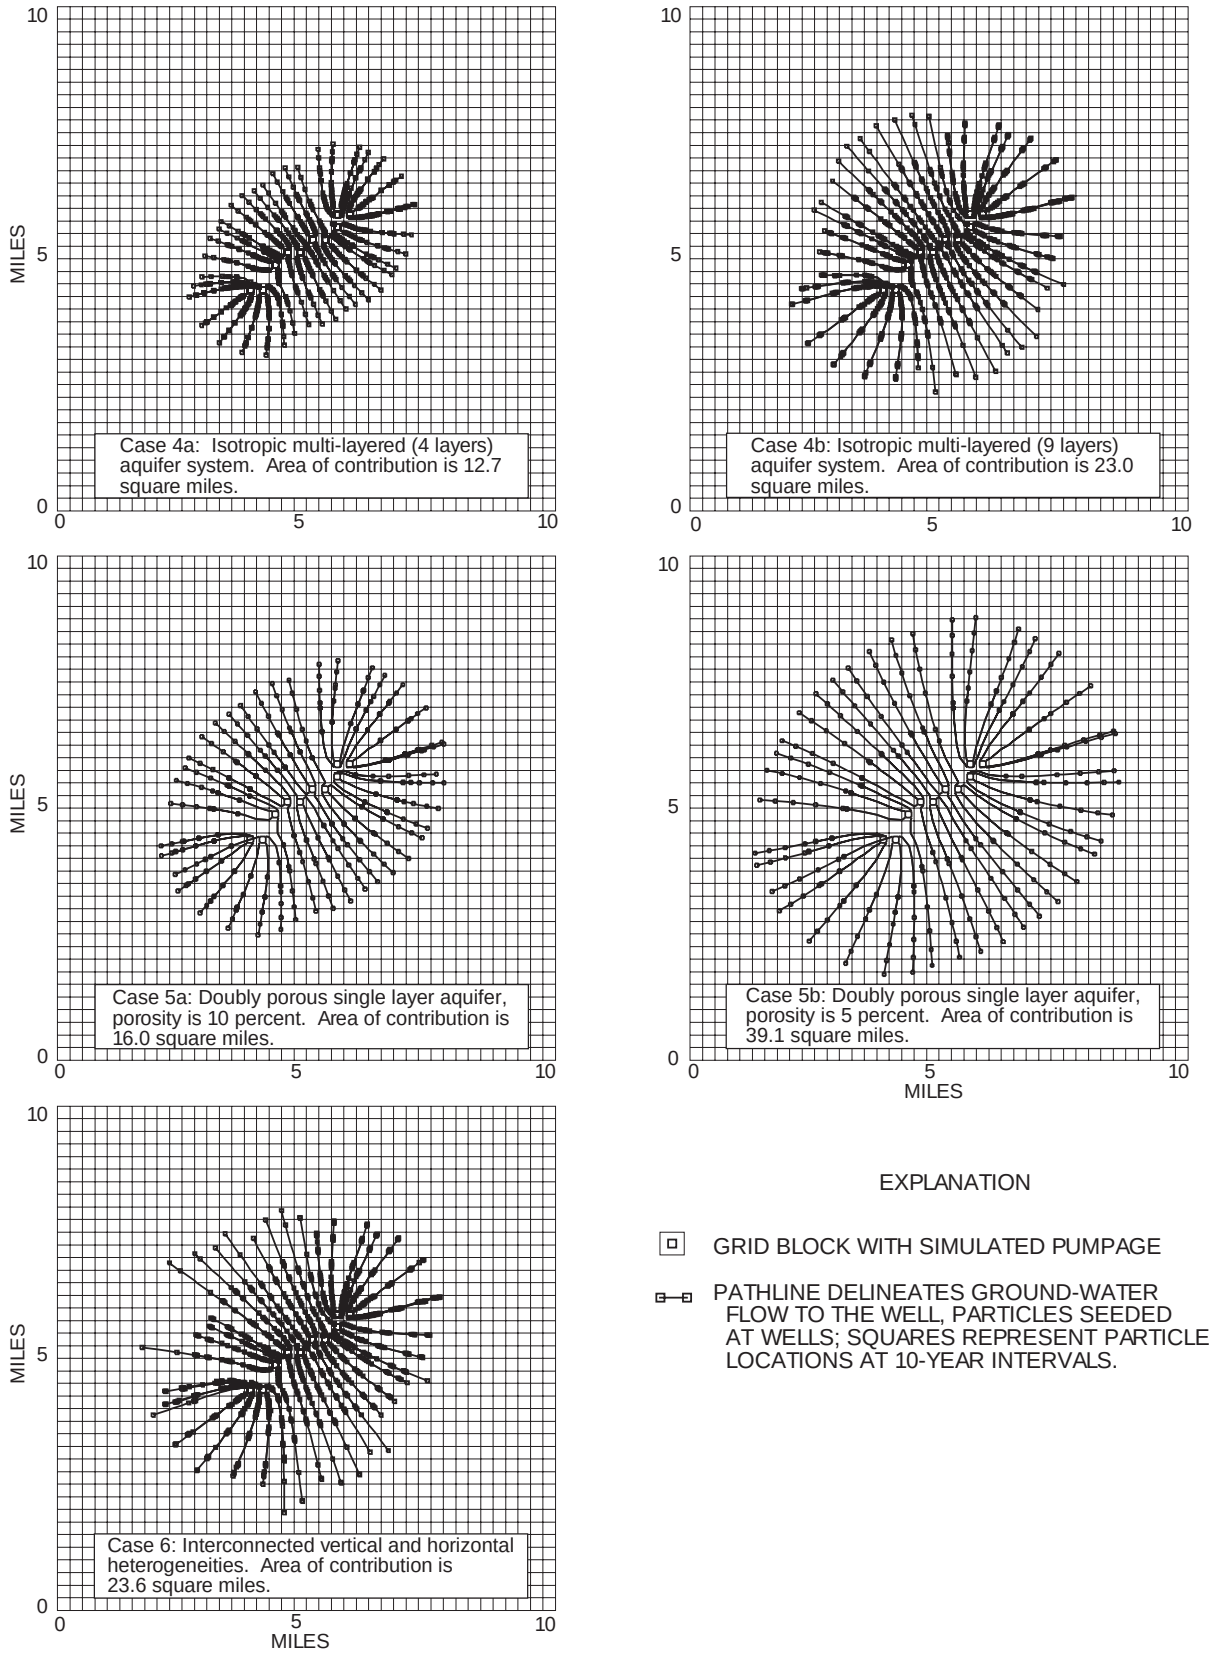

Figure 14. (Continued) Fifty-year time-related area of contribution for the hypothetical carbonate aquifer systems in the Central Swamp region.

The shape is irregular, especially in the vicinity of the simulated fracture network. The ZONEBUDGET results for Case 6 indicate that boundary inflows are nearly the same as for Case 4B. This indicates that enhanced lateral flow zones in the pumped aquifer control the source of boundary inflow to a greater extent than enhanced vertical interconnection between flow zones even though the shape of the area of contribution is affected by these simulated vertical fractures.

Figure 15 is included in the report to show the effects of aquifer heterogeneity in cross section. The cross-section view is along row 20 in the Central Swamp region and particle paths are projected onto a two-dimensional slice corresponding to row 20. Particles were seeded in each well in row 20, and all wells were pumped during simulation. The projection can be misleading in that particles that do not travel in the specified row are projected onto that row. However, the figure does present the vertical flow deviations not readily discernible in plane view. The vertical flow deviations shown in figure 15 are discussed in terms of observed variations for the particular row.

Case 1.—The particle paths are evenly spaced and become more vertical near the top of the simulated carbonate aquifer system.

Cases 2A and 2B.—The predominant direction of aquifer anisotropy is readily apparent. By using the cross-section projection along a row, lateral spread of pathlines is small when flow is predominantly along columns and large when flow is predominantly along rows.

Cases 3A, 3B, and 3C.—Discrete fracture networks influence the lateral spread of pathlines by limiting pathline length when intersecting closed fractures and increasing lateral spread in the direction of high permeability fractures.

Case 4A.—Simulation of a multilayered aquifer system with contrasting hydraulic properties had a pronounced effect on flowlines and simulated particle paths. The particles tend to move more horizontally in permeability layers and more vertically in low permeability layers.

Case 4B.—Simulation of discrete producing zones has an even more pronounced effect because of the greater contrasts in hydraulic properties among the hydrologic units. Flow is predominantly horizontal in the enhanced flow zones and nearly vertical in the less permeable zones.

Cases 5A and 5B.—Selection of simulated porosity affects the lateral spread of pathlines. The lower the porosity the larger the spread.

Case 6.— The distribution of pathlines in the cross section does not appear to be affected by enhanced vertical connectivity between zones and is identical to case 4B.

All of the hydrogeologic factors tested had some effect on the simulated flow fields that defined the areas of contribution in the Central Swamp region. Generally, the simulated areas of contribution represent a composite area that results from pumping interference among supply wells. Well orientation, distribution, and pumping rates have an underlying effect on the size, shape, and orientation of the areas of contribution. Differing types of simulated aquifer anisotropy and heterogeneity affected the areas of contribution in a variety of ways. The size of the simulated areas of contribution is mostly affected by heterogeneous layering of aquifer properties and the selection of effective porosity. The shape of simulated areas of contribution to supply wells is mostly affected by the location of the discrete fracture network, and the orientation of simulated areas of contribution is mostly affected by aquifer anisotropy.

The Lake Terrace Region

The size, shape, and orientation of the areas of contribution in the Lake Terrace region for the hypothetical carbonate aquifer systems were delineated by seeding cells containing production wells with particles and by analyzing the flow path patterns in plane view (fig. 16). In addition, boundary fluxes were calculated by using the computer program ZONEBUDGET. ZONEBUDGET can be used to calculate the subregional water budgets using results from MODFLOW (Harbaugh, 1990). The appendix contains a list of inflow percentages from each of the constant-head boundaries. Inflow from the constant-head water table ranged from 38 to 65 percent. A brief discussion of the ZONEBUDGET results among the various cases is included in the discussion of the individual cases.

Case 1.—The isotropic, homogeneous, single-layer, carbonate aquifer system has a 4.0-mi^2 area of contribution. The shape and orientation that were delineated are roughly radial particle paths surrounding an individual grid block containing wells. The combined areas of contribution for the well field roughly follow the orientation of the supply wells. The ZONE

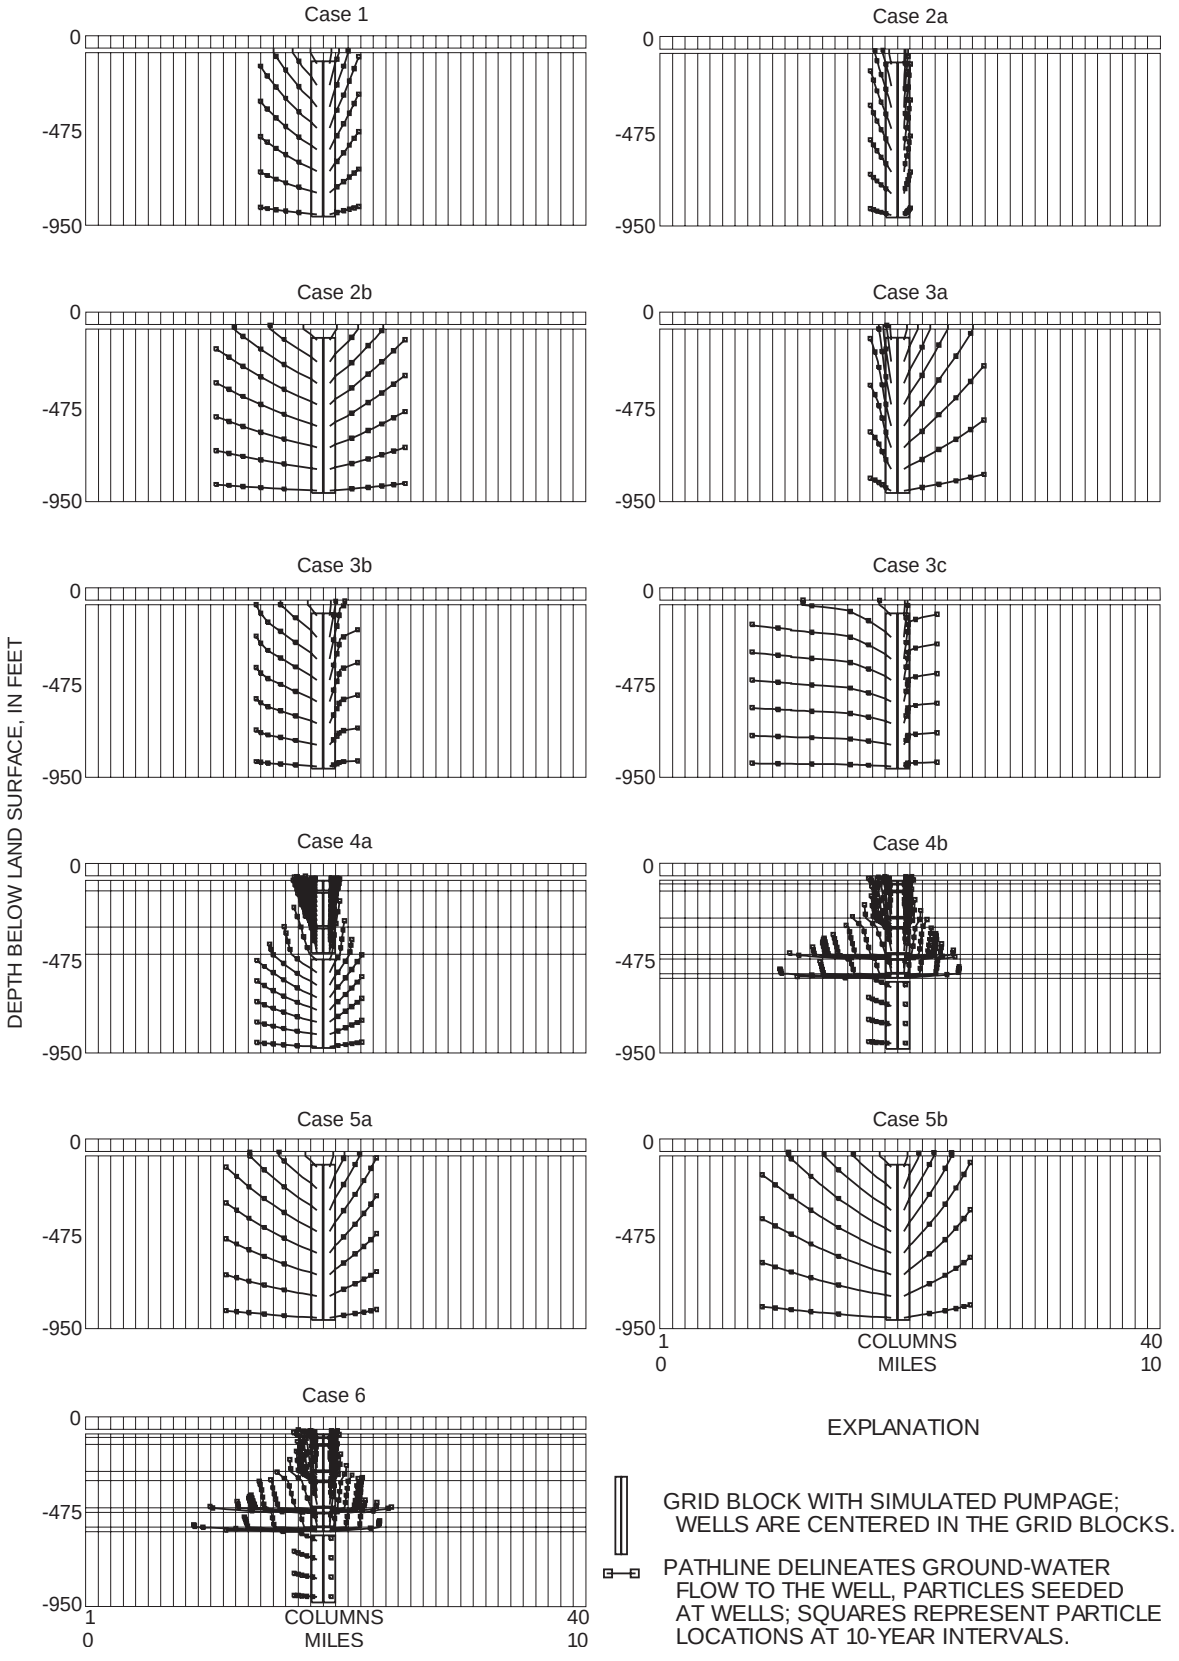

Figure 15. Fifty-year traveltimes for particles projected onto a two-dimensional slice corresponding to row 20 for the hypothetical carbonate aquifer systems in the Central Swamp region.

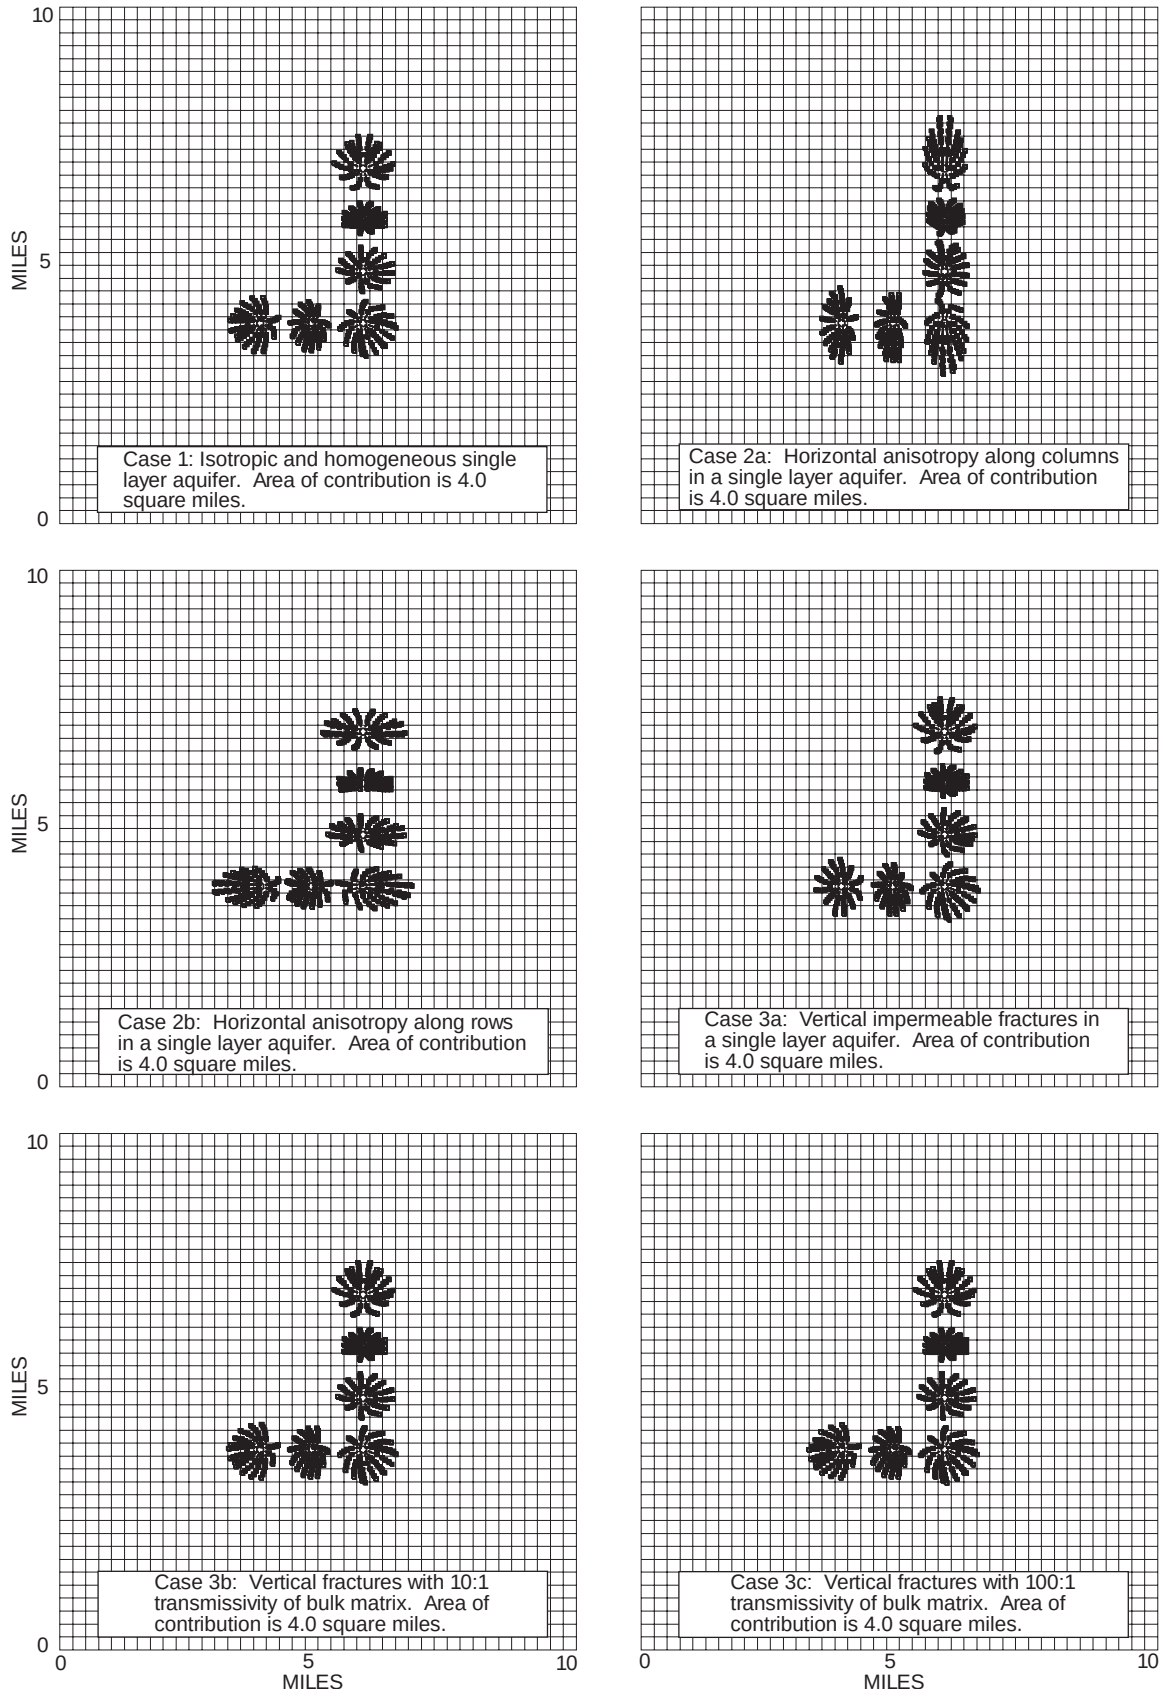

Figure 16. Fifty-year time-related areas of contribution for the hypothetical carbonate aquifer systems in the Lake Terrace region.

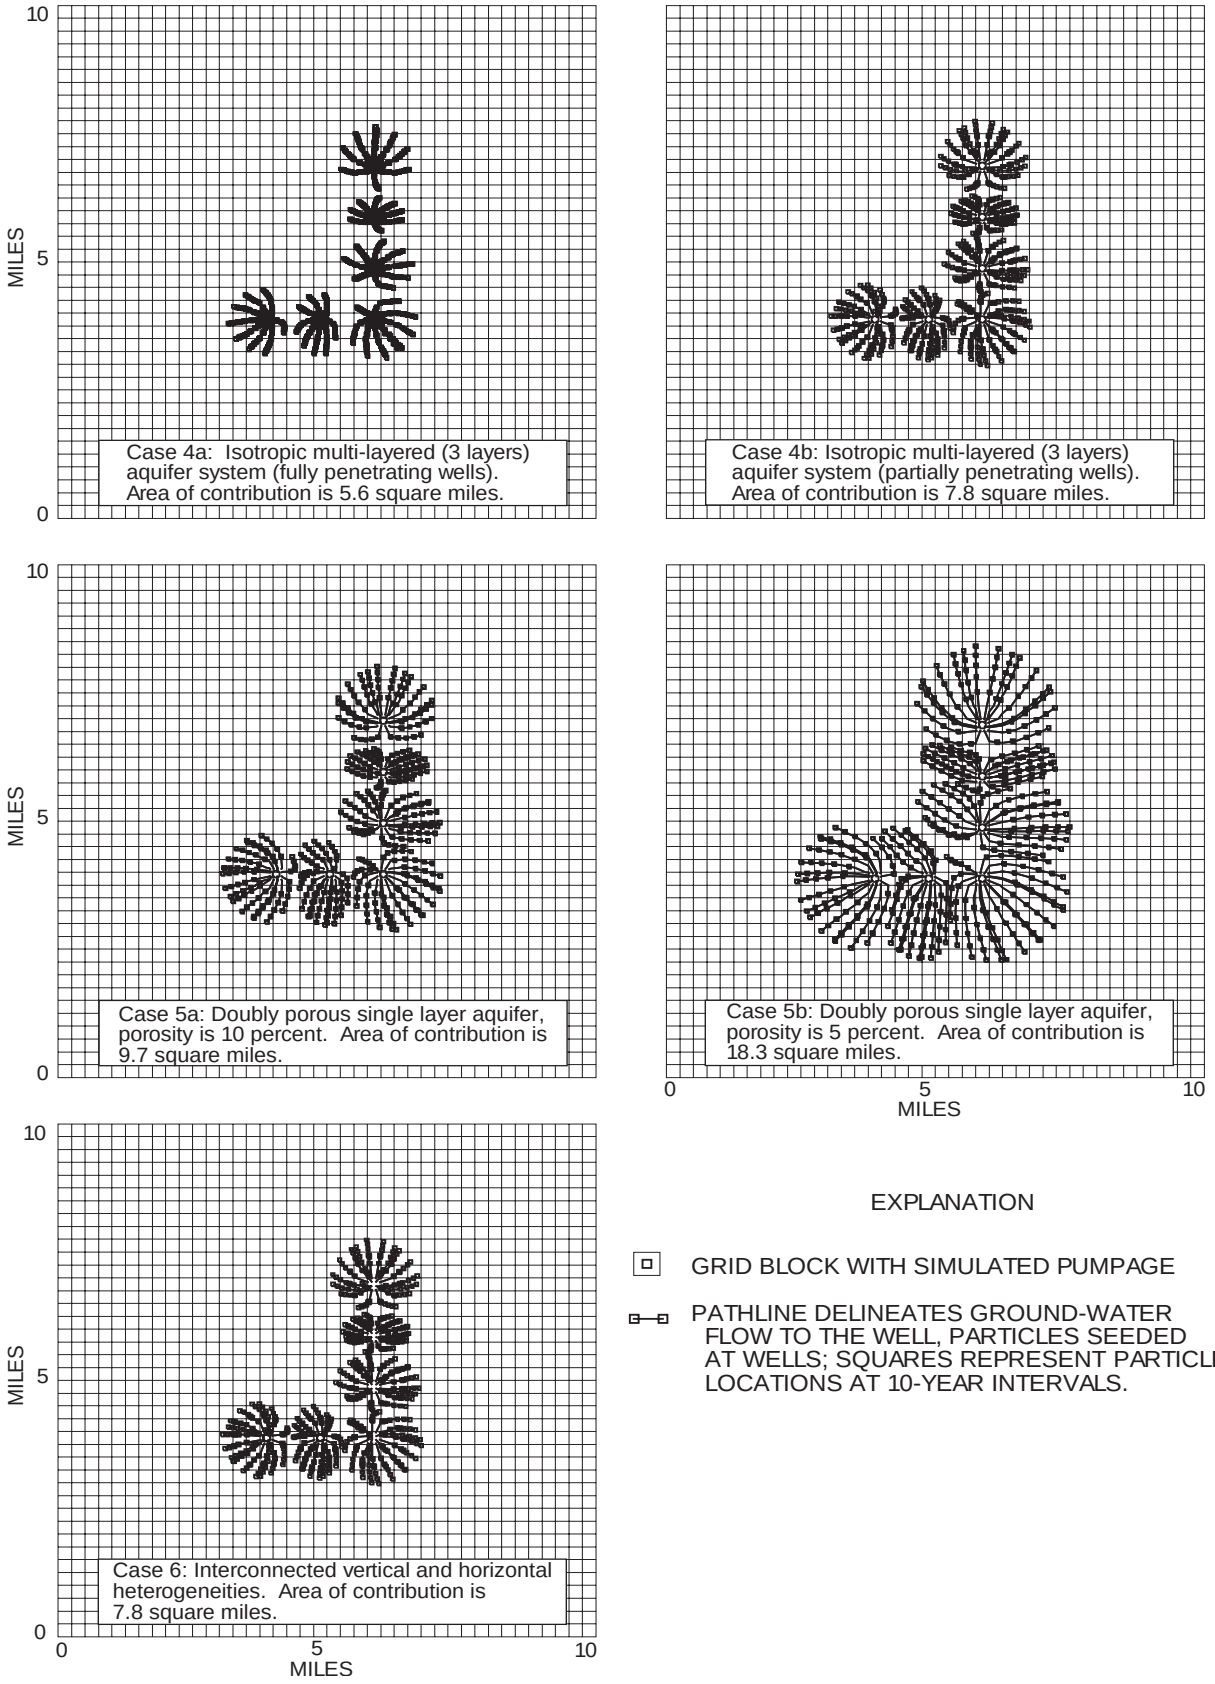

Figure 16. (Continued) Fifty-year time-related areas of contribution for the hypothetical carbonate aquifer systems in the Lake Terrace region.

BUDGET results for Case 1 indicate that about 58 percent of the boundary inflow is derived from the water table. The lateral boundaries contribute varying percentages ranging between 8 and 12 percent. The differences among percentages derived from the individual lateral boundaries is probably the result of well locations relative to the boundaries.

Cases 2A and 2B.—The anisotropic, single-layer, carbonate aquifer system also has a 4.0 mi^2 area of contribution. The shape and orientation of particle paths are elliptical and elongated in the direction of the maximum transmissivity tensor. The ZONEBUDGET results for Cases 2A and 2B indicate that about 48 percent of the boundary inflow is derived from the water table. This is 10 percent less than in the isotropic case (Case 1) and is probably the result of enhanced direction-dependent lateral transmissivity in the pumped aquifer. The combined inflow from the lateral boundaries normal to the maximum transmissivity tensor contribute 50 percent.

Cases 3A, 3B, and 3C.—Neither the simulated impermeable nor permeable, fractured, single-layer, carbonate aquifer system affected the size, shape, or orientation of the simulated areas of contribution. The 50-year particle paths do not intersect the simulated fracture locations. The area of contribution is the same as for Case 1. Whereas simulated fracture locations did not affect the size, shape, or orientation of the areas of contribution, the ZONEBUDGET results were affected. The ZONEBUDGET results for Case 3A indicate that about 66 percent of the boundary inflow is derived from the water table. This is 8 percent more than in the isotropic case and is probably the result of the flow field attenuation by the simulated fractures in the pumped aquifer. A combined lateral inflow of about 32 percent is almost equally contributed from boundaries 1, 3, and 4. Lateral boundary 2 contributes only about 2 percent. This is probably due to the close proximity of an impermeable fracture to the wells. The ZONEBUDGET results for Case 3B and 3C indicate that about 56 and 55 percent of the boundary inflow is derived from the water table, respectively. This is 2 and 3 percent less than in the isotropic case and is probably the result of the enhanced transmissivity of the simulated permeable fractures; however, the lateral inflow is not significantly increased because the fractures blocks are located distant from the pumped wells. The greatest increase in contribution between impermeable and permeable fracture simulations is from lateral boundary 2.

Case 4.—Two scenarios of well construction, fully and partially penetrating, were simulated in the multilayered carbonate aquifer system. The simulated areas of contribution for the fully and partially penetrating wells tapping a multilayered carbonate aquifer system are 5.6 and 7.8 mi^2, respectively. The general shape and orientation is the same as for the previous cases. The difference between the sizes in areas for case 4A and 4B is the result of greater well interference, as exhibited by the particle paths in case 4B. The representation of the partial penetrating wells coincide with actual well depths in the Cosme-Odessa well field. The ZONEBUDGET results for Cases 4A and 4B indicate that between 38 and 40 percent of the boundary inflow is derived from the water table and is nearly 20 percent less than in the isotropic case. The effects of partial penetration did not substantially change inflow from the water table (<2 percent). Inflow from the lateral boundaries for Case 4A ranges from about 13 to 18 percent and in Case 4B from about 12 to 17 percent.

Cases 5A, 5B, and 5C.—The simulated areas of contribution for the doubly porous carbonate aquifer system with an effective porosity of 20 and 10 percent are 5.6 and 9.7 mi^2, respectively. The simulated areas of contribution for the doubly porous carbonate aquifer system with an effective porosity of 5 percent is 18.3 mi^2. As the simulated effective porosity decreased, the area of contribution increased. The composite shape and orientation are similar but the particle paths around individual wells are less radial due to competition among the wells. The area of contribution for 20 percent porosity is not shown in figure 16. The ZONEBUDGET results for Case 5 when using a 5 percent porosity indicate that about 38 percent of the boundary inflow is derived from the water table. This is 20 percent less than in the isotropic case and is probably the result of the higher simulated transmissivity in the pumped aquifer.

Case 6.—The simulated areas of contribution for the fully and partially penetrating wells tapping an vertically and horizontally interconnected heterogeneous, carbonate aquifer system are 5.6 and 7.8 mi^2, respectively. The simulated areas of contribution are nearly identical to Case 4; therefore, only the partially penetrating well simulation is shown in figure 16. The enhanced vertical connection between layers in the simulated fractured grid blocks did not affect the areas of contribution. The ZONEBUDGET results for Case 6 indicate that boundary inflows are nearly the same as for Case 4B. This indicates that enhanced lateral flow

zones in the pumped aquifer control the source of boundary inflow to a greater extent than enhanced vertical interconnection between flow zones even though the shape of the area of contribution is affected by these simulated vertical fractures.

Figure 17 is included in the report to show the effects of aquifer heterogeneity in cross section. The cross-section view is along row 25 in the Lake Terrace region and particle paths are projected onto a two-dimensional slice corresponding to row 25. Slight variations in the flow fields can be observed that are not readily apparent in plane view.

Case 1.—The particle paths are evenly spaced and become more vertical near the top of the simulated carbonate aquifer system.

Cases 2A and 2B.—The predominant direction of anisotropy is readily apparent. The lateral spread of pathlines is small when flow is predominantly along columns and large when flow is predominantly along rows.

Cases 3A, 3B, and 3C.—Particle paths closest to the simulated impermeable fracture network (Case 3A) reflect slight effects from the no-flow grid blocks by becoming more vertical. Slight variations in the flow field as represented by particle paths (case 3B and 3C) are the result of location and permeability of the discrete fracture network, but, because the fracture network is not intersected directly, effects are minimal.

Case 4A and 4B.—Layering and well penetration affect the flow field by creating variations in fluid movement direction and velocity. The lateral spread of particles is small in the simulated semiconfining unit relative to the more permeable units (Case 4A). When only the upper producing zone is being stressed, flow paths are predominantly horizontal in the high permeability layers and vertical in the low permeability layer (Case 4B). The flow velocities vary by layer due to differing effective porosities and permeabilities.

Case 5.—Selection of simulated porosity affects the lateral spread of pathlines. The lower the porosity, the larger the spread, which results in competition for flow among wells.

Case 6.—The particle paths are identical to those for Case 4. The fracture network is not intersected and, therefore, has little effect on particle paths.

In the Lake Terrace region, the hydrogeologic factors tested affected the areas of contribution to supply wells. The well distribution, orientation, and pumping rates resulted in the distinct shape of the areas of contribution. Pumping interference is minimal, and each well is characterized by an individual contributing area for isotropic, homogeneous conditions (Case 1). Incorporation of aquifer anisotropy and heterogeneity does affect the size, shape, and orientation of areas of contribution, but not as dramatically as expected. The size of the simulated areas of contribution is mostly affected by heterogeneous layering of aquifer properties (Cases 4 and 6) and by the selection of effective porosity (Case 5). The shape of simulated areas of contribution is mostly affected by well orientation and distribution, and the orientation is mostly affected by aquifer anisotropy (Case 2).

Comparisons Between Simulated Areas of Contribution in the Central Swamp and Lake Terrace Regions

The simulated areas of contribution for the prototype regions were compared to illustrate the effects of withdrawal rates, well distribution, and hydrogeologic differences on size, shape, and orientation of the areas. The major difference between the simulated areas of contribution in the Central Swamp and Lake Terrace regions is size. Generally, the simulated areas of contribution are about 60 percent larger in the Central Swamp region where the pumping rate is more than double and transmissivity is about half that of the Lake Terrace region. However, the difference in contributing area size between the two regions was not constant for all the hypothetical carbonate aquifer systems simulated. The largest difference in simulated contributing area size between the Central Swamp and Lake Terrace regions was 64 percent, a result of the simulation of the vertically and horizontally interconnected heterogeneities (Case 6). The smallest difference in contributing area size between the regions was 31 percent, a result of the simulation of a multilayered system (Case 4).

The shapes of the simulated areas of contribution in the Lake Terrace region are predominantly controlled by well location and distribution and generally follow the outline of supply wells at the Cosme-Odessa well field. The shapes of simulated areas of contribution in the Central Swamp region are primarily affected by locations of simulated fracture networks. The larger the ratio of fracture to bulk matrix permeability, the more linear the flow field becomes. The shapes of particle paths for the multilayered carbonate aquifer system in the Central Swamp region were irregular, rosette-shaped areas of contribution because of the variability in flow direction and velocity between high

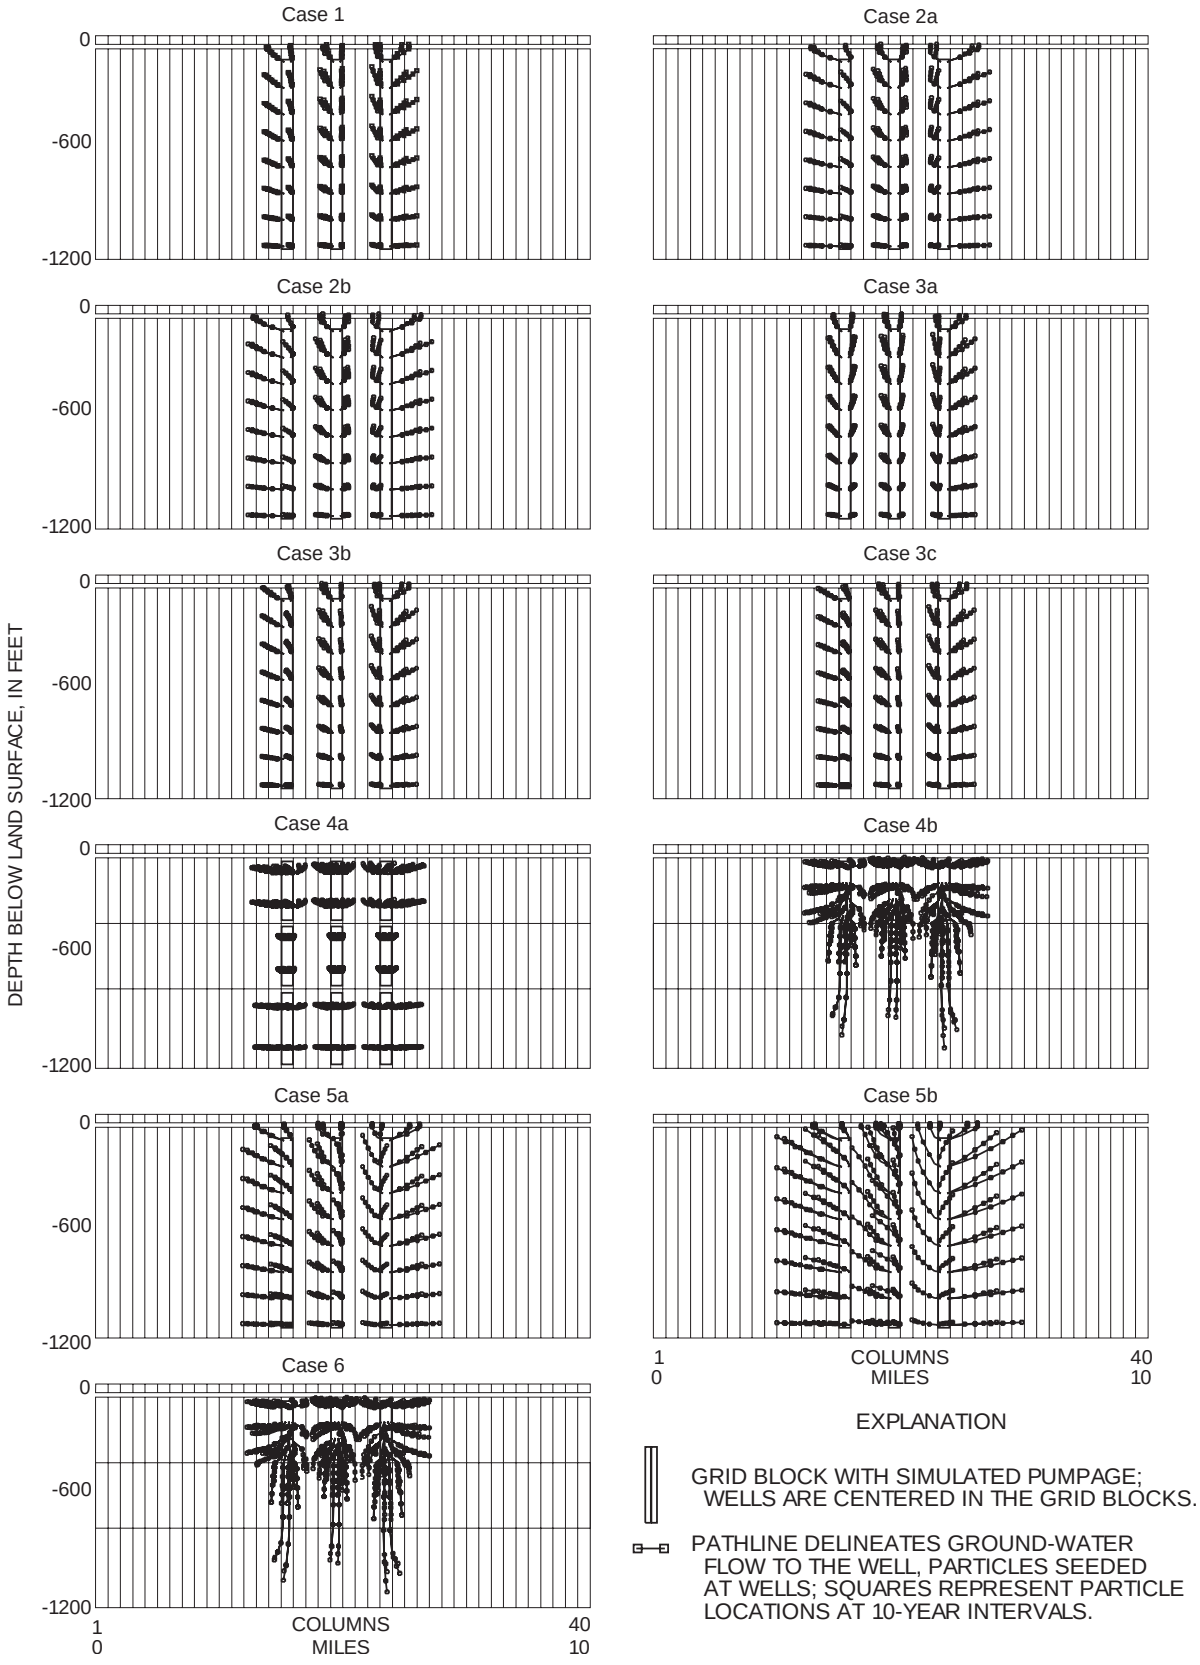

Figure 17. Fifty-year traveltimes for particles projected onto a two-dimensional slice corresponding to row 25 for the hypothetical carbonate aquifer systems in the Lake Terrace region.

and low permeability layers. The shapes of the areas of contribution for simulations incorporating aquifer anisotropy in both regions are elongated ellipses. Aquifer anisotropy has similar effects on the orientation of simulated areas of contribution in the Central Swamp and Lake Terrace regions. The orientation of these areas of contribution is controlled by the maximum transmissivity tensor. In the Central Swamp region, orientation of particle paths is affected by the fracture network. Flow deviates from radial to linear paths once the fracture network is intersected. The 50-year traveltimes in the Lake Terrace region are unaffected by the simulated fracture network, because the 50-year traveltimes of particle paths do not intersect the discrete fracture network. The first particles just reach the fracture network after 100 years.

Simulations incorporating generalized representations of nonisotropic and nonhomogeneous aquifer behavior including anisotropy, vertical fractures, and multiple layers do affect the size, shape, and orientation of areas of contribution. Therefore, local-scale heterogeneities should be considered when delineating areas of contribution for karst carbonate aquifer systems.

COMPARISON OF NUMERICAL SIMULATION RESULTS WITH RESULTS USING ANALYTICAL METHODS

Major differences in the methodology between analytical and numerical delineation of protection zones to supply wells result from the strict limiting assumptions when implementing analytical techniques. Analytical models are typically one-dimensional. Consequently, three-dimensional aquifer anisotropy and heterogeneity cannot be incorporated. The numerical models developed for this study were designed to approximate varying degrees of aquifer anisotropy and heterogeneity.

Vecchioli and others (1989) used a radial, volumetric displacement, analytical method to delineate protection zones at well fields in the Upper Floridan aquifer in west-central Florida. The analytical method used was based on equations derived from Darcy's law and assumes uniform, radial flow. A porosity of 5 percent was selected for the analysis. The selection of a 5 percent porosity value is based on the characterization of the Upper Floridan aquifer system as a doubly porous system having both primary and secondary porosity. Fluid flow tends to be through the solution features (secondary porosity) which make up only a small part of the total porosity. Therefore, the rate of fluid movement can be more accurately estimated by using a porosity value only associated with the conduits. Protection zones were delineated for a specified traveltime of 5 years, flow was assumed to be lateral in the aquifer, and the aquifer thickness was taken equal to the well penetration. Where the protection zones overlapped, composite protection zones were delineated. Limitations of the analytical method include the inability to incorporate the natural slope of the potentiometric surface, complex hydrologic boundaries, and variations in porosity and aquifer thickness (Vecchioli and others, 1989, p. 33).

The numerical model that most closely approximates the conditions used in the analytical model is the doubly porous model when using an aquifer porosity of 5 percent (Case 5). To make comparisons with the analytically derived protection zones, 5-year time related areas of contribution were numerically simulated for the Central Swamp and Lake Terrace regions. The numerically simulated contributing areas for the two regions and the analytically delineated protection zones for the Cypress Creek and Cosme-Odessa well fields (from Vecchioli and others, 1989) are shown in figure 18.

The areas of contribution that were delineated using numerical methods are different in both shape and size from protection zones that were delineated using analytical methods. The protection zones that were delineated for the Cypress Creek and Cosme-Odessa well fields using the analytical model are 7.85 and 8.24 mi^2, respectively. The contributing areas that were delineated for the Central Swamp and Lake Terrace regions are about 4 and 1 mi^2, respectively. This discrepancy in size can be the result of various factors. The most critical factor is that the analytically derived protection zone size was determined for a 5-year lateral traveltime, which does not correspond to a 5-year traveltime for seeded particles because particles can move both laterally and vertically. Some of the assumptions of analytical methods that may affect the size, shape, and orientation of delineated protection zones are that ground-water flow to wells is uniform and that the aquifer is bounded by nonleaky confining beds. The assumption of uniform, radial flow is only approximated near the well bore and the deviation from radial flow increases as the distance from the well is increased. The assumption of nonleaky confining beds is a poor assumption, because relatively few confined

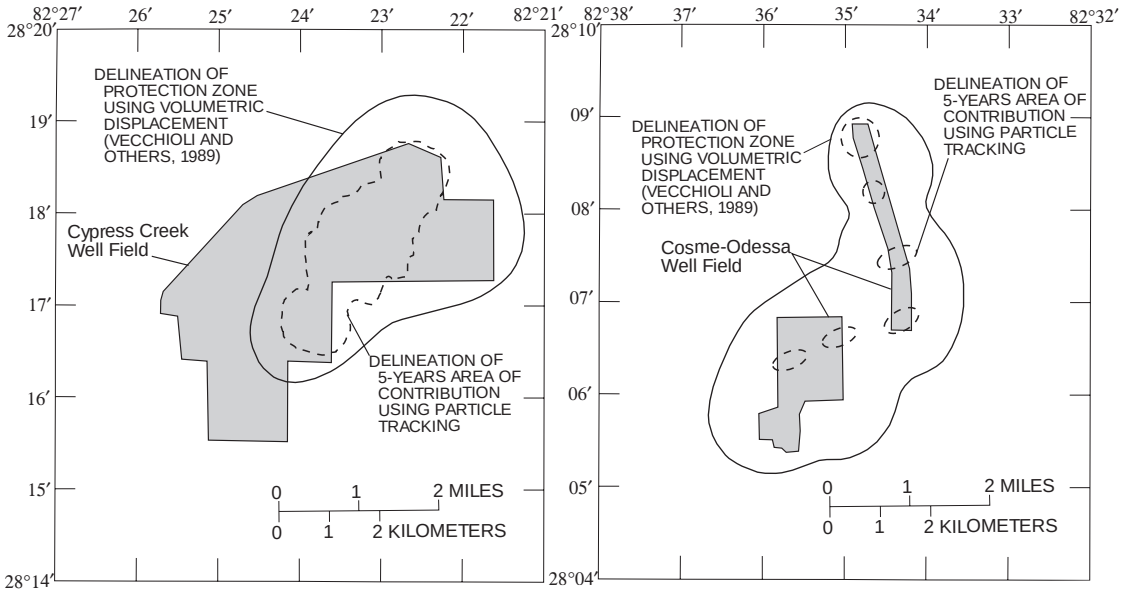

Figure 18. Delineation of protection zones using analytical methods, and areas of contribution using numerical methods for the Central Swamp and Lake Terrace regions.

aquifers do not receive water from adjacent beds. In addition the analytically derived protection zones do not account for changes in the flow field caused by changes in the local hydraulic gradient in response to pumping.

Numerical models should be more accurate than analytical models simply because greater aquifer complexities can be incorporated in the model. However, these numerical models are hypothetical in that distributions and behaviors of aquifer heterogeneities are not well understood. The analytically derived protection zones are very conservative when compared with the contributing areas delineated by numerical modeling.

SUMMARY AND CONCLUSIONS

The highly permeable, karst carbonate Floridan aquifer system underlies Florida and much of the southeastern Coastal Plain and is a principal source of drinking water. Public supply wells in karst carbonate aquifers are particularly vulnerable to contamination. Estimation of areas of contribution in karst carbonate aquifers can be extremely difficult, because permeability in carbonate aquifers is greatly enhanced by dissolution of rock, which creates an uneven distribution of permeability along preferred flow paths.

Traditional strategies to protect ground-water resources have been through land-use regulation within a prescribed radial area around supply wells. Hydrogeologic factors operating at a site that may affect the size, shape, and orientation of areas of contribution to supply wells often are not considered. Ground-water flow to wells in karst carbonate aquifer systems tends to be through solution-enhanced conduits. Nonradial flow along preferential zones can result in inaccurate estimations of flow paths and traveltimes. A better understanding of the effects of aquifer heterogeneity on flow fields is needed to protect the ground-water resources.

The influence of aquifer anisotropy and heterogeneity on the movement of ground water can often be inferred from aquifer and tracer test data. Evaluation of aquifer test, tracer test, and borehole geophysical log data available for the study area indicate various nonuniform flow conditions. Based on field evidence of nonuniform flow, six hypothetical carbonate aquifer systems were conceptualized. These conceptualized systems were designed to approximate anisotropic and heterogeneous aquifer behavior and to evaluate how incorporation of aquifer anisotropy and heterogeneity may affect the size, shape, and orientation of areas of contribution.

Although many hydrogeologic factors affect the estimation of contributing areas to well fields, this report focused primarily on the effects of aquifer heterogeneity and anisotropy on the size, shape, and orientation of the simulated areas. The method used to estimate contributing areas was a three-dimensional numerical flow model and particle tracking subroutine used as a postprocessor. MODFLOW and MODPATH numerical models were used to generate time-related areas of contribution for six carbonate aquifer system types. These include: an isotropic and homogeneous single-layer system; an anisotropic in a horizontal plane single-layer system; a discrete vertically fractured single-layer system; a multilayered system; a doubly porous single-layer system; and a vertically and horizontally interconnected heterogeneous system. The simulated aquifer anisotropy was 5:1 and was determined from TENSOR2D results. The simulated vertical discrete fracture network represents locations of photolineaments. The simulated enhanced flow zones were determined from borehole video and geophysical logs. The hypothetical carbonate aquifer systems were simulated for two prototype regions. The two regions, Central Swamp and Lake Terrace, were selected to be representative of the hydrologic diversity within the study area.

The simulated distributions of aquifer heterogeneity and anisotropy are highly conceptualized, but are based on plausible carbonate aquifer heterogeneities observed in west-central Florida that are typical of carbonate aquifers everywhere. This study indicates that the distribution and nature of aquifer heterogeneities will affect the size, shape, and orientation of areas of contribution in a karst carbonate aquifer system. The size of the 50-year time-related areas of contribution ranged from 8.2 to 39.1 square miles in the Central Swamp region. The size of the 50-year time-related areas of contribution ranged from 4.0 to 18.3 square miles in the Lake Terrace regions. The differences in size between the regions are primarily the results of variability in withdrawal rates, well distribution, and aquifer transmissivity. The simulated areas of contribution are 60 percent larger in the Central Swamp region where pumpage is more than double and transmissivity is about half that of the Lake Terrace region. Simulations showed that the size of areas of contribution is primarily affected by simulated withdrawal rates, effective porosity of the carbonate rock, and transmissivity. The shape and orientation of the simulated areas of contribution primarily result from aquifer anisotropy, well distribution, flow along solution-enhanced zones, and short-circuiting of flow through fracture networks. Flow velocities and particle path length respond to withdrawal rates, simulated effective porosity, short-circuiting of flow by fractures, and effective transmissivity.

Results of simulations incorporating aquifer heterogeneity indicate that oversimplification of the flow system may result in erroneous definition of flow fields. For example, aquifer anisotropy typical of many carbonate aquifers creates elliptical flow fields. Circular protection zones do not adequately characterize the elliptical areas of contribution. Also, areas of contribution were larger when the carbonate aquifer system was simulated as a multilayered system with discrete flow zones. This type of carbonate aquifer system is observed in west-central Florida. Simulated areas of contribution are significantly influenced by the choice of effective porosity. However, accurate, quantitative values of effective porosity in a carbonate aquifer system like the Upper Floridan aquifer are extremely difficult to measure.

Although the effective porosity from core analyses can characterize the primary porosity of the Upper Floridan aquifer, fluid flow tends to be through solution features that make up only a small part of the total porosity. The inclusion of a vertical fracture network may or may not affect the delineation of areas of contribution. In the Lake Terrace region, the simulated fractures had little effect on the short term (50-year) area of contribution. In the Central Swamp region, the simulated fractures have a large effect, because the simulated flow field intersected these fractures. Flow in fractures is linear rather than radial and velocities increase. Areas of contribution are difficult to precisely determine where a high degree of aquifer anisotropy and heterogeneity exists. The anisotropies and heterogeneities were simulated to show their possible effects on the size, shape, and orientation of areas of contribution.

SELECTED SERIES OF U.S. GEOLOGICAL SURVEY PUBLICATIONS

Periodicals

Earthquakes & Volcanoes (issued bimonthly).
Preliminary Determination of Epicenters (issued monthly).

Technical Books and Reports

Professional Papers are mainly comprehensive scientific reports of wide and lasting interest and importance to professional scientists and engineers. Included are reports on the results of resource studies and of topographic, hydrologic, and geologic investigations. They also include collections of related papers addressing different aspects of a single scientific topic.

Bulletins contain significant data and interpretations that are of lasting scientific interest but are generally more limited in scope or geographic coverage than Professional Papers. They include the results of resource studies and of geologic and topographic investigations, as well as collections of short papers related to a specific topic.

Water-Supply Papers are comprehensive reports that present significant interpretive results of hydrologic investigations of wide interest to professional geologists, hydrologists, and engineers. The series covers investigations in all phases of hydrology, including hydrogeology, availability of water, quality of water, and use of water.

Circulars present administrative information or important scientific information of wide popular interest in a format designed for distribution at no cost to the public. Information is usually of short-term interest.

Water-Resources Investigations Reports are papers of an interpretive nature made available to the public outside the formal USGS publications series. Copies are reproduced on request unlike formal USGS publications, and they are also available for public inspection at depositories indicated in USGS catalogs.

Open-File Reports include unpublished manuscript reports, maps, and other material that are made available for public consultation at depositories. They are a nonpermanent form of publication that may be cited in other publications as sources of information.

Maps

Geologic Quadrangle Maps are multicolor geologic maps on topographic bases in 7.5- or 15-minute quadrangle formats (scales mainly 1:24,000 or 1:62,500) showing bedrock, surficial, or engineering geology. Maps generally include brief texts; some maps include structure and columnar sections only.

Geophysical Investigations Maps are on topographic or planimetric bases at various scales; they show results of surveys using geophysical techniques, such as gravity, magnetic, seismic, or radioactivity, which reflect subsurface structures that are of economic or geologic significance. Many maps include correlations with the geology.

Miscellaneous Investigations Series Maps are on planimetric or topographic bases of regular and irregular areas at various scales; they present a wide variety of format and subject matter. The series also includes 7.5-minute quadrangle photogeologic maps on planimetric bases that show geology as interpreted from aerial photographs. Series also includes maps of Mars and the Moon.

Coal Investigations Maps are geologic maps on topographic or planimetric bases at various scales showing bedrock or surficial geology, stratigraphy, and structural relations in certain coal-resource areas.

Oil and Gas Investigations Charts show stratigraphic information for certain oil and gas fields and other areas having petroleum potential.

Miscellaneous Field Studies Maps are multicolor or black-and-white maps on topographic or planimetric bases for quadrangle or irregular areas at various scales. Pre-1971 maps show bedrock geology in relation to specific mining or mineral-deposit problems; post-1971 maps are primarily black-and-white maps on various subjects such as environmental studies or wilderness mineral investigations.

Hydrologic Investigations Atlases are multicolored or black-and-white maps on topographic or planimetric bases presenting a wide range of geohydrologic data of both regular and irregular areas; principal scale is 1:24,000, and regional studies are at 1:250,000 scale or smaller.

Catalogs

Permanent catalogs, as well as some others, giving comprehensive listings of U.S. Geological Survey publications are available under the conditions indicated below from the U.S. Geological Survey, Information Services, Box 25286, Federal Center, Denver, CO 80225. (See latest Price and Availability List.)

"Publications of the Geological Survey, 1879–1961" may be purchased by mail and over the counter in paperback book form and as a set of microfiche.

"Publications of the Geological Survey, 1962–1970" may be purchased by mail and over the counter in paperback book form and as a set of microfiche.

"Publications of the U.S. Geological Survey, 1971–1981" may be purchased by mail and over the counter in paperback book form (two volumes, publications listing and index) and as a set of microfiche.

Supplements for 1982, 1983, 1984, 1985, 1986, and for subsequent years since the last permanent catalog may be purchased by mail and over the counter in paperback book form.

State catalogs, "List of U.S. Geological Survey Geologic and Water-Supply Reports and Maps For (State)," may be purchased by mail and over the counter in paperback booklet form only.

"Price and Availability List of U.S. Geological Survey Publications," issued annually, is available free of charge in paperback booklet form only.

Selected copies of a monthly catalog "New Publications of the U.S. Geological Survey" are available free of charge by mail or may be obtained over the counter in paperback booklet form only. Those wishing a free subscription to the monthly catalog "New Publications of the U.S. Geological Survey" should write to the U.S. Geological Survey, 582 National Center, Reston, VA 22092.

Note—Prices of Government publications listed in older catalogs, announcements, and publications may be incorrect. Therefore, the prices charged may differ from the prices in catalogs, announcements, and publications.

Ground Water Issue

Design Guidelines for Conventional Pump-and-Treat Systems

Robert M. Cohen[1], James W. Mercer[1], Robert M. Greenwald[1], and Milovan S. Beljin[2]

The RCRA/Superfund Ground-Water Forum is a group of scientists representing EPA's Regional Superfund Offices, committed to the identification and resolution of ground-water issues affecting the remediation of Superfund sites. Design of conventional ground-water extraction and injection (i.e., pump-and-treat) systems has been identified by the Forum as an issue of concern to decision makers. This issue paper focuses on design of conventional ground-water extraction and injection systems used in subsurface remediation.

For further information contact Steve Acree (405) 436-8609 or Randall Ross (405) 436-8611 at the Subsurface Remediation and Protection Division of the National Risk Management Research Laboratory, Ada, Oklahoma.

Introduction

Containment and cleanup of contaminated ground water are among the primary objectives of the CERCLA (Comprehensive Environmental Response, Compensation, and Liability Act; also known as Superfund) and RCRA (Resource Conservation and Recovery Act) remediation programs. Ground-water contamination problems are pervasive in both programs; over 85 percent of CERCLA National Priority List sites and a substantial portion of RCRA facilities have some degree of ground-water contamination (U.S. EPA, 1993a). A common approach to deal with contaminated ground water is to extract the contaminated water and treat it at the surface prior to discharge or reinjection as illustrated in Figure 1. This is referred to as conventional pump-and-treat (P&T) remediation.

Conventional pump-and-treat is an applicable component of many remedial systems. However, such a system will not be appropriate to achieve restoration in portions of many sites due to hydrogeologic and contaminant-related limitations such as those presented by significant accumulations of DNAPLs (denser-than-water nonaqueous phase liquids) trapped below the water table. Such limitations will directly impact the effectiveness of P&T at many sites and the selection of remedial actions. Detailed discussion of the contaminant transport and fate processes that limit the potential for subsurface restoration using P&T and their characterization is beyond the scope of this document.

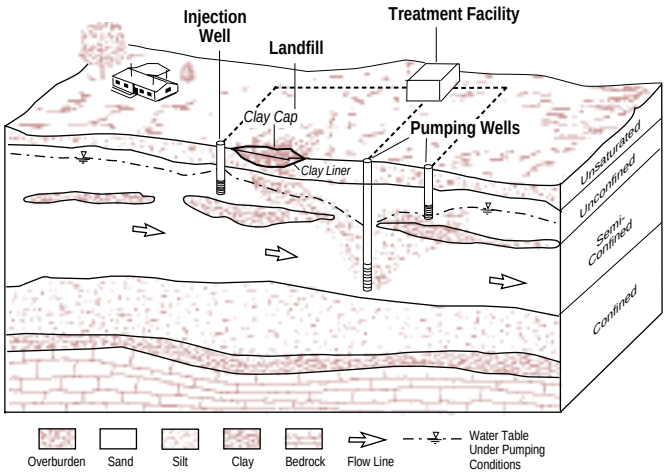

Figure 1. Example of a P&T system (after Mercer et al., 1990).

Inadequate design and implementation also may severely impact the performance of a P&T system. Examples of design inadequacies include too few recovery wells, insufficient pumping rates, deficient well locations or completion intervals, and failure to account for complex chemistry of contaminants. Similarly, poor system operation, exemplified by excessive downtime or failure to manipulate pumping schemes to limit ground-water stagnation, will restrict P&T effectiveness. This document provides guidance on designing conventional ground-water P&T systems. Chemical enhancements to P&T and immiscible contaminant recovery methods are addressed elsewhere (e.g., American Petroleum Institute, 1989, 1992; Palmer and Fish, 1992; U.S. EPA, 1992a, 1995; Grubb and Sitar, 1994; NRC, 1994).

P&T Remediation Strategies

In order to determine an appropriate strategy to manage contaminated ground water, it is necessary first to evaluate site conditions and define remediation goals. Historically, the goal of ground-water remediation has been to protect human health and the environment and to restore ground water to beneficial uses where practicable. For ground water that is or may be used for drinking, clean-up goals under CERCLA and RCRA generally are set at drinking water standards such as Maximum Contaminant Levels (MCLs) established under the Safe Drinking Water Act. Other clean-up requirements may be appropriate for ground water that is not used for drinking.

It has long been recognized that chemical transport from contaminant source/release areas, such as abandoned landfills and leaking tanks, contaminates ground water and other media in downgradient areas (e.g., OTA, 1984). As such, a common strategy for managing contaminated ground water has been to remove or contain contaminant sources (e.g., by excavation, construction of physical barriers, and/or pumping) and to address downgradient contamination using P&T technology.

Strategies for managing ground-water contamination (Figure 2) using P&T technology include: (1) hydraulic/physical containment, (2) ground-water quality restoration, and (3) mixed objective strategies. Several innovative technologies, such as air sparging, engineered bioremediation, and permeable treatment walls, can be used in conjunction with P&T, or alone, to address these ground-water remediation objectives. At some sites, natural attenuation processes may limit the need for P&T. The management strategy selected depends on site-specific hydrogeologic and contaminant conditions, and remediation goals.

Hydraulic Containment

P&T systems are frequently designed to hydraulically control the movement of contaminated ground water in order to prevent continued expansion of the contamination zone. At sites where the contaminant source cannot be removed (e.g., a landfill or bedrock with DNAPLs), hydraulic containment is an option to achieve source control. Hydraulic containment of dissolved contaminants by pumping ground water from wells or drains has been demonstrated at numerous sites. The concept is illustrated in Figure 3. Properly controlled fluid injection using wells, drains, or surface application (e.g., along the downgradient periphery of the proposed containment area) and physical containment options (e.g., subsurface barrier walls and surface covers to limit inflow) can enhance hydraulic containment

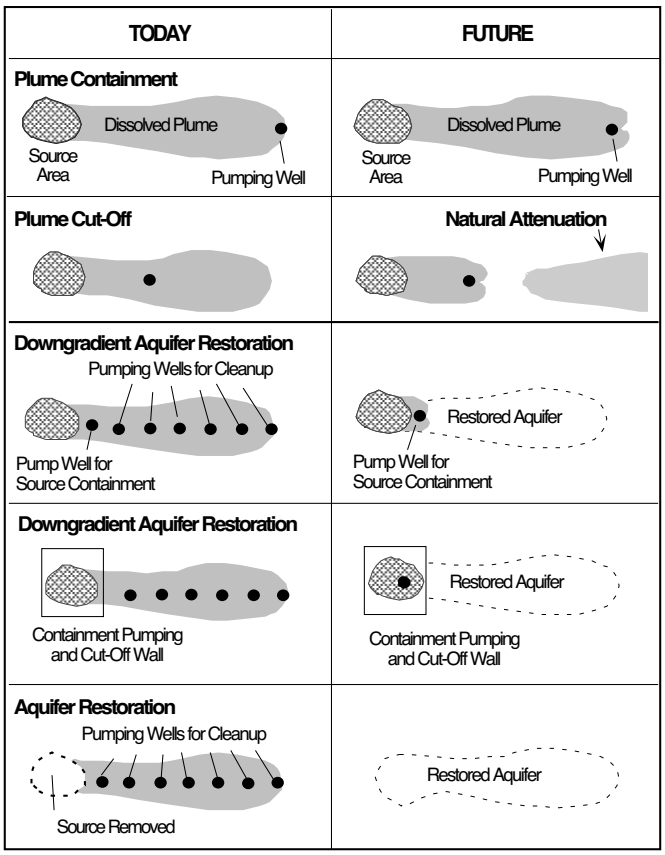

Figure 2. Several ground-water contamination management strategies using P&T technology (after NRC, 1994; Cherry et al., 1992).

systems by reducing the pumping rate required to maintain containment. In many cases, hydraulic containment systems are designed to provide long-term containment of contaminated ground water or source areas at the lowest cost by optimizing well, drain, surface cover, and/or cutoff wall locations and by minimizing pumping rates.

Cleanup/Restoration

For sites where the contaminant source has been removed or contained, it may be possible to clean up the dissolved plume. P&T technology designed for aquifer restoration generally combines hydraulic containment with more aggressive manipulation of ground water (i.e., higher pumping rates) to attain clean-up goals during a finite period. Ground-water cleanup is typically much more difficult to achieve than hydraulic containment. Hydrogeologic and contaminant conditions favorable to cleanup (e.g., degradable dissolved contaminants in uniform, permeable media) are summarized in Figure 4.

Mixed Objective Strategies

At many sites, P&T systems can be used to contain contaminant source areas and attempt restoration of downgradient dissolved plumes (Figure 2). A mixed P&T strategy is appropriate, therefore, at sites where different portions of the contaminated

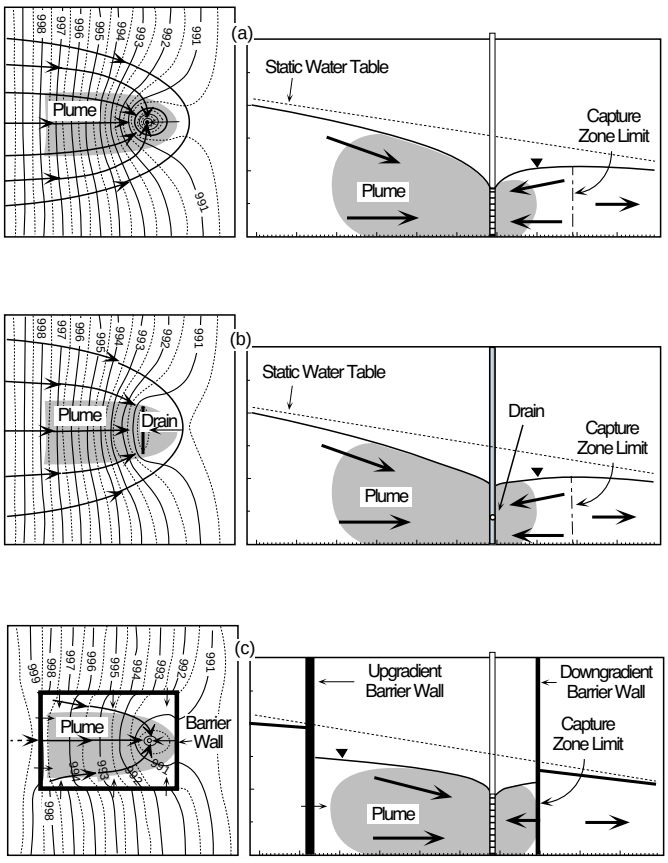

Figure 3. Examples of hydraulic containment in plan view and cross section using an extraction well (a), a drain (b), and a well within a barrier wall (c).

region are amenable to remediation using different methods. At sites contaminated with LNAPLs (lighter-than-water NAPLs), for example, a mixed remedial strategy may include: (1) vacuum-enhanced pumping to recover free product, affect hydraulic containment, and stimulate bioremediation in the LNAPL release area; and (2) restoring downgradient ground water via natural attenuation, P&T, and/or air sparging.

Characterizing Sites for P&T Design

The main goal of site characterization should be to obtain sufficient data to select and design a remedy (NRC, 1994). This is accomplished by investigating: (1) the nature, extent, and distribution of contaminants in source areas and downgradient plumes; (2) potential receptors and risks posed by contaminated ground water; and (3) hydrogeologic and contaminant properties that affect containment, restoration, and system design in different site areas. Categories of data used to formulate a site conceptual model for remedy evaluation are identified in Figure 5. The conceptual model is used to formulate remedial strategies such as restoration and/or containment.

Inadequate site characterization can lead to flawed P&T design and poor system performance. A complete understanding of a contamination site is unobtainable, however, due to subsurface complexities and investigation cost. Thus, characterization efforts must develop sufficient data to select and design an effective remedy while recognizing that significant uncertainties about subsurface conditions will persist.

Site characterization for remedial design is an extensive subject, key aspects of which are addressed briefly below. Additional information regarding procedures and strategies for investigating contamination sites is provided by U.S. EPA (1988a, 1991a, 1993b), Nielsen (1991), Cohen and Mercer (1993), Sara (1994), CCME (1994), and Boulding (1995).

Using a Phased and Integrated Approach

Due to slow contaminant transport and interphase transfer, many P&T systems will operate for decades to contain and clean up contaminated ground water. Data collected during investigation and remediation should be reviewed periodically to refine the site conceptual model and identify modifications that will improve P&T system performance. Thus, as depicted in Figure 6, a phased and integrated approach should be taken to site characterization and remediation. For example, given significant uncertainty regarding well locations and pumping rates needed to achieve remedial objectives, it may be prudent to initiate pumping at several locations and then determine system expansion requirements based on performance monitoring data. This phased approach to system installation may be more cost effective than grossly overdesigning the system to account for uncertainty in subsurface characterization at many sites.

During the initial phase of site investigation, prior studies and background information are reviewed to identify likely

CONTAMINANT AND HYDROGEOLOGIC CHARACTERISTICS	GENERALIZED RESTORATION DIFFICULTY SCALE — Increasing Difficulty →
SITE USE	
Nature of Release	Small volume, Short duration, Slug release → Large volume, Long duration, Continual
CONTAMINANT PROPERTIES	
Biotic/Abiotic Decay Potential	High → Low
Volatility	High → Low
Contaminant Sorption Potential	Low → High
CONTAMINANT DISTRIBUTION	
Contaminant Phase	Aqueous, Gaseous → LNAPL → DNAPL
Volume of Contaminated Media	Small → Large
Contaminant Depth	Shallow → Deep
GEOLOGIC CONDITIONS	
Stratigraphy	Simple → Complex
Unconsolidated Media Texture	Coarse-grained → Fine-grained
Degree of Heterogeneity	Low → High
GROUNDWATER FLOW PARAMETERS	
Hydraulic Conductivity	High (> 0.01 cm/s) → Low (< 0.0001 cm/s)
Temporal Variation	Little → High
Vertical Flow	Little → High downward

Figure 4. Generalized ground-water restoration difficulty scale (modified from U.S. EPA, 1993a).

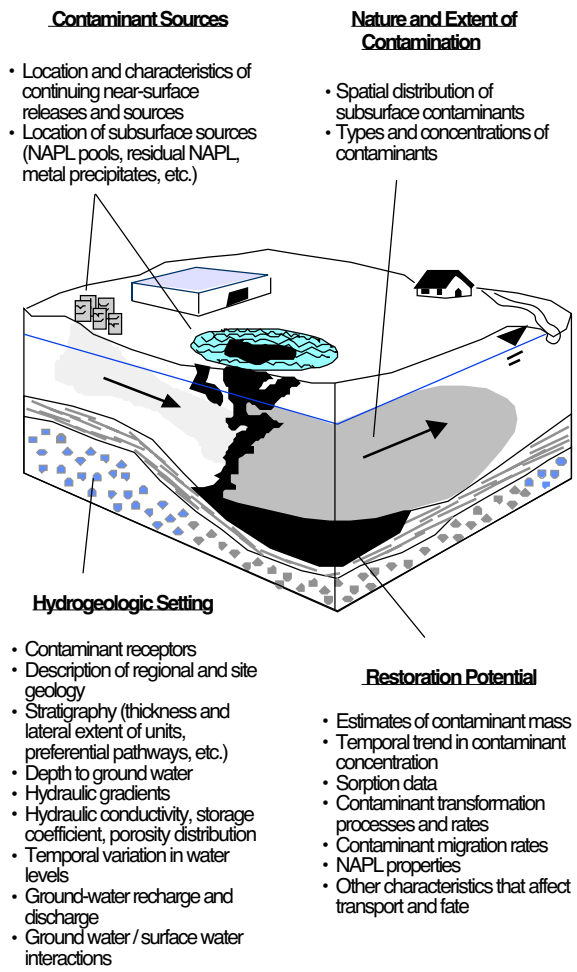

Figure 5. Types of data used to develop a site conceptual model for remedy assessment (modified from U.S. EPA, 1993a).

contaminant sources, transport pathways, and receptors. Based on this initial conceptualization, a data collection program is devised to better define the nature and extent of contamination and provide information (i.e., hydraulic conductivity distribution, aquifer boundary conditions, and initial hydraulic gradients) for remedy design. Contaminant source and downgradient dissolved plume areas should be delineated early during the characterization process to clarify site management strategies. P&T systems can often be designed to contain source and downgradient plume areas based on data acquired during the early and intermediate phases of investigation. Additional studies, including monitoring of actual P&T performance, are usually required, however, to assess the potential to restore ground-water quality in different site areas.

Mathematical models representing aspects of the site conceptual model should be used to evaluate alternative extraction/injection schemes, perform sensitivity analysis, and identify additional data needs. Integrating P&T operation and monitoring data can lead to model refinements and design enhancements.

P&T performance is typically assessed by measuring hydraulic heads and gradients, ground-water flow directions and rates, pumping rates, pumped water and treatment system effluent quality, and contaminant distributions in ground water and porous media. Guidance on methods for monitoring P&T performance is provided by Cohen et al. (1994). Careful examination of system performance, considering transient effects, is commonly warranted during the first months after start-up, and after subsequent major changes to P&T operation. Remediation, therefore, should be considered part of site characterization, yielding data that may lead to improved P&T system design and operation.

In recognition of inherent uncertainty and the potential for phased remediation, a reasonable degree of flexibility should be incorporated in P&T design to accommodate modifications. This may involve overdesign of certain system components (e.g., pipe or electric wire size), use of modular equipment (e.g., package treatment units), and strategic placement of junction boxes. Overdesign may allow system modifications such as

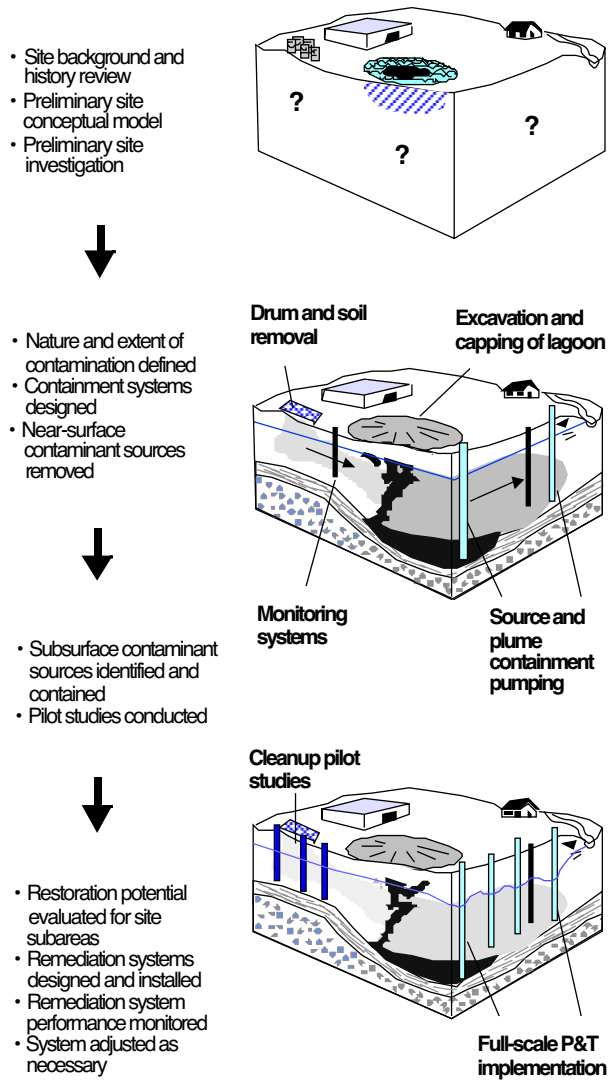

Figure 6. Iterative phases of site characterization and remediation (modified from U.S. EPA, 1993a; NRC, 1994).

incorporation of additional extraction wells or higher flow rates at relatively minimal expense. The degree of overdesign required as a contingency for uncertainties in subsurface conditions will be site specific and largely dependent on the level of site characterization performed prior to design. Estimates of potential ranges of required flowrates may be obtained at many sites during design-stage ground-water flow modeling.

Contaminant Characterization

Contaminant characterization is a key element of remedial evaluations. The nature, distribution, and extent of contamination will influence the selection of remedial actions and specific system designs. Contaminant characterization data needed to select and design a P&T system are listed in Figure 5. Important goals include: (1) delineating contaminant source areas and release characteristics; (2) defining the nature and extent (horizontal and vertical) of contamination; (3) characterizing contaminant transport pathways, processes, and rates; (4) estimating risks associated with contaminant transport; and (5) assessing aquifer restoration potential (see below). Contaminant characterization efforts generally involve document review, indirect and direct field characterization methods (e.g., soil, soil gas analysis and ground-water sampling), and data analysis.

Assessing Potential Limitations to P&T

Monitoring contaminant concentrations in ground water with time at P&T sites often reveals "tailing" and "rebound" phenomena. "Tailing" refers to the progressively slower rate of dissolved contaminant concentration decline observed with continued operation of a P&T system (Figures 7 and 8). The tailing contaminant concentration may exceed clean-up standards. Another problem is that dissolved contaminant concentrations may "rebound" if pumping is discontinued after temporarily attaining a clean-up standard (Figure 7).

If aquifer restoration is a potential remediation goal, then site characterization should investigate the physical and chemical phenomena that cause tailing and rebound. At many sites, most of the contaminant mass is not dissolved in ground water, but is present as NAPL, adsorbed species, and solids. Slow mass transfer of contaminants from these phases to ground water during P&T will cause tailing and prolong the clean-up effort. Physical causes of tailing include ground-water velocity and flowpath variations, and the slow diffusion of contaminants from low permeability zones during P&T operation. These phenomena are briefly discussed in Appendix A.

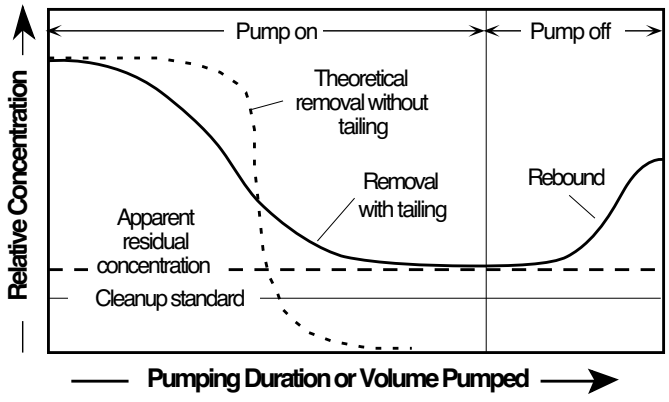

Figure 7. Concentration versus pumping duration or volume showing tailing and rebound effects (modified from Keely, 1989).

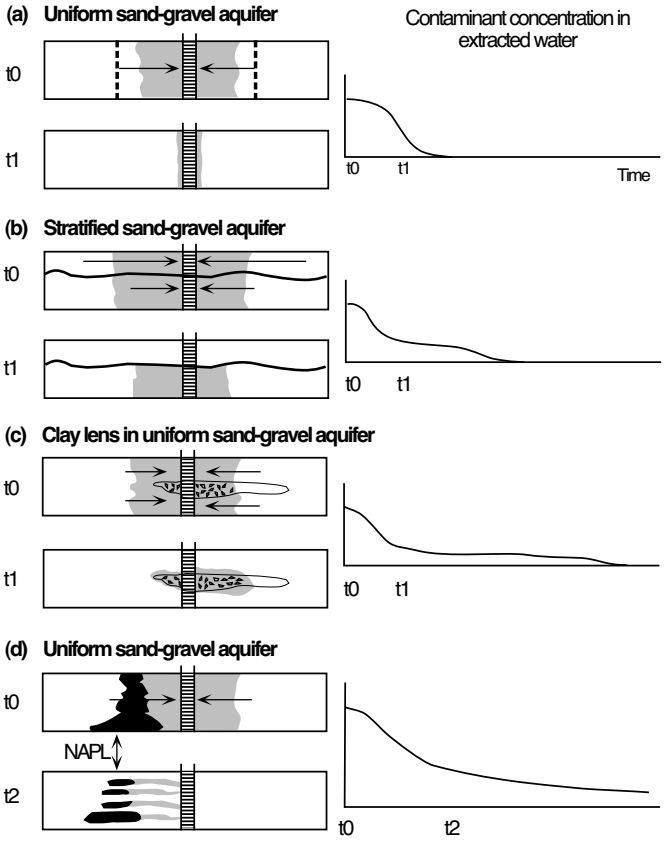

Figure 8. Hypothetical examples of contaminant removal using P&T (modified from Mackay and Cherry, 1989). Black indicates NAPL; stippling indicates contaminant in dissolved and sorbed phases (with uniform initial distribution); and arrows indicate relative ground-water velocity. Ground water is pumped from the well at the same rate for each case. The dotted lines in (a) represent the volume of water that would have to be pumped to flush slightly retarded contaminants from the uniform aquifer.

Tailing and rebound patterns associated with different physical and chemical processes are similar. Multiple processes (i.e., dissolution, diffusion, and desorption) will typically be active at a P&T site. Diagnosis of the cause of tailing and rebound, therefore, requires careful consideration of site conditions and usually cannot be made by examining concentration-versus-time data alone. Quantitative development of the conceptual model using analytical or numerical methods may help estimate the relative significance of different processes that cause tailing and rebound. Knowledge of the potential limitations at each site may allow more detailed analyses of the potential effectiveness of different P&T remediation strategies and different system configurations.

Hydrogeologic Characterization

Components of hydrogeologic investigation needed for P&T design are listed in Figure 5. Care must be taken to avoid exacerbating the contamination problem as a result of field work (e.g., inducing unwanted migration via drilling or pumping), or performing investigations not needed for risk or remedy assessment. Characterizing ground-water flow and contaminant transport is particularly challenging in heterogeneous media, especially where contaminants have migrated into fractured rock. Methods for characterizing fractured rock settings include drilling/coring, aquifer tests, packer tests, tracer tests, surface and borehole geophysical surveys, borehole flowmeter surveys, and air photograph fracture trace analysis (Sara, 1994). At the scale of many contaminated sites, complete characterization of fractured rock (and other heterogeneous media) may be economically infeasible (Schmelling and Ross, 1989), and not needed to design an effective P&T system (NRC, 1994). The appropriate characterization methods and level-of-effort must be determined on a site-specific basis.

Long-term aquifer tests and phased-system installations are often cost-effective means for acquiring field-scale hydrogeologic and remedial design data. Aquifer tests should be conducted to acquire field-scale measurements of hydrogeologic properties, such as formation transmissivity and storage coefficient, that are critical to extraction system design. Test results are used to: (1) determine well pumping rates and drawdowns; (2) assess well locations and pumping rates needed for full-scale operation; (3) evaluate the design of well and treatment system components; and (4) estimate capital and O&M costs. Recommended procedures for conducting aquifer tests are described by Osborne (1993) and others.

The number and duration of tests required to obtain sufficient data to design a P&T system depends on many factors, including plume size, the distribution of hydrogeologic units, their hydraulic properties, and hydrogeologic boundary conditions. In general, multiple tests are warranted at large and heterogeneous sites. Test design parameters (including specification of observation well locations, test duration, and pumping rate) can be assessed using well hydraulics solutions, ground-water flow models, and/or by conducting short-term step tests.

Observation wells should be located close enough to the pumping well to ensure adequate responses to pumping stress. Drawdowns will depend on site-specific hydrologic conditions that influence ground-water elevations during the test. Wells should also be located so that data may be used to evaluate heterogeneity and anisotropy, if warranted.

Although reasonable estimates of formation transmissivity can generally be obtained using data acquired during the first several hours of pumping (if observation wells are close to the pumping well), it may be advisable to extend aquifer tests to days or weeks to evaluate capture zones, boundary conditions, and ground-water treatability issues. Slug tests can also be used to augment aquifer test results. However, short-term aquifer and slug tests generally are not as reliable indicators of system performance as long-term aquifer tests.

Disposal options for aquifer test water are subject to site conditions and regulations but may include: discharge to a storm or sanitary sewer, discharge to the ground, discharge to surface water, reinjection to the subsurface, and transport to an off-site disposal facility. Regulatory agencies should be contacted to determine disposal requirements.

Ground-Water Treatability Studies

Treatability data needed for design of ground-water treatment systems generally should be acquired by conducting chemical analyses and treatability studies on contaminated ground water extracted during aquifer tests. Analysis of water samples obtained at different times during an aquifer test often will provide data regarding the initial range of contaminant concentrations in influent water to the treatment plant. Bench- and pilot-scale treatability studies are valuable means for determining the feasibility of candidate processes for treating contaminated ground water (U.S. EPA, 1989, 1994a). Laboratory bench-scale tests use small quantities of extracted ground water to provide preliminary data on various treatment processes, pretreatment requirements, and potential costs. During pilot-scale tests, skid-mounted or mobile pilot equipment is operated to study the effect of varying system parameters (e.g., flow rate) on treatment results and to identify potential problems, such as chemical precipitation of dissolved iron (Fe) and manganese (Mn) in an air stripper.

Air stripping and granular activated carbon (GAC) units may be used to remove organic compounds from ground water during aquifer tests; ion exchange/adsorption can be used to remove most metals (U.S. EPA, 1996). Air stripping is generally more cost-effective than GAC for treating volatile organic compounds when flow rates exceed 3 gpm (Long, 1993), but may require additional vapor phase treatment.

Potential for Fluid Injection

Artificial fluid injection/recharge is used to enhance hydraulic control and flushing of contamination zones. Treatment plant effluent or public supply water can be injected above or below the water table via wells, trenches, drains, or surface application (sprinkler, furrow, or basin infiltration). The applied water can be amended to stimulate bioremediation or to minimize well and formation clogging problems. Recharge is typically controlled by maintaining the water level in injection wells or drains or by pumping at specified rates. Regulatory agencies should be contacted to determine injection permit requirements. Potential problems with the use of injection include undesired horizontal or vertical contaminant migration due to the increased hydraulic gradients. Sites where injection is to be used should be carefully characterized and monitored to ensure that environmental problems are not exacerbated.

Aspects of site characterization critical to fluid injection design include determination of: (1) site stratigraphy and permeability distribution, (2) hydrogeologic boundary conditions, (3) possible injection rates and resulting hydraulic head and ground-water flow patterns, and (4) the potential for well and formation clogging due to injection.

Hydraulic parameters estimated from analysis of standard aquifer tests are often used to design injection systems. Constant-head, constant-rate, and stepped rate or head injection tests can also be conducted to evaluate hydraulic properties and injection potential using standard aquifer test procedures (Driscoll, 1986; Kruseman and deRidder, 1990). More discrete

techniques (e.g., packer tests, borehole flowmeter surveys) may be desirable to identify high permeability zones. Hydraulic heads and ground-water flow patterns resulting from injection can be examined and predicted using well or drain hydraulics equations and ground-water flow models. Such analysis can also be used to determine potential injection rates, durations, and monitoring locations for injection tests. In addition to helping estimate formation hydraulic properties, injection tests provide information on water compatibility and clogging issues that are critical to injection design.

The most common problem associated with fluid injection is permeability reduction due to clogging of screen openings. This causes a decline in injection rates. Clogging results from physical filtration of solids suspended in injected water, chemical precipitation of dissolved solids, and the excessive growth of microorganisms (also known as biofouling). Less frequently, well or formation damage results from air entrainment, clay swelling, and clay dispersion due to injection. In general, the injection capacity of a system is often overdesigned by a significant factor (e.g., 1.5 to 2) to account for loss of capacity under operating conditions due to such problems as permeability reduction and the temporary loss of capacity during well maintenance. The optimal degree of overdesign is site specific and will depend on such factors as the rate at which clogging occurs and the cost of maintenance.

The potential for well clogging and mitigative measures can be examined by analysis of the injected fluid and bench scale testing. In general, injection water should contain: (1) no suspended solids to minimize clogging; (2) little or no dissolved oxygen, nutrients, and microbes to minimize biofouling; and (3) low concentrations of constituents that are sensitive to changes in pH, redox, pressure, and temperature conditions (e.g., Fe and Mn) to minimize precipitation. Column permeameter tests can be conducted to examine changes in hydraulic conductivity resulting from injection. Due to the potential significance of many hydrogeologic, physical, and chemical factors, however, fluid injection is best evaluated by conducting extended injection tests during which injection rates and hydraulic heads are monitored carefully. Results of field tests help define formation hydraulic properties, potential injection rates, injection well spacings, mounding response, and clogging potential.

Dissolved or suspended solids may need to be removed from water by aeration, flocculation, and filtration prior to injection. Similarly, nutrients and/or dissolved oxygen may need to be removed to prevent biofouling. Water should be injected below the water table through a pipe to prevent its aeration in the well. Injecting warm water can also promote biofouling. Clogging problems can be minimized by overdesigning injection capacity (e.g., by installing more wells, longer screens, etc.) and implementing a regular well maintenance program.

Extraction and injection rate monitoring and well inspection, using a downhole video camera or other means, can help identify wells in need of treatment or replacement. Periodic rehabilitation of wells or drains (by surging, jetting, chlorination, or acid treatment) may be required to restore declining injection rates (Driscoll, 1986). Chemical incrustation can be addressed by acid treatment, backwashing, mechanical agitation (with a wire brush or surge block), and pumping. Strong oxidizing agents, such as a chlorine solution, can be used in conjunction with backwashing, mechanical agitation, and pumping to treat wells damaged by slime-producing bacteria. Acidification and chlorination, however, may interfere with interpretation of ground-water chemistry data. Fine particles can be removed (to some extent) using standard well development techniques. Experienced well drillers should be contacted for advice on rehabilitation methods. These potential problems need to be considered when projecting P&T costs. Significant maintenance may be required at many sites to retain desired injection capacity. More detailed discussions of the engineering aspects of water injection are provided by Pyne (1995).

Data Presentation

Complete discussion of methods for characterization and remedial design analyses and supporting data is beyond the scope of this document. In general, such information should be presented graphically and accompanied by supporting calculations and analyses. Tools for electronic storage, manipulation, analysis, and display of data and designs are generally available and often provide a convenient format for storage and access of this information (e.g., database, CAD, and/or GIS programs). Characterization data such as three-dimensional contaminant distribution are best presented on site maps and in representative cross sections. Hydraulic properties and hydraulic head data may also be presented in similar fashion. Pertinent features such as well locations (i.e., monitoring, production, injection), surface water bodies, potential source areas, and relevant structures should be included, as appropriate. Supporting data should be provided in tabular or spreadsheet form and accompany the maps and cross sections.

Capture Zone Analysis for P&T Design

P&T design is refined by performing field tests, modeling alternative injection/extraction schemes, and monitoring system performance. The first step in establishing design criteria, after characterizing pre-remedy ground-water flow patterns and contaminant distributions, is to determine the desired containment and/or restoration area (two-dimensional) and volume (three-dimensional). These should be clearly specified in the remedial design and monitoring plans. After defining the proposed containment area, a capture zone analysis is conducted to design the P&T system and a performance monitoring plan is developed based on the predicted flow field.

The capture zone of an extraction well or drain refers to that portion of the subsurface containing ground water that will ultimately discharge to the well or drain (Figures 3 and 9). It should be noticed that the capture zone of a well is not coincident with its drawdown zone of influence (ZOI) (Figure 9). The extent of the ZOI depends largely on transmissivity and pumping rate under steady-state conditions. However, the shape of the capture zone depends on the natural hydraulic gradient as well as pumping rate and transmissivity. Relatively high natural hydraulic gradients result in narrow capture zones that do not extend far in the downgradient direction. Therefore, some sidegradient and downgradient areas within the ZOI of a recovery well will be beyond its capture zone, and “rules-of-thumb” regarding overlapping drawdown zones should not be used to determine well spacings or pumping rates for P&T design.

In recent years, many mathematical models have been developed or applied to compute capture zones, ground-water pathlines, flushing rates, and associated travel times to extraction

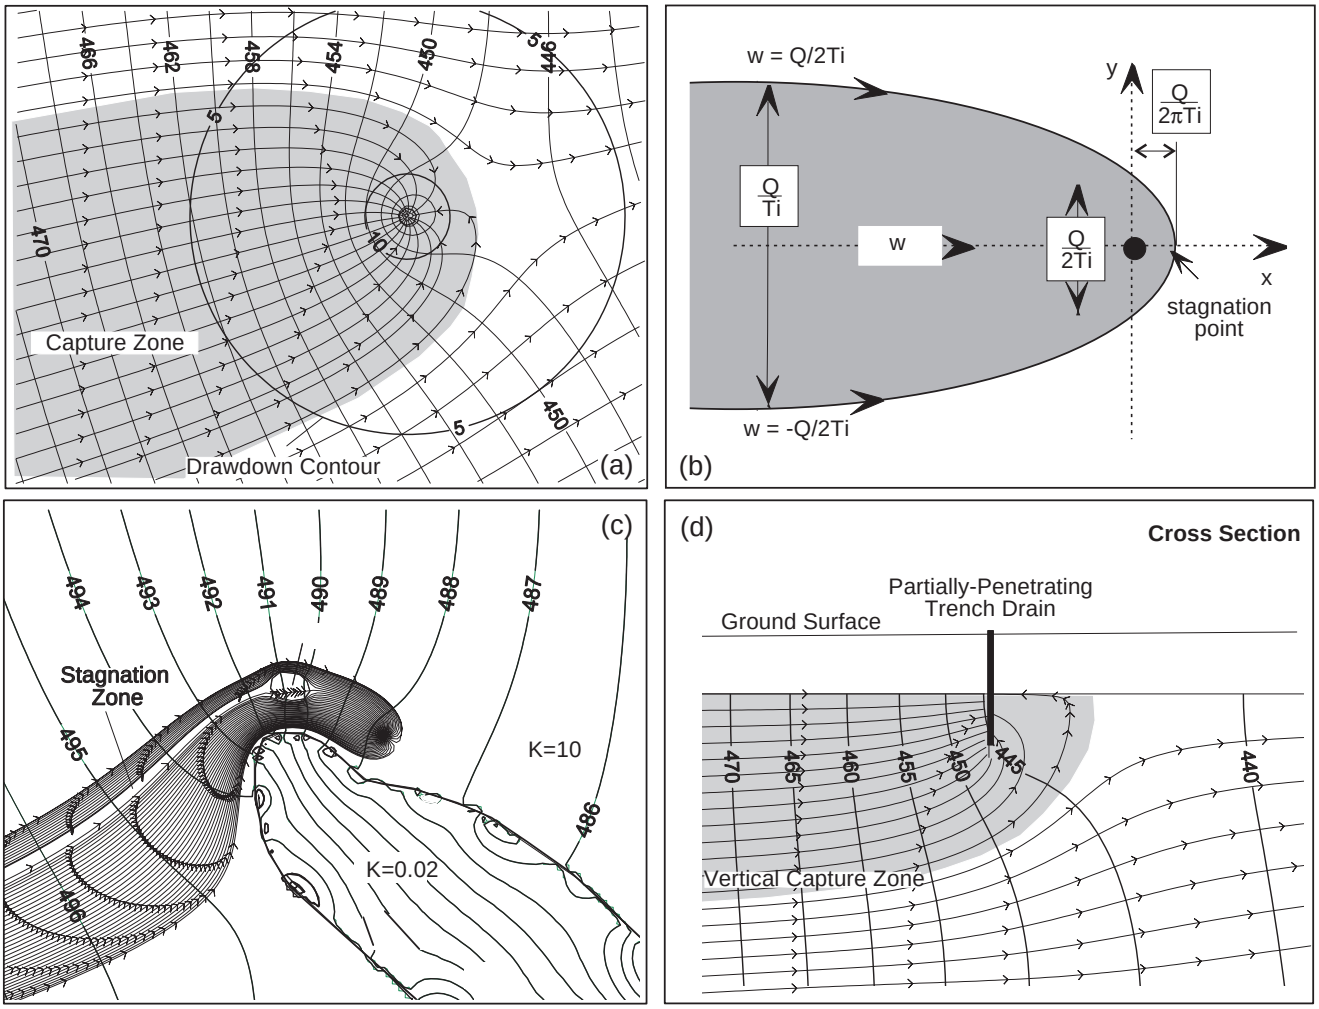

Figure 9. ***(a) Illustration of drawdown contours (i.e., zone of influence) and the capture zone of a single pumping well in a uniform medium. Equations for the dividing streamlines (w = Q/2Ti) that separate the capture zone of a single well from the rest of an isotropic, confined aquifer with a uniform regional hydraulic gradient are given in (b) where T = transmissivity, Q = pumping rate, and i = initial uniform hydraulic gradient. Simplified capture zone analysis methods may provide misleading results when applied to more complex problems, such as those dealing with heterogeneous media, as depicted in (c) where K = relative hydraulic conductivity, and three-dimensional flow (d).***

wells or drains (Javandel et al., 1984; Javandel and Tsang, 1986; Shafer, 1987a,b; Newsom and Wilson, 1988; Fitts, 1989,1994; Strack, 1989; Bonn and Rounds, 1990; Bair et al., 1991; Rumbaugh, 1991; Bair and Roadcap, 1992; Blandford et al., 1993; Gorelick et al., 1993; Pollock, 1994; Strack et al., 1994). These models provide insight into flow patterns generated by alternative P&T schemes and the selection of monitoring locations and frequency. Additionally, linear programming methods are being used to optimize P&T design (Ahlfeld and Sawyer, 1990; Gorelick et al., 1993; Hagemeyer et al., 1993) by specifying an objective function subject to various constraints (e.g., minimize pumping rates but maintain inward hydraulic gradients).

Model selection for P&T design analysis depends on the complexity of the site, available data, and the familiarity of the analyst with different codes. In general, the simplest tool applicable to site conditions and the desired degree of uncertainty should be used in design. However, conditions at many sites will be sufficiently complex that screening level characterizations and design tools will result in significant uncertainty. Regardless of the design tools which are used, capture zone analysis should also be conducted, and well locations and pumping rates optimized, by monitoring hydraulic heads and flow rates during aquifer tests and system operation. Conceptual model refinements gained by monitoring lead to enhanced P&T design and operation. In some cases, these refinements are incorporated in a mathematical model that is used to reevaluate and improve system design.

Capture Zone Analysis Tools

Many types of tools are available for capture zone analysis and system design (Table 1). Graphical methods are useful screening level design tools in many situations. Based on this approach, the simple graphical method shown in Figure 9 can be used to locate the stagnation point and dividing streamlines, and then

Table 1. P&T Design Tools (modified from van der Heijde and Elnawawy, 1993)

Method	*Example*	*Description*
Aquifer Tests and Pilot Testing		Controlled and monitored pilot tests are conducted to assist P&T design. Suggested operating procedures for aquifer tests and analytical methods are described by Osborne (1993) and many others. Test results should be used to improve P&T design modeling, where applicable.
Graphical - Capture Zone Type Curves	(Javandel and Tsang, 1986)	A simple graphical method can be used to determine minimum pumping rates and well spacings needed to maintain capture using 1, 2, or 3 pumping wells along a line perpendicular to the regional direction of ground-water flow in a confined aquifer.
Semi-analytical Ground-Water Flow and Pathline Models	WHPA (Blandford et al., 1993) WHAEM (Strack et al., 1994; Haitjema et al., 1994)	These models superposition analytic functions to simulate simple or complex aquifer conditions including wells, line sources, line sinks, recharge, and regional flow (Strack, 1989). Advantages include flexibility, ease of use, speed, accuracy, and no model grid. Generally limited to analysis of 2-D flow problems.
Numerical Models of Ground-Water Flow	MODFLOW (McDonald and Harbaugh, 1988)	Finite-difference (FD) and finite element (FE) ground-water flow models have been developed to simulate 2-D areal or cross-sectional and quasi- or fully- 3-D, steady or transient flow in anisotropic, heterogeneous, layered aquifer systems. These models can handle a variety of complex conditions allowing analysis of simple and complex ground-water flow problems, including P&T design analysis. Various pre- and post-processors are available. In general, more complex and detailed site characterization data are required for simulation of complex problems.
Pathline and Particle Tracking Post-Processors	MODPATH (Pollock, 1994) GPTRAC (Blandford et al., 1993)	These programs use particle tracking to calculate pathlines, capture zones, and travel times based on ground-water flow model output. Programs vary in assumptions and complexity of site conditions that may be simulated (e.g., 2-D or 3-D flow, heterogeneity, anisotropy).
Numerical Models of Ground-water Flow and Contaminant Transport	MT3D (Zheng, 1992) MOC (Konikow and Bredehoeft, 1989)	These models can be used to evaluate aquifer restoration issues such as changes in contaminant mass distribution with time due to P&T operation.
Optimization Models	MODMAN (Greenwald, 1993)	Optimization programs designed to link with ground-water flow models yield answers to questions such as: (1) where should pumping and injection wells be located, and (2) at what rate should water be extracted or injected at each well? The optimal solution maximizes or minimizes a user-defined objective function and satisfies all user-defined constraints. A typical objective may be to maximize the total pumping rate from all wells, while constraints might include upper and lower limits on heads, gradients, or pumping rates. A variety of objectives and constraints are available to the user, allowing many P&T issues to be considered.

Software is available from a variety of sources including the Center for Subsurface Modeling Support at the U.S. EPA's Robert S. Kerr Environmental Research Center in Ada, Oklahoma (405-436-8594).

sketch the capture zone of a single well in a uniform flow field. This analysis is extended by Javandel and Tsang (1986) to determine the minimum uniform pumping rates and well spacings needed to maintain a capture zone between two or three pumping wells along a line perpendicular to the regional direction of ground-water flow. Their capture zone design criteria and type curves can be used for capture zone analysis, but more efficient P&T systems can be designed with nonuniform pump well orientations, spacings, and extraction rates. The extent to which the results of these simple models represent actual conditions depends on the extent to which the assumptions vary from actual site conditions.

More complex tools are often necessary to optimize P&T design and reduce uncertainty. Several semianalytical models employ complex potential theory to calculate stream functions, potential functions, specific discharge distribution, and/or velocity distribution by superimposing the effects of multiple extraction/injection wells using the Thiem equation on an ambient uniform ground-water flow field in a two-dimensional, homogeneous, isotropic, confined, steady-state system (e.g., RESSQC, Blandford et al., 1993). Streamlines, flushing rates, and capture zones associated with irregular well spacings and variable pumping rates can be simulated by these models. Many of these models support reverse and forward particle tracking to trace capture zones and streamlines. For example, reverse particle tracking is implemented in RESSQC to derive steady-state capture zones by releasing particles from the stagnation point(s) of the system and tracking their advective pathlines in the reversed velocity field. Similarly, time-related captures zones (Figure 10) are obtained by tracing the reverse pathlines formed by particles released around each pumping well (Shafer, 1987a; Blandford et al., 1993).

Application of semianalytical models to field problems requires careful evaluation of their limiting assumptions (e.g., isotropic and homogeneous hydraulic conductivity, fully-penetrating wells, no recharge, no vertical flow component, and constant transmissivity). Several analytical models relax these restrictive assumptions by superposition of various functions to treat recharge, layering, heterogeneity, three-dimensional flow, etc. Examples of two-dimensional time-related capture zones determined using TWODAN (Fitts, 1994; 1995) are shown in Figure 10. Given their ease of use and inherent uncertainties regarding the ground-water flow field, the more robust semianalytical models are ideal tools for evaluating alternative injection/extraction well locations and pumping rates at many sites. Where field conditions do not conform sufficiently to model assumptions, the simulation results will be invalid.

Numerical models are generally used to simulate ground-water flow in complex three-dimensional hydrogeologic systems (e.g., MODFLOW, McDonald and Harbaugh, 1988; and SWIFT/486, Ward et al., 1993). For example, the benefits of using partially-penetrating recovery wells to minimize pumping rates and unnecessary vertical spreading of contaminants can be examined using a three-dimensional flow model. Numerical flow model output is processed using reverse or forward particle-tracking software such as MODPATH (Pollock, 1994), GWPATH (Shafer, 1987b), and PATH3D (Zheng, 1990) to assess pathlines and capture zones associated with P&T systems at sites that cannot be adequately modeled using simpler techniques. Solute transport models are primarily run to address aquifer restoration issues such as changes in contaminant mass distribution with time due to P&T operation.

Ground-water flow models can be coupled with linear programming optimization schemes to determine the most effective well placements and pumping rates for hydraulic containment. The optimal solution maximizes or minimizes a user-defined objective function subject to all user-defined constraints. In a P&T system, a typical objective function may be to minimize the pumping rate to reduce cost, while constraints may include specified inward gradients at key locations, and limits on drawdowns, pumping rates, and the number of pumping wells. Gorelick et al. (1993) present a review of the use of optimization techniques in combination with ground-water models for P&T system design. Available codes include AQMAN (Lefkoff and Gorelick, 1987), an optimization code that employs the Trescott et al. (1976) two-dimensional ground-water flow model, and MODMAN (Greenwald, 1993), which adds optimization capability to the three-dimensional USGS MODFLOW model (McDonald and Harbaugh, 1988). A case study of optimization code use to assist P&T design is given by Hagemeyer et al. (1993).

Techniques have been presented in the literature for combining nonlinear optimization methods with contaminant transport simulation models (Gorelick, 1983; Wagner and Gorelick, 1987; Ahlfeld et al., 1988). These techniques are intended to provide solutions to problems formulated in terms of predicted concentrations (e.g., minimize pumping such that TCE is below the required clean-up level within five years at target locations). However, such analysis requires the use of a solute transport model and solution of a relatively difficult nonlinear problem. As a result, computation effort is large and uncertainty in results is high compared to optimization based on ground-water flow. Nonlinear optimization methods using solute transport models have not yet been packaged into commercial software and have rarely been applied to ground-water contamination problems.

Extraction / Injection Scheme Design

For a successful hydraulic containment, contaminants moving with ground water in the desired containment zone must follow pathlines that are captured by the P&T system. An appropriate remedial objective might be to minimize the total cost required to maintain perpetual containment and satisfy regulatory requirements. Given this objective, installing low permeability barriers (Figure 3c) to reduce pumping rates might be cost-effective. At sites with an objective of contaminant mass removal (i.e., where the containment area size may be diminished or P&T discontinued if clean-up goals are met), a more complex cost-effectiveness trade-off exists between minimizing hydraulic containment costs and maximizing contaminant mass removal rates.

Unless natural attenuation mechanisms are being relied upon to limit plume migration, hydraulic containment is generally a prerequisite for aquifer restoration. Restoration P&T design will typically reflect a compromise among objectives that seek to: (1) reduce contaminant concentrations to clean-up standards, (2) maximize mass removal, (3) minimize clean-up time, and (4) minimize cost. Due to the limitations described in Appendix A, P&T for aquifer restoration requires a high degree of performance monitoring and management to identify problem areas and improve system design and operation.

Restoration P&T ground-water flow management involves optimizing well locations, depths, and injection/extraction rates to maintain an effective hydraulic sweep through the

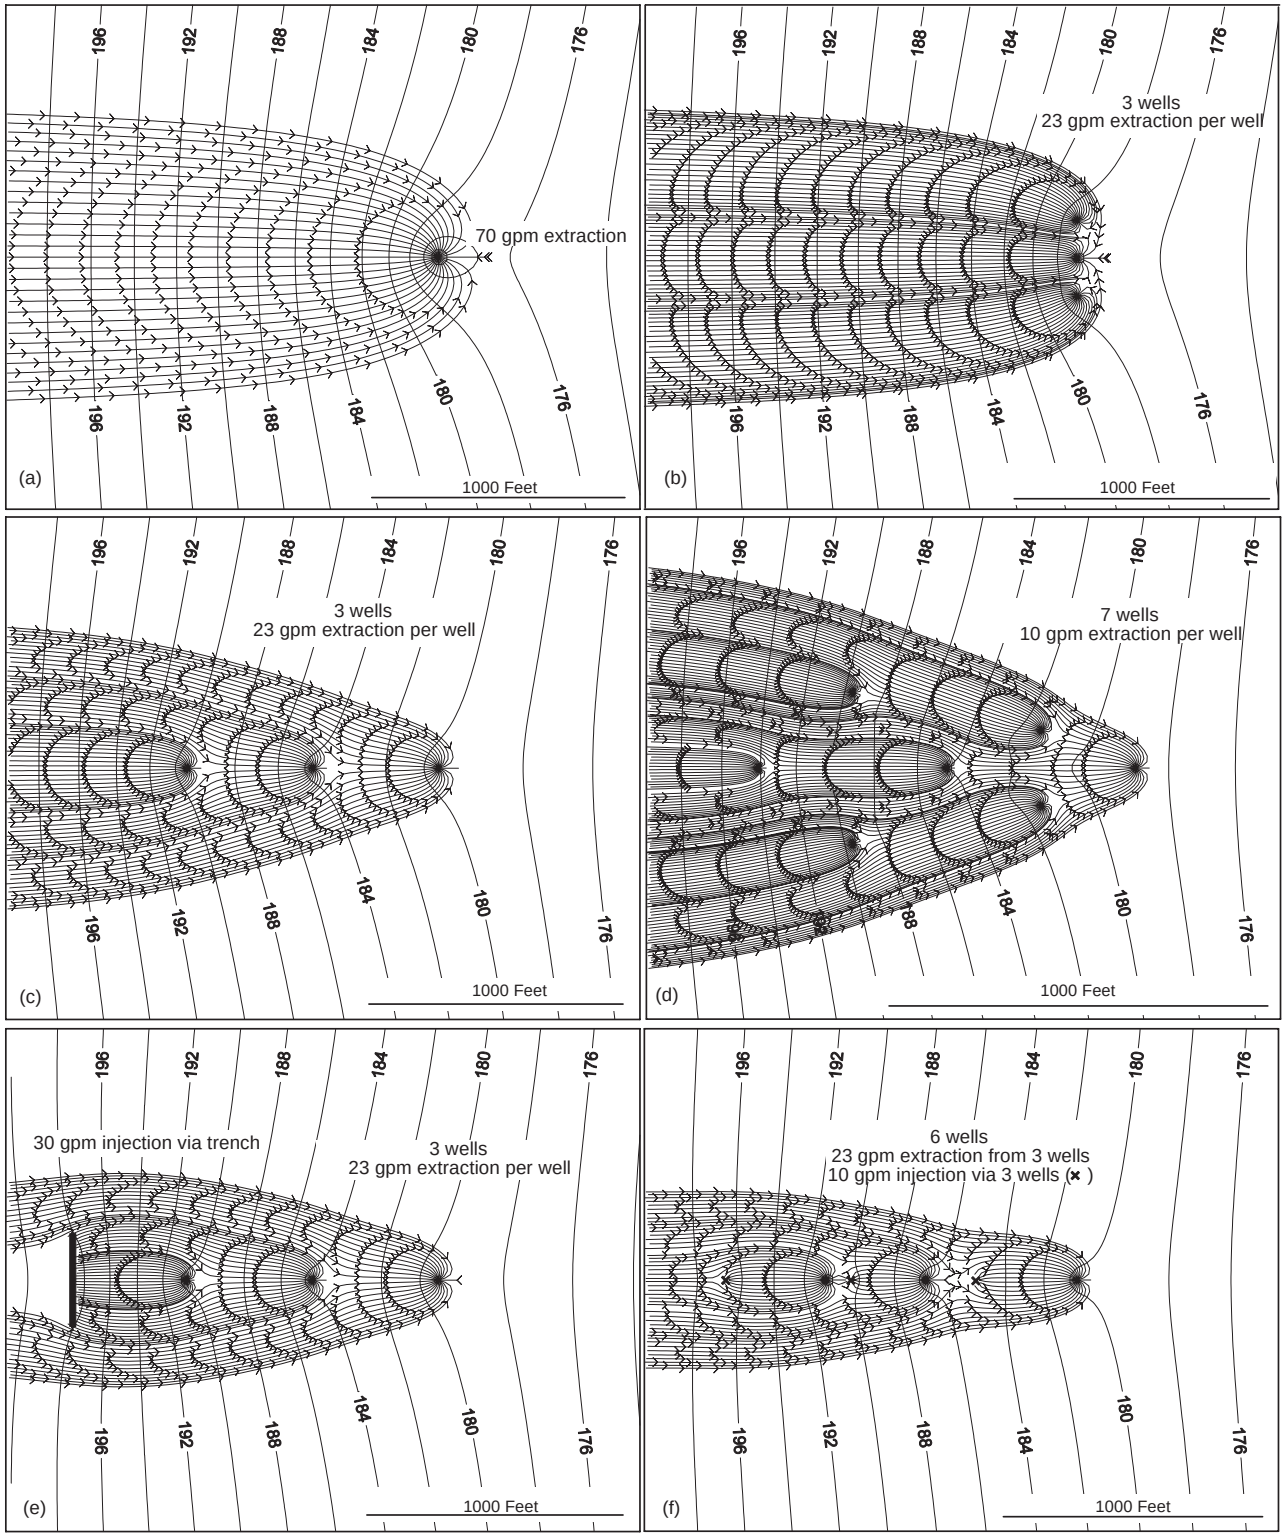

Figure 10. Hydraulic head contours and capture zones simulated using TWODAN (Fitts, 1995) for several extraction/injection schemes in an aquifer with a uniform transmissivity of 1000 ft²/d, and an initial hydraulic gradient of 0.01. Pathline time intervals of one year are marked by arrows. Note the stagnation zones that develop downgradient of extraction wells and upgradient of injection wells.

contamination zone, minimize stagnation zones, flush pore volumes through the system, and contain contaminated ground water. Wells are installed in lines and other patterns to achieve these objectives (Figure 10). Horizontal wells and drains are constructed to create ground-water line sinks and mounds, and thereby affect linear hydraulic sweeps.

Pore Volume Flushing

Restoration requires that sufficient ground water be flushed through the contaminated zone to remove both existing dissolved contaminants and those that will continue to desorb from porous media, dissolve from precipitates or NAPL, and/or diffuse from low permeability zones. The sum of these processes and dilution in the flow field yields persistent acceptable ground-water quality at compliance locations.

The volume of ground water within a contamination plume is known as the pore volume (PV), which is defined as

$$PV = \int_A bn \, dA \qquad (1)$$

where b is the plume thickness, n is the formation porosity, and A is the area of the plume. If the thickness and porosity are relatively uniform, then

$$PV = BnA \qquad (2)$$

where B is the average thickness of the plume.

Assuming linear, reversible, and instantaneous sorption, no NAPL or solid contaminants, and neglecting dispersion, the theoretical number of PVs required to remove a contaminant from a homogeneous aquifer is approximated by the retardation factor, R, which is the ground-water flow velocity relative to velocity of dissolved contaminant movement. An example of the relationship between the number of PVs and R, that also accounts for dispersion, is demonstrated by a numerical model used to evaluate a P&T design at the Chem-Dyne site in Ohio (Ward et al., 1987). Due to simulation of linear sorption, a nearly linear relationship was found to exist between retardation and the duration of pumping (or volume pumped) needed to reach the ground-water clean-up goal. Batch flush models (e.g., U.S. EPA, 1988b; Zheng et al., 1992) often assume linear sorption to calculate the number of PVs required to reach a clean-up concentration, C_{wt} in ground water as a function of the retardation factor, R, and the initial aqueous-phase contaminant concentration, C_{wo}:

$$\text{No. of PVs} = -R \ln (C_{wt} / C_{wo}) \qquad (3)$$

Though useful for simple systems, the representation of linear, reversible, and instantaneous sorption in contaminant transport models can lead to significant underestimation of P&T clean-up times. For example, the desorption of most inorganic contaminants (e.g., chromium and arsenic) is nonlinear. In addition, much of the pore space in aquifer materials may not be available for fluid flow. In such situations, flushing is not efficient and removal of a greater number of pore volumes of water will be required.

Kinetic limitations often may prevent sustenance of equilibrium contaminant concentrations in ground water (Bahr, 1989; Brogan, 1991; Haley et al., 1991; Palmer and Fish, 1992). Such effects occur in situations where contaminant mass transfer to flowing ground water is slow relative to ground-water velocity. For example, contaminant mass removal from low permeability materials may be limited by the rate of diffusion from these materials into more permeable flowpaths. In this situation, increasing ground-water velocity and pore volume flushing rates beyond a certain point would provide very little increase in contaminant removal rate. Kinetic limitations to mass transfer are likely to be relatively significant where ground-water velocities are high surrounding injection and extraction wells.

The number of PVs that must be extracted for restoration is a function of the clean-up standard, the initial contaminant distribution, and the chemical/media phenomena that affect cleanup. Screening-level estimates of the number of PVs required for cleanup can be made by modeling and by assessing the trend of contaminant concentration versus the number of PVs removed. At many sites, numerous PVs (i.e., 10 to 100s) will have to be flushed through the contamination zone to attain clean-up standards.

The number of PVs withdrawn per year is a useful measure of the aggressiveness of a P&T operation. Many current systems are designed to remove between 0.3 and 2 PVs annually. For example, less than 2 PVs per year were extracted at 22 of the 24 P&T systems studied by U.S. EPA (1992b) and reviewed by NRC (1994). Low permeability conditions or competing uses for ground water may restrict the ability to pump at higher rates. As noted above, kinetic limitations to mass transfer also may diminish the benefit of higher pumping rates. The potential significance of such limitations should be evaluated prior to installation of aggressive systems designed for relatively high flushing rates. If limiting factors are not present, pumping rates may be increased to hasten cleanup.

The time required to pump one pore volume of ground water from the contaminated zone is a fundamental parameter that should be calculated for P&T systems. NRC (1994), however, determined that the number of PVs withdrawn at P&T sites is rarely reported. Restoration assessments should include estimates of the number of PVs needed for cleanup. However, it must be noted that such analyses generally oversimplify highly complex site conditions. It may often be impracticable to characterize the site in sufficient detail to reduce uncertainty in estimates of restoration time frames to insignificant levels. Uncertainty in these estimates should be considered during remedial evaluations.

Poor P&T design may lead to low system effectiveness and contaminant concentration tailing. Poor design factors include low pumping rates and improper location of pumping wells and completion depths. A simple check on the total pumping rate is to calculate the number of PVs per year. Inadequate location or completion of wells or drains may lead to poor P&T performance even if the total pumping rate is appropriate. For example, wells placed at the containment area perimeter may withdraw a large volume of clean ground water from beyond the plume via flowlines that do not flush the contaminated zone. Similarly, pumping from the entire thickness of a formation in which the contamination is limited vertically will reduce the fraction of water that flushes the contaminated zone. In general, restoration pumping wells or drains should be placed in areas of relatively high contaminant concentration as well as locations suitable for achieving hydraulic containment.

Well placement can be evaluated by: (1) using ground-water flow and transport models; (2) comparing contaminant mass removed to contaminant mass dissolved in ground water; and (3) applying expert knowledge. P&T system modifications should be considered if any of these methods indicate that different pumping locations or rates will improve system effectiveness.

Minimize Ground-Water Stagnation

Ground-water flow patterns need to be managed to minimize stagnation during P&T operation. Stagnation zones develop in areas where the P&T operation produces low hydraulic gradients (e.g., downgradient of a pumping well and upgradient of an injection well) and in low permeability zones regardless of hydraulic gradient. Ground-water flow modeling can be used to assess ground water and solute velocity distributions, travel times, and stagnation zones associated with alternative pumping schemes. During operation, stagnation zones can be identified by measuring hydraulic gradients, tracer movement, ground-water flow rates (e.g., with certain types of downhole flowmeters or in situ probes), and by modeling analysis. Low permeability heterogeneities should be delineated as practicable during the site characterization and P&T operation. Stagnation zones associated with different pumping schemes are evident in Figure 10.

Once identified, the size, magnitude, and duration of stagnation zones can be diminished by changing pumping (extraction and/or injection) schedules, locations, and rates. Again, flow modeling based on field data may be used to estimate optimum pumping locations and rates to limit ground-water stagnation. An adaptive pumping scheme, whereby extraction/injection pumping is modified based on analysis of field data, should result in more expedient cleanup.

Guidance from Modeling Studies

Several modeling studies have been conducted to examine the effectiveness of alternative extraction and injection well schemes with regard to hydraulic containment and ground-water clean-up objectives (e.g., Freeberg et al., 1987; Satkin and Bedient, 1988; Ahlfeld and Sawyer, 1990; Tiedeman and Gorelick, 1993; Marquis, Jr. and Dineen, 1994; Haggerty and Gorelick, 1994). Although the optimum extraction/injection scheme depends on site-specific conditions, objectives, and constraints, consideration should be given to guidance derived from simulation studies of P&T performance.

A conceptual modeling analysis using FTWORK (Faust et al., 1993) of three alternative pumping strategies for an idealized site with a uniform medium, linear equilibrium sorption, a single non-degrading contaminant, and a continuing release is presented in Figure 11. The plume management strategies include: (1) downgradient pumping, (2) source control with downgradient pumping, and (3) source control with mid-plume and downgradient pumping. As shown, downgradient pumping by itself allows and increases the movement of highly contaminated ground water throughout the flowpath between the release area and the downgradient recovery well. This alternative results in expansion of the highly contaminated plume and makes it more difficult to achieve cleanup. The importance of source control is clearly demonstrated by comparing the management alternatives. Source control pumping prevents continued offsite migration and thereby facilitates downgradient cleanup of contaminated ground water. The combined source control, mid-plume, and downgradient pumping alternative reduces the flowpath and travel time of contaminants to extraction wells and diminishes the impact of processes which cause tailing. As such, with more aggressive P&T, cleanup is achieved more quickly and the volume of ground water that must be pumped for cleanup is less than for the other alternatives.

The effectiveness of seven injection/extraction well schemes shown in Figure 12 at removing a contaminant plume was evaluated by Satkin and Bedient (1988) using the MOC transport model (Konikow and Bredehoeft, 1989). The performance of each scheme was assessed for eight different hydrogeologic conditions, which were simulated by varying maximum drawdown, dispersivity, and regional hydraulic gradient. Effectiveness was judged based on simulated cleanup, flushing rate, and the volume of water requiring treatment. Findings of this study include (Satkin and Bedient, 1988): (1) multiple extraction wells located along the plume axis (the center line scheme) reduce clean-up time by shortening contaminant travel paths and allowing higher pumping rates; (2) the three-spot, double-cell, and doublet schemes were effective under low hydraulic gradient conditions, but require onsite treatment and reinjection; (3) the three-spot pattern outperformed the other schemes for simulations incorporating a high regional hydraulic gradient; and, (4) the center line pattern was effective under all simulated conditions. Andersen et al. (1984) and Satkin and Bedient (1988) showed that the five-spot pattern (Figure 12) may be a relatively inefficient scheme for cleanup.

Brogan (1991) and Gailey and Gorelick (1993) used simulations to demonstrate that the best single recovery well location is somewhat downgradient of a plume's center of mass. The optimum location (requiring the lowest pumping rate) for a single extraction well to remediate a plume within a given time period increases in distance downgradient from the center of contaminant mass with increasing remediation time (Gailey and Gorelick, 1993; Haggerty and Gorelick, 1994). Thus, optimum pumping locations and rates depend on the specified clean-up time frame.

The relative merits of conventional extraction/injection well schemes, in-situ bioremediation, and P&T enhanced by injecting oxygenated water to stimulate biodegradation for containing and cleaning up a hypothetical naphthalene plume in a uniform aquifer were examined by Marquis and Dineen (1994). Nineteen remediation alternatives were modeled using BIOPLUME II (Rifai et al., 1987), a modified version of the MOC code (Konikow and Bredehoeft, 1989) that simulates oxygen transport and oxygen-limited biodegradation. Key findings made by Marquis and Dineen (1994) include the following: (1) ground-water extraction was more effective at preventing offsite migration than bioremediation; (2) P&T enhanced by injecting highly oxygenated water (with 50 mg/L dissolved oxygen) provided the most effective plume control and cleanup; (3) greater contaminant mass reductions occurred when extraction or injection wells were located in the more contaminated portions of the plume; (4) cleanup is hastened by minimizing the distances that contaminants must travel to extraction wells or that dissolved oxygen must travel to reach degradable contaminants; (5) to maximize containment, P&T schemes should be designed to produce convergent flow toward a central extraction location and to minimize divergent flow along the plume periphery; and (6) extraction/injection schemes should be designed to minimize the presence of upgradient and intraplume stagnation areas.

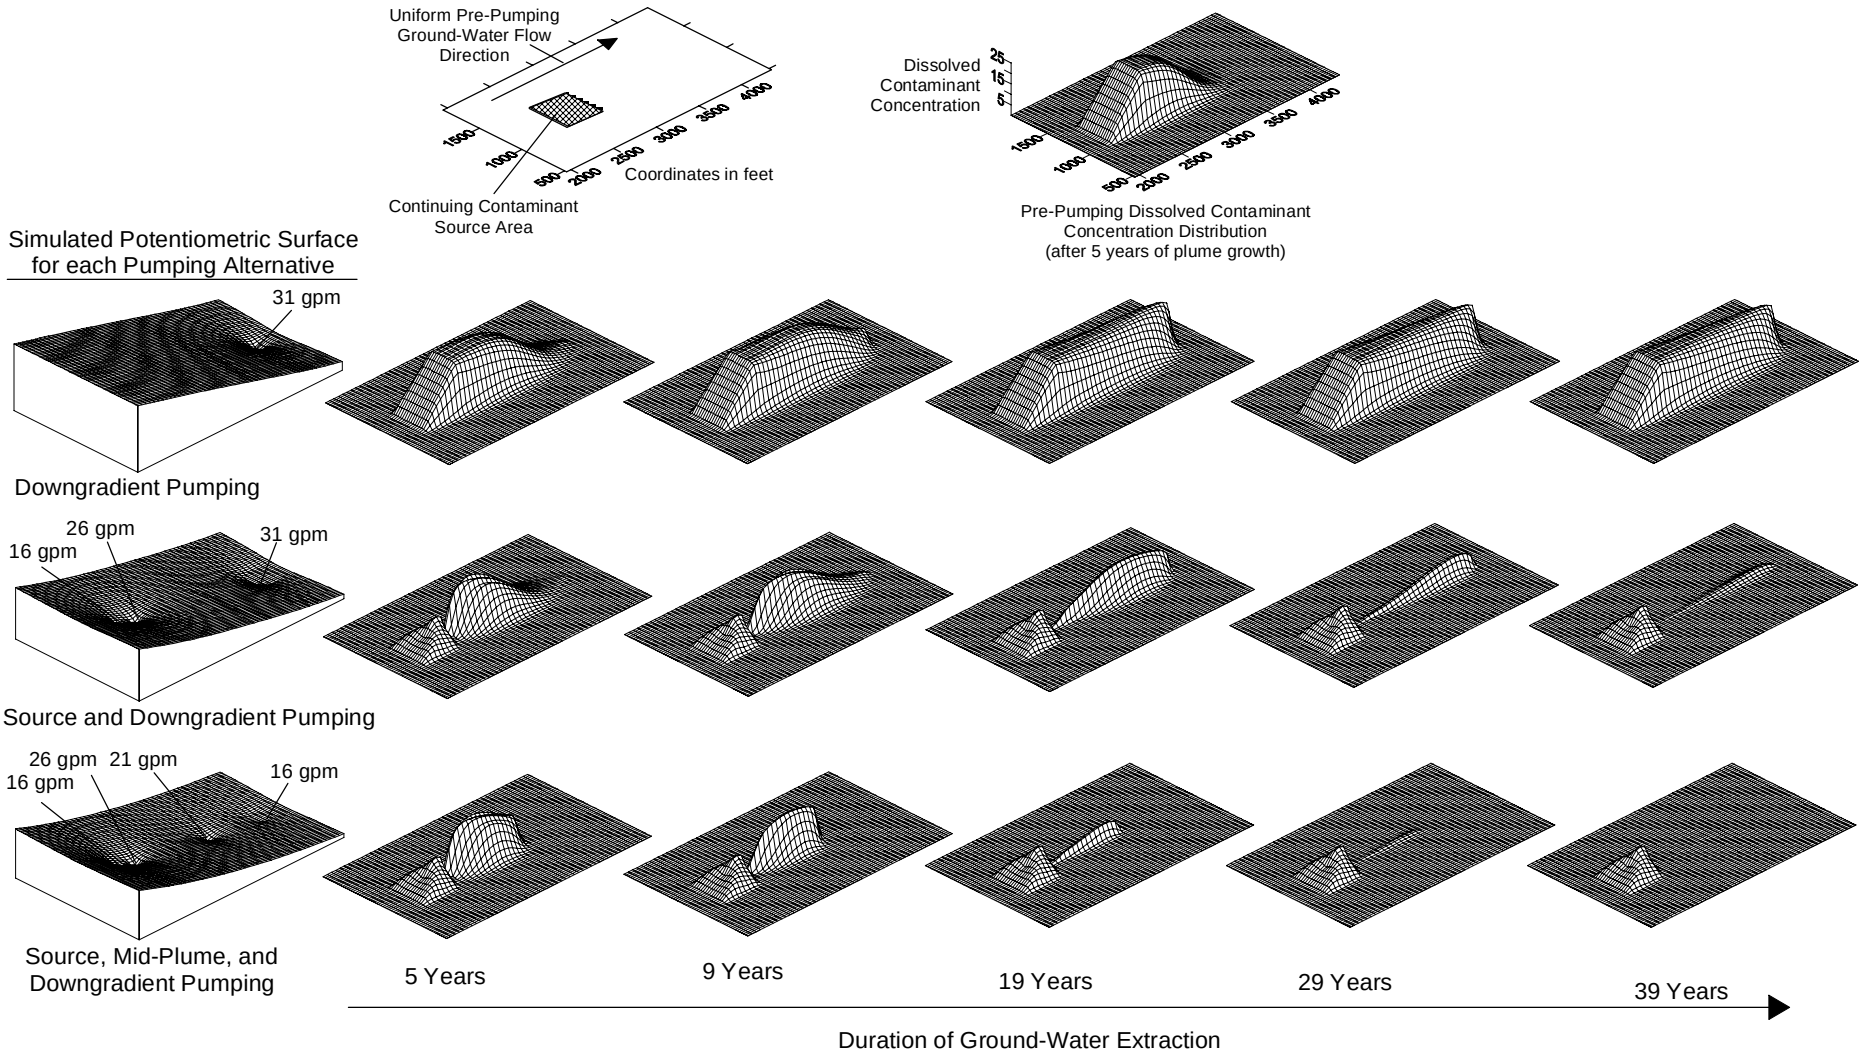

Figure 11. Results of FTWORK (Faust et al., 1993) simulation analysis of three P&T alternatives for an idealized site (with uniform media, linear equilibrium sorption, and a single non-degrading contaminant) showing dissolved contaminant concentrations with time of pumping.

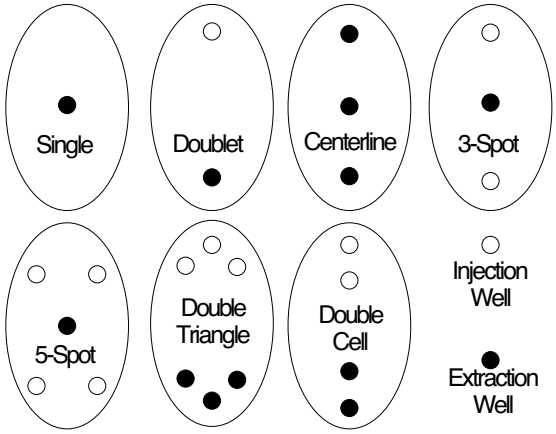

Figure 12. Well schemes evaluated by Satkin and Bedient (1988).

Pulsed Pumping

Pulsed pumping, with alternating pumping and resting periods as illustrated in Figure 13, has been suggested as a means to address tailing, flush stagnation zones by selective well cycling, and increase P&T efficiency (Keely, 1989; Borden and Kao, 1992; Gorelick et al., 1993). Dissolved contaminant concentrations increase due to diffusion, desorption, and dissolution in slower-moving ground water during the resting phase of pulsed pumping. Once pumping is resumed, ground water with higher concentrations is removed, thus increasing the rate of mass removal during active pumping. Due to slow mass transfer from immobile phases to flowing ground water, however, contaminant concentrations decline with continued pumping until the next resting phase begins.

Several simulation studies have been conducted to evaluate the effectiveness of pulsed pumping (Powers et al., 1991; Brogan, 1991; Borden and Kao, 1992; Armstrong et al., 1994; Rabideau and Miller, 1994; and Harvey et al., 1994). Harvey et al. (1994) found that: (1) for equal volumes of ground water extracted, pulsed pumping does not remove more contaminant mass than pumping continuously at the lower equivalent time-averaged rate; (2) if the resting period is too long, pulsed pumping will remove much less mass than pumping continuously at an equivalent time-averaged rate; and, (3) if pulsed and continuous pumping rates are the same, pulsed pumping will take longer to achieve clean-up goals, but will require significantly less time of pump operation. At many sites with significant tailing and rebound, it will be preferable, therefore, to pump continuously at a lower average rate than to initiate pulsed pumping. Cost savings associated with less time of pump operation, however, may make pulsed pumping advantageous.

If used, pulsed pumping schedules can be developed based on pilot tests, modeling analysis, or ongoing performance monitoring of hydraulic heads and contaminant concentrations. The pumping period should be long enough to remove most of the contaminant mass in the mobile ground water. The resting period should not be so long that the dissolved concentration in mobile ground water exceeds 70% to 90% of its equilibrium value. Additional resting becomes inefficient as equilibrium is approached because the rate of mass transfer from immobile to mobile phases is driven by the concentration gradient. Care must be taken to ensure that the hydraulic containment objective is met during pump rest periods. Further guidance on interpreting field data to designate pulsed pumping parameters is provided by Harvey et al. (1994). Simulation results showing the sensitivity of pulsed pumping performance to rest period duration are shown in Figure 13.

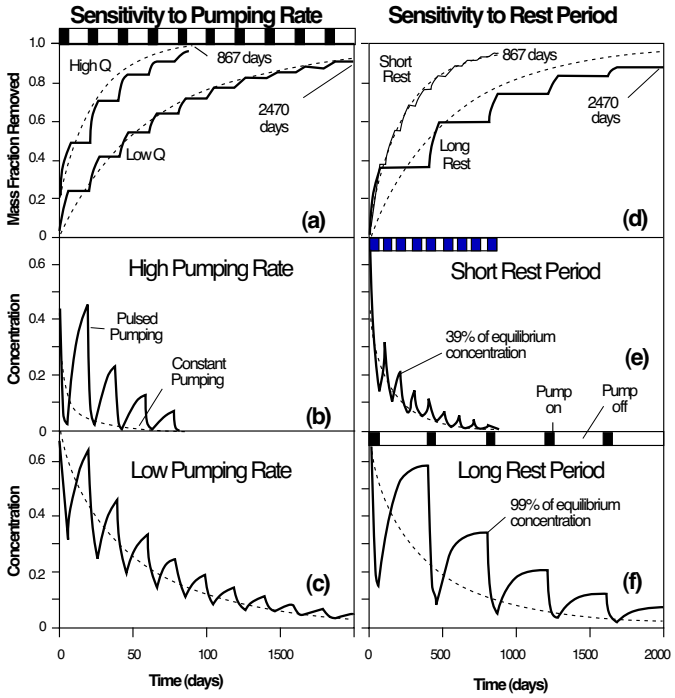

Figure 13. Effects of varying pulsed pumping parameters (after Harvey et al., 1994). The fraction of total mass removed with time is shown in (a) and (d); pumping well concentrations are shown in (b), (c), (e), and (f). Dashed lines represent equivalent constant pumping rates. Black bars at top of figures represent pumping periods and white bars represent rest periods.

Dealing with Multiple Contaminant Plumes

Multiple contaminants that migrate at different velocities in ground water are commonly encountered at contamination sites. Compounds that partition more strongly to the solid phase are transported more slowly, remain closer to source areas, and are more difficult to extract from the subsurface by pumping than the more mobile compounds. Thus, a P&T design that is ideal for a single contaminant plume might perform poorly at a site with multiple contaminants.

Haggerty and Gorelick (1994) used a solute transport model and optimization analysis to examine the ability of five pumping schemes to simultaneously remediate three contaminant plumes that were chromatographically separated during ground-water transport. The simulated problem and alternative extraction schemes are shown in Figure 14.

In the single well scheme, one well is placed along the plume axis at one of the indicated locations. For the other schemes,

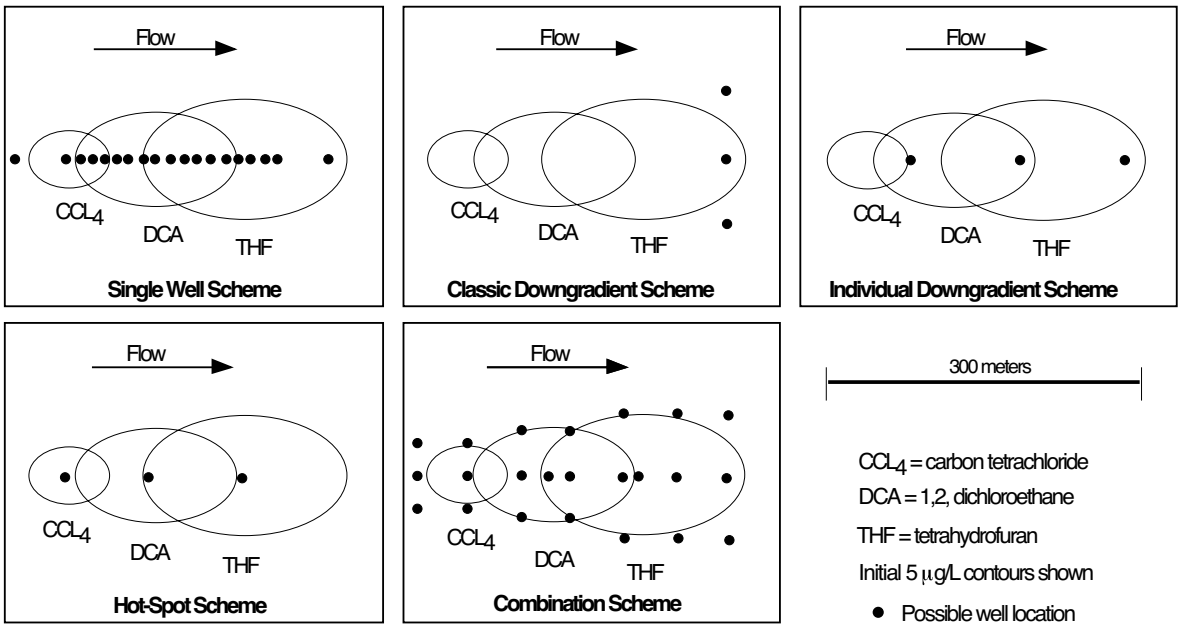

Figure 14. Map view of five pumping schemes studied by Haggerty and Gorelick (1994) overlain on the initial 5 µg/L contours of simulated CCl_4, DCA, and THF plumes. Many of the possible well locations were not used because the optimization analysis determined pumping at some locations to be 0 liters/sec. Only the optimum single well location was used for pumping under the single well scheme (modified from Haggerty and Gorelick, 1994).

wells can be placed at any number of the sites shown. The optimum number, location, and pumping rates of wells in each scheme were determined using the optimization model to achieve cleanup at the lowest possible pumping rate within a specified remediation period. Sensitivity analyses were conducted to examine the influence of mass transfer rate limitations on contaminant mobilization and removal. Findings presented by Haggerty and Gorelick (1994) for each pumping scheme are summarized in Figure 15.

For the smallest mass transfer rate parameter, $\xi = 0.005$ day^{-1}, none of the schemes can achieve cleanup within three years regardless of pumping rate due to mass transfer rate limitations. Assuming that the site is cleaned up everywhere with no dilution caused by mixing with uncontaminated ground water, then the minimum remediation time due to mass transfer limitations can be calculated as,

$$t_{min} = -(\rho_b \lambda_k / \xi) \ln (s_k^* / s_k') \qquad (4)$$

where ρ_b is the formation bulk density (M/L^3), λ_k is the distribution coefficient for compound k (L^3/M), ξ is a first-order mass transfer rate parameter (1/T), s_k^* is the immobile domain concentration standard (M/M), and s_k' is the initial maximum immobile concentration of contaminant k found at the site (M/M). Rate-limited mass transfer hinders short-term cleanup, but may have negligible impact on long-term P&T. Desorption or diffusion rate limitations may make it impossible to achieve cleanup within a short time.

For the combination scheme shown in Figure 14, seven or eight wells are optimal to achieve cleanup within three years to sufficiently reduce the distance contaminants must travel within the short remediation period. Ground water is pumped at the highest rates along the plume axis and in the location of the most retarded compounds to compensate for their low velocities.

The combination scheme essentially reduces to an individual downgradient well design for longer remediation periods. Only two or three wells along the plume axis are needed for cleanup and the ideal well locations approximate those of the individual downgradient scheme (e.g., one well cleans up the most retarded plume and the other cleans up the more mobile, downgradient plumes). The individual downgradient scheme, which requires fewer wells, therefore, is well-suited for longer-term P&T efforts.

For fast cleanup, the hot spot scheme requires less pumping than all but the combination scheme. More pumping, however, is required using the hot spot wells for a 15-year clean-up period compared to the individual downgradient scheme. This is because individual downgradient wells take advantage of the plume migration via slow regional ground-water flow during the longer clean-up period.

The classic downgradient scheme (Figure 14) is the least desirable alternative shown for attaining cleanup because the contaminants must travel completely across the multiplume site to reach the recovery wells. As a result, the more retarded contaminant plumes are smeared to the wells, an excessive volume of ground water must be extracted for cleanup, and short-term cleanup is infeasible. The single recovery well option also has significant drawbacks. It will generally require pumping more ground water and result in more contaminant smearing than all of the other schemes except the classic downgradient design.

A good P&T design must address mobile, weakly-sorbed and slow-moving, highly-sorbed contaminants to be effective at

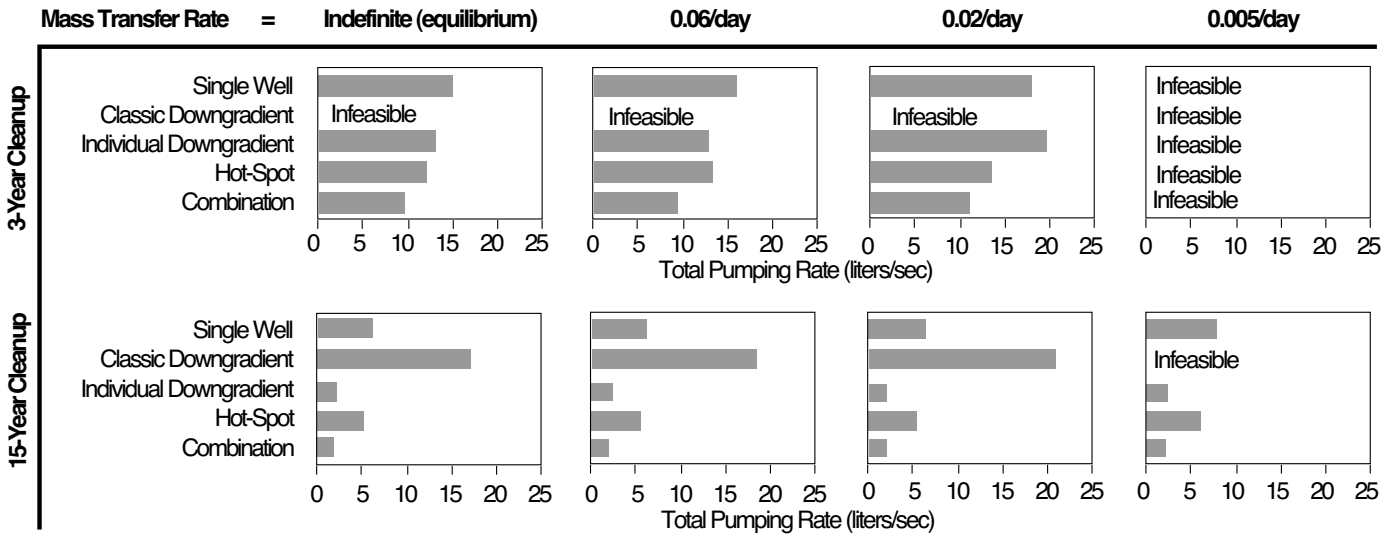

Figure 15. Optimal pumping rates for each well scheme (Figure 14) showing the minimum rate needed to capture and clean up the contaminants for the 3-year and 15-year pumping periods and mass transfer rates ranging from infinite (at equilibrium) to 0.005/day (modified from Haggerty and Gorelick, 1994).

cleanup. Substantial pumping should occur in the upgradient portion of a multiplume site to minimize both the smearing of strongly sorbed contaminants and the total volume of ground water that must be extracted for cleanup.

Other Considerations

Cyclic water-level fluctuations — Ground-water levels near surface water respond to changes in surface water stage. Cyclic stage fluctuations occur in tidal waters and in some streams that are regulated by pumping or discharge control. Where the surface water fluctuates as a harmonic motion, as occurs due to tides, a series of sinusoidal waves is propagated into the aquifer (Ferris, 1963). The amplitude of each transmitted wave decreases and the time lag of a given wave peak increases with distance from the surface water. Hydraulic gradients between contamination sites and nearby tidal water bodies, therefore, increase at low tide and decrease (or may be locally reversed) at high tide. As a result, these cyclic water-level fluctuations tend to enhance ground-water capture during high tide periods and inhibit capture during low tide periods. The impact of cyclic water-level fluctuations can be examined using analytical solutions (Jacob, 1950; Ferris, 1963) or numerical models with highly refined time steps and boundary conditions. At contamination sites that are influenced by cyclic water-level fluctuations, consideration should be given to adopting a variable rate pumping schedule, with higher extraction rates during low stage periods, to provide cost-effective hydraulic containment throughout the surface water stage cycle.

Dewatering — Water flushing will be limited to infiltration rates where P&T operation has lowered the water table and partially dewatered contaminated media. As a result, dissolved contaminant concentrations may rebound when the water table rises after pumping is reduced or terminated. Water can be injected or infiltrated, and pumping locations and rates can be varied, to both minimize this potential problem and increase the rate of flushing. Where injection is not feasible, soil vapor extraction or other vadose zone remedial measures might be needed to remove contaminant mass above the water table.

Drawdown limitations — Under some conditions, hydraulic containment cannot be maintained unless barrier walls are installed and/or water is injected (or infiltrated) downgradient of, or within, the contaminated zone. Limited aquifer saturated thickness, a relatively high initial hydraulic gradient, a sloping aquifer base, and low permeability are factors that can prevent hydraulic containment using wells or drains (Saroff et al., 1992). Where these conditions exist and hydraulic containment is planned, particular care should be taken during pilot tests and monitoring to assess this limitation.

Fractured and karst media — Fractured and solution-channeled geologic materials often represent highly heterogeneous and anisotropic systems to which techniques developed for characterization and evaluation of porous media are not readily applicable. Characterization techniques in such systems are an area of continuing research and beyond the scope of this document. Contaminant transport and P&T design/operation will be largely controlled by such factors as orientation, density, and connectivity of transmissive fracture systems. Techniques used to evaluate potential capture zones and remedial time frames based on porous-media assumptions often will not be applicable. Evaluations of capture zones will generally be based on site-specific characterization of the fractured or karst system and may involve use of tracer tests, observations during aquifer tests, and other specialized techniques such as borehole flowmeter investigations to define transmissive fracture systems and evaluate connectivity.

Information required for extraction well design will include characterization of transmissive, contaminated areas and intervals in fractured/karst systems and characterization of flow and transport parameters in any overlying porous materials (e.g., overburden, saprolite). At some sites where overburden and fractured rock are contaminated, extraction wells screened/

open across both units may be acceptable with adjustments in filter pack/screen specification for each unit. Conversely, it may be practical to screen wells only in the more transmissive unit to capture contaminants in both units. Such determinations depend on the distribution of hydraulic parameters in each affected unit. Ultimately, pilot testing of wells with careful monitoring generally will be required to evaluate the effectiveness of such systems.

In some situations, rock units may be sufficiently fractured as to approximate porous media behavior (de Marsily, 1986) allowing use of more traditional design evaluations discussed elsewhere in this document. In other situations, contaminants may be moving only in very discrete fracture systems rendering characterization difficult and necessitating careful delineation of dominant fractures and design of wells with very discrete screen/open intervals for optimum operation. The usual design approach in this situation is to locate and screen wells to intersect as many contaminated, transmissive fractures as possible (Gorelick et al., 1993). Testing of each well will be required to determine specific drawdown/flowrate relationships and evaluate potential gradient control.

The optimal well design for each of these situations will depend on the site-specific distribution of contaminants and hydraulic properties of each rock and overburden unit. However, similar design principles apply to fractured systems as to heterogeneous porous media. Design should be based on three-dimensional contaminant distribution and three-dimensional analysis of hydrologic properties of each unit within the system. In general, there still will be a significant degree of uncertainty associated with determinations of flow/transport in fractured/karst systems at most sites due to the impracticability of defining contaminant distribution and transport parameters in sufficient detail using available characterization techniques. A flexible design approach and performance monitoring can be used to minimize the effect of these uncertainties.

Highly permeable and heterogeneous media — In highly permeable media, high pumping rates are usually required to attain demonstrable hydraulic containment. Barrier walls and low-permeability surface covers installed to reduce the rate of pumping needed for containment also facilitate demonstration of inward hydraulic gradients (Figure 3). Hydraulic containment and site characterization can also be enhanced in heterogeneous media by installing barrier drains and walls, particularly if done in a manner that allows subsurface examination during construction.

Horizontal anisotropy — Significant horizontal anisotropy may be present at some sites, particularly where strata are inclined or fractured. The directions of maximum and minimum permeability are usually aligned parallel and perpendicular, respectively, to foliation or fractures. In anisotropic media, the flow of ground water (and contaminants moving with ground water) is offset from the hydraulic gradient in the direction of maximum permeability. Interpretation of hydraulic head data and capture zone analysis must account for anisotropy to evaluate extraction/injection wellfield effectiveness. Various well hydraulics equations (Papadopulos, 1965; Kruseman and deRidder, 1990) and numerical models can be employed to account for anisotropic conditions during P&T design.

Injection/extraction cells — Recharging upgradient of the contaminant plume and flushing the contaminant toward a downgradient extraction well can be designed to create a ground-water recirculation cell that isolates the plume from the surrounding ground water (Figure 16). Injection and extraction rates and locations can be adjusted to minimize the volume of ground water requiring treatment, increase flushing rates through the contamination zone (thereby reducing the flushing time), and provide additional containment (Wilson, 1984). If permitted and properly designed, water injection can greatly enhance hydraulic control and contamination zone flushing. Of course, due to water balance considerations (i.e., recharge from the land surface), it is generally not possible to reinject and recapture all of the extracted ground water. Poorly designed and inadequately monitored injection can lead to unintended horizontal and/or vertical contaminant migration.

Partial penetration — Construction of wells that only partially penetrate the aquifer may be desirable or undesirable in different situations. Contaminated ground water emanating from shallow source areas frequently is limited to the upper portion of a hydrogeologic unit. For this case, partially-penetrating recovery wells should be constructed to limit the downward spread of contaminants and the extraction of clean deep ground water. In situations where extraction wells or drains partially penetrate a contaminant plume capture may not extend to the lower limits of the plume. Three-dimensional data (e.g., hydraulic head, hydraulic conductivity distribution, contaminant distribution) are required to evaluate and monitor three-dimensional capture. In such situations, construction of wells or drains that fully penetrate the contaminated interval may reduce uncertainty and costs associated with monitoring vertical capture.

Physical barriers — Physical barriers to ground-water flow (e.g., slurry walls, grout curtains, sheet piling, etc.) reduce inflow into the system and often allow use of lower ground-water extraction and treatment rates to achieve a particular hydraulic head distribution (e.g., inward hydraulic gradient or significant dewatering). Surface caps may also be used to reduce infiltration and further reduce extraction requirements. In addition, use of such barriers and maintenance of an inward hydraulic gradient will generally reduce the complexity of adequately monitoring capture zones.

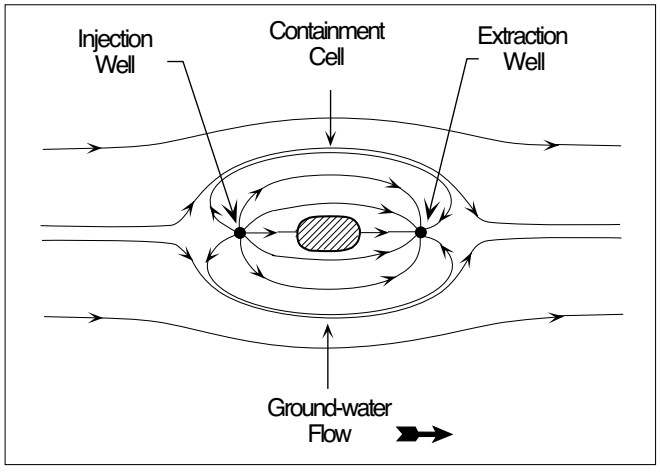

Figure 16. Plan view of a single-cell hydraulic containment, showing flow lines and a hatched contaminant plume (modified from Wilson,1984).

Situations in which use of physical barriers may be advantageous or cost effective include sites where treatment capacity for extracted ground water is limited, reductions in treatment costs outweigh barrier construction costs, and heterogeneous sites or sites with relatively high pre-design hydraulic gradients where uncertainty in capture zone determinations is high. Additional details regarding design and construction aspects of physical barriers may be found in U.S. EPA (1984), Evans (1991), Grube (1992), and Rumer and Ryan (1995).

Although these features may be used as enhancements to a P&T system, they often will not be appropriate replacements for P&T. Physical barriers without the use of P&T to lower hydraulic head within the enclosure will generally result in increasing hydraulic head within the wall. This may result in leakage over the wall, under the wall, or through relatively minor imperfections in the wall.

Physical constraints — Many ground-water contamination sites are located in developed areas where the presence of roads, buildings, and other structures constrain the placement of P&T components (i.e., wells, pipelines, and treatment plants). Such constraints should be identified early in the design process and incorporated into the analysis of feasible remedies. In some cases, it will be necessary to assess potential for subsidence that may result from pumping.

Surface-water interactions — Streams, rivers, lakes, and other surface water bodies frequently act as discharge boundaries to local and regional ground-water flow systems (and dissolved contaminants migrating therein). A variety of complex leakage and discharge relationships, however, exist spatially and temporally between surface water and ground water. Interaction between ground water and surface water may help or hinder P&T operations. At some sites, P&T design can take advantage of induced infiltration along stream line sinks to enhance hydraulic containment and flushing rates. Elsewhere, it may be desirable to limit streambed leakage (e.g., using physical barriers) to minimize requisite pumping rates or the inflow of surface water that has been contaminated at upstream locations. Consideration should also be given to potential hydraulic benefits of discharging treated ground water at alternative stream locations. Relatively complex interactions between surface water and ground water can best be analyzed by numerical model analysis and monitoring system performance.

Timeliness of remedial action — Research has shown that contaminants that have been in contact with porous media for long times are much more resistant to desorption, extraction, and degradation (Brusseau, 1993). As the residence time of a contaminant plume increases, so do potential contaminant tailing and rebound problems associated with sorption/desorption and matrix diffusion. Old plumes are likely to exhibit significant nonideal behavior, making cleanup difficult. Remedial efforts should be implemented as soon as practicable following a release to limit the difficulty of removing contaminant mass from low permeability zones and sorbed phases.

Well completion interval — Well completion intervals are selected based on site conditions and P&T strategy. Maximum well yield can generally be obtained by screening 80 percent to 90 percent of the thickness of a confined aquifer. In an unconfined formation, the screen should be placed low enough in the contaminated section so that the pumping level is not drawn into the screen. This will prevent aeration of the screen and extend the service life of the screen and pump. Longer screens may be needed in thick contamination zones and in low permeability formations to achieve an acceptable yield.

An individual well (with zone-dependent screen and sandpack characteristics) may be completed in multiple transmissive zones and hydrogeologic units if such a construction will not exacerbate vertical contaminant migration or prevent the cost-effective cleanup of individual layers. In general, (1) screens should not be constructed to hydraulically connect transmissive zones across an aquitard; (2) it is undesirable to pump ground water directly from uncontaminated intervals; and (3) partially-penetrating recovery wells can be used to limit the downward contaminant spreading and recovery pumping rates at sites where contaminants are limited to the upper portion of a thick hydrogeologic unit. Open-hole bedrock well completions are usually acceptable, but care must be taken to not promote contaminant migration (e.g., by completing an open-hole well across an effective aquitard).

Site characterization activities (such as interval-specific packer-aquifer tests, borehole flowmeter testing, and ground-water sampling) and three-dimensional simulation analysis can be used to help evaluate complicated cost-benefit trade-offs between alternative well designs in vertically heterogeneous media.

P&T Components

Ground-water extraction/injection systems are tailored to site-specific conditions and remediation goals. As a result, system component combinations yield a large variety of P&T configurations. A conceptual process flow diagram for a typical P&T system where volatile organic contaminants are removed from ground water by air stripping (and carbon adsorption polishing, as needed) is shown in Figure 17. Selected P&T system components are described below and in Table 2. Specific guidance regarding component selection and monitoring treatment system discharge compliance with appropriate regulations is beyond the scope of this document. Guidance regarding monitoring system effectiveness with respect to remedial design objectives is provided in Cohen et al. (1994).

Vertical Wells

Vertical wells are integral components of most P&T systems. Extraction wells are intended to capture and remove contaminated ground water; injection wells are used to enhance hydraulic containment and ground-water flushing rates. Basic component considerations include drilling/installation method, well diameter, screen and casing specifications, completion depth interval, and pump specifications. Detailed guidance on well drilling, construction, and development methods is provided by Repa and Kufs (1985), Driscoll (1986), Bureau of Reclamation (1995), and others.

Well yield and efficiency are of prime concern when designing extraction and injection wells. Yield is the rate at which ground water can be pumped under site-specific conditions (e.g., desired drawdown limits). Well losses caused by poor design or construction decrease well efficiency and result in increased drawdown within the well to maintain a particular yield. This is one reason that hydraulic head measurements taken in a pumping well are often poor indicators of hydraulic head in the formation immediately adjacent to the well. Within

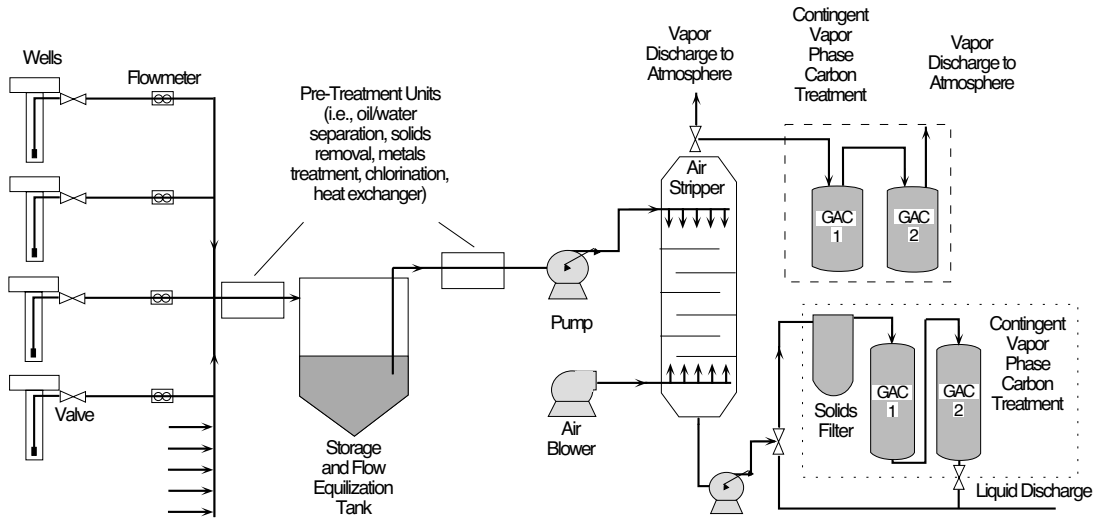

Figure 17. Example conceptual treatment diagram for a P&T system using air-stripping and optional granular activated carbon polishing treatment of liquid and vapor phase effluent from the air stripper.

Table 2. Appurtenant Pump-and-Treat Equipment

Equipment	*Description*
Piping	Conveys pumped fluids to treatment system and/or point of discharge. Piping materials will dictate if the system may be installed above or below grade with or without secondary containment measures. Piping materials (i.e., steel, HDPE, PVC, etc.) are selected based on chemical compatibility and strength factors.
Flowmeters	Measures flow rate at given time and/ or the cumulative throughput in a pipe. Typically installed at each well, at major piping junctions, and after major treatment units. Some designs allow for the instrument to act as an on/off switch or flow regulator. Many different types are available.
Valves	The primary use of valves (i.e., gate, ball, check, butterfly) is to control flow in pipes and to connections in the pipe manifold. Valves may be operated manually or actuated by electrical or magnetic mechanisms. Check valves are used to prevent backflow into the well after pumping has ceased and siphoning from tanks or treatment units. Other uses for valves include sample ports, pressure relief, and air vents.
Level Switches Sensors	Float, optical, ultrasonic, and conductivity switches/sensors are used to determine the level of fluids in a well or tank. Used to actuate or terminate pumping and to indicate or warn operators of rising or falling fluid levels in wells and tanks.
Pressure Switches	Used to shut off pumps after detecting a drop in discharge pressure caused by a loss in suction pressure.
Pressure and Vacuum Indicators	Used to measure the pressure in pipes, across pipe connections, and in sealed tanks and vessels.
Control Panels	Device which provides centralized, global control of P&T system operation and monitors and displays system status. Control panels are typically custom designed for specific applications.
Remote Monitoring, Data Acquisition, & Telemetry Devices	Provides interactive monitoring and control of unattended P&T systems. Allows for real-time data acquisition. Alerts operators to system failures and provides an interface for remote reprogramming of operations. Remote monitoring devices should also be accessible from the Control Panel.
Pull and Junction Boxes	Above and/or below grade installations that allow access to connections in the piping manifold, electric wiring, and system controls. Strategic placement provides flexibility for system expansion.
Pitless Adaptor Unit	Allows for the transfer of extracted ground water from the well to buried piping outside of the well casing.
Well Cover	Available with padlock hasps, with and without a connection to the electrical conduit for submersible pumps.

limits, such parameters as screen diameter, screened interval, and screen open area are specified to optimize yield and maximize efficiency. Increased yield results in minimizing the number of wells required to attain specific system design objectives.

The well diameter must be large enough to accommodate the pump and other downhole instrumentation. The size of the pump required to obtain the desired yield, within the site-specific hydrogeologic limits, will determine the size of the casing. Although several different types of pumps may be selected, standard electric submersible pumps are most commonly used for extracting ground water at contamination sites. A close fit between the pump and casing promotes cooling of the submersible pump motor; but can lead to insertion or removal difficulties. Commonly, the casing diameter is sized two standard pipe sizes larger than the pump. For example, a 4-inch diameter pump is set in a 6-inch diameter well. The well diameter generally should be no less than one pipe size larger than the nominal pump diameter. Except for well point systems, pumping wells are usually at least four inches in diameter. The casing size should also be selected to ensure that the uphole velocity during pumping is <5 ft/sec (Driscoll, 1986) to prevent excessive head losses.

Pump selection depends on the desired pumping rate, well yield, and the total hydraulic head lift required. Designers should consult performance curves and data provided by pump manufacturers. Pneumatic pumps are used in some P&T applications, particularly at sites where providing electrical service is problematic, combustible vapors are present, or excessive drawdown might damage electric submersible pumps. Electric and pneumatic pumps that extract total fluids or separate liquid phases (e.g., LNAPL, water, and DNAPL) are readily available.

Extraction wells may be driven (or jetted) well points, naturally developed wells, or filter-packed wells. Screens and filter packs should be appropriately sized to the native media. Grain-size analyses of unconsolidated formation samples are highly recommended to determine appropriate slot and sandpack sizes. Wells can often be developed with natural packs in areas where the formation materials are permeable and relatively coarse grained. In naturally developed wells, the slot size is chosen so that most fines adjacent to the borehole are pumped through the screen during development. Custom screen design using sections with different slot sizes based on the grain size distribution of the different materials in the screened interval may be useful at sites where the highest possible specific capacity is desired.

Use of an artificial filter pack is advantageous when the geologic materials are highly laminated; highly uniform, fine-grained deposits; or in situations where a small screen slot size (e.g., <0.010 inch) dictated by natural pack criteria would significantly reduce the water transmitting capability of the screen (Driscoll, 1986). Filter pack materials generally are composed of clean, well-rounded, uniformed-sized, siliceous grains and designed to retain most of the natural formation materials. The screen slot size is then typically selected to retain 90 percent of the sandpack. Grading of the filter pack is based on the finest-grained layer in the screened interval. Such a design generally does not restrict flow from coarser-grained layers as the hydraulic conductivity of the filter pack is significantly higher than the conductivity of these layers.

Filter packs mechanically retain formation particles. The factor controlling formation retention is the ratio of pack grain size to that of the formation, not pack thickness. Pack thickness recommendations from the literature for production wells range from approximately 3 inches to 8 inches (U.S. EPA, 1975). Pack thickness in the lower end of the recommended range will often be required to allow sufficient development for maximum well efficiency. Two common errors in filter packed wells that lead to low yields are use of a standard filter pack regardless of formation characteristics and use of screens with improper slot sizes for given filter pack characteristics (Driscoll, 1986).

Bedrock wells can be completed as open-holes; but screen and sandpack may be desirable to prevent caving and limit sand pumping. Well development by surging, jetting, backwashing, and pumping improves well efficiency. Driscoll (1986) provides a comprehensive treatise on well design, construction, and development and should be consulted prior to design.

Well screen and casing are frequently constructed of black low-carbon steel, Type 304 or Type 316 stainless steel, and PVC. Although low-carbon steel is frequently used for well casing, serious iron oxidation problems may occur when sodium hypochlorite is used to redevelop the wells. Iron flaking may cause clogging in injection wells. Manufacturers can provide advice on material compatibility with ground water and contaminants regarding the potential for corrosion, incrustation, and chemical attack. Material compatibility guidance is also available in various documents (e.g., Driscoll, 1986; McCaulou et al., 1995). The physical strength of the screen and casing materials is a concern for very deep wells. PVC casing may not be suitable for depths exceeding 300 feet, especially for large-diameter wells. Screens do not need to be as strong as casing because their openings relieve hydrostatic pressure, but must be able to withstand stresses associated with well installation and development. Screens are more susceptible to corrosion failure than steel casing. Whereas casing can suffer substantial corrosion and still function, minor screen corrosion can enlarge slot openings and result in severe sand pumping. This accounts for the use of stainless steel screens in conjunction with mild steel casing. For an economical well installation that resists degradation due to high concentrations of organic chemicals, stainless screen and casing can be threaded to PVC riser above the water table. Properties and dimensions of selected well casing products are highlighted in Table 3.

Generally, well screen diameter is selected to provide sufficient open area so that the velocity of water entering the screen is less than 0.1 ft/s to minimize friction losses, corrosion, and incrustation (Driscoll, 1986). Screen diameter influences well yield but to a lesser extent than does screen length. The potential increase of well yield with increasing screen diameter depends on site-specific conditions. Potential increases in some situations may be relatively insignificant. For example, in relatively conductive material where yields are high, increasing the screen diameter from 6 inches to 12 inches may only result in yield increases of several percent. In materials with low hydraulic conductivity, potential yield increases resulting from increased screen diameter may be significant and should be considered.

Open area of the screen affects entrance velocity and well efficiency. Limited open area limits well development and results in increased drawdown within the well for a specific yield.

Table 3. Properties and Dimensions of Selected Well Casing Products

Casing Material	Size (in.)	OD (in.)	ID (in.)	Wall thickness (in.)	Weight (lb/ft)	Collapse Strength (psi)	Comments
Black Steel Thin Wall Water Well Casing	4	4.500	4.216	0.142	6.60		+ Stronger, more rigid, and less temperature sensitive than PVC.
	6	6.625	6.249	0.188	12.9	1030	+ Much less expensive than stainless steel.
Black Steel Schedule 40	4	4.500	4.026	0.237	10.8		- Rusts easily, providing sorptive and reactive capacity for metals and organic chemicals.
	6	6.625	6.065	0.280	19.0	2286	- Subject to corrosion (given low pH, high dissolved oxygen, H_2S presence, >1000 mg/L TDS, >50 mg/L Cl^-).
PVC Schedule 40 (PVC 12454)	4	4.500	4.026	0.237	2.0	158	+ Lightweight, easy workability, inexpensive.
	6	6.625	6.065	0.280	3.6	78	+ Completely resistant to galvanic and electrochemical corrosion.
							+ High strength-to-weight ratio.
PVC Schedule 80 (PVC 12454)	4	4.500	3.826	0.337	2.8	494	+ Resistant to low concentrations of most organic contaminants.
	6	6.625	5.761	0.432	5.4	314	- Poor chemical resistance to high concentrations of aromatic hydrocarbons, esters, ketones, and organic solvents.
							- Lower strength than steel; may not be suitable for very deep applications.
Stainless Steel Schedule 5	4	4.500	4.334	0.083	3.9	315	+ Stronger, more rigid, and less temperature sensitive than PVC.
	6	6.625	6.407	0.109	7.6	129	+ Good chemical resistance to organic chemicals.
							+ Resistant to corrosion and oxidation.
Stainless Steel Schedule 40	4	4.500	4.026	0.237	10.8	2672	- Expensive.
	6	6.625	6.065	0.280	19.0	1942	- May corrode if exposed to long-term corrosive conditions.

Open area for different slot configurations (e.g., machine slotted vs. continuous slot) varies significantly. Continuous slot screens have significantly more open area per foot of screen than other slot configurations. Manufacturers should be consulted regarding open area of their screens. If the entrance velocity is calculated to be too high (i.e., > 0.1 ft/s), longer screens with greater open area, or larger diameter screens, where practical, should be considered.

The pump intake generally should not be placed in the well screen. Such placement may result in high screen entrance velocity, increased incrustation or corrosion rates, sand pumping, or dewatering of the screen (Driscoll, 1986). In general, the pump intake position does not greatly affect the relative volumes of water produced by different formation materials in the screened interval. In most situations, this distribution is predominantly controlled by the hydraulic properties (e.g., hydraulic conductivity) of the various materials.

Due to their tendency to clog, injection wells are typically overdesigned in terms of well diameter or screen length to reduce maintenance activities. Rather than using vertical wells, artificial recharge may be better accommodated by surface spreading, infiltration galleries, trenches, or horizontal wells. These options have greater surface area and are less likely to clog than vertical wells.

Vertical Well Point Systems

Well point systems are comprised of multiple closely spaced wells that are connected via a main pipe header to a suction lift pump. Suction lift systems are limited to pumping shallow ground water at depths of less than approximately 25 feet. Such systems are based on construction dewatering technology. Well point systems are often used at sites where the hydraulic conductivity of aquifer materials is relatively low and large numbers of wells would be required to meet design objectives, particularly hydraulic containment or dewatering objectives. Where applicable, such systems may be more cost-effective than conventional wells. Well point systems are described in more detail in Bureau of Reclamation (1995).

Horizontal and Slant Wells

During recent years, directional drilling rigs from the utility, mining, and petroleum industries have been adapted to install horizontal wells at contaminated sites (Kaback et al., 1989;

Karlsson and Bitto, 1990; Langseth, 1990; Kaback et al., 1991; Morgan, 1992; Conger and Trichel, 1993; WSRC, 1993; U.S. EPA, 1994b; and CCEM, 1995). As of January 1996, more than 370 horizontal wells had been drilled at contamination sites in the United States for ground-water extraction (33%), soil vapor extraction (35%), air sparging (21%) and other purposes (11%) including petroleum recovery, ground-water infiltration, and bioventing (CCEM, 1996). Most of these wells (73%) were installed less than 26 feet deep by utility type contractors.

Horizontal wells can be drilled in soil or rock as continuous holes with surface access at each end or as blind holes (Figure 18). Slant wells are completed in straight angle borings. As shown in Figure 18, slant or horizontal wells can be strategically installed to: (1) allow injection or extraction in inaccessible areas such as beneath buildings, ponds, or landfills; (2) intercept multiple vertical fractures; and (3) provide hydraulic control along the leading edge of a plume or elsewhere by creating hydraulic line sinks (extraction) or pressure ridges (injection) without the need to excavate trenches. Horizontal wells with long screens may be more cost-effective than vertical wells, particularly at sites where contaminated ground water is extensive horizontally, but not vertically. The higher cost of horizontal wells, compared to vertical wells, may be offset by savings derived from more efficient remediation, drilling fewer wells, the purchase of fewer pumps, etc.

Horizontal well construction methods are described by U.S. EPA (1994b), CCEM (1995), and in drilling contractor literature. Continuous holes are typically drilled as inverted arcs from a surface entry point to a surface exit point. Using an adjustable angle, slant rotary drill rig, a pilot boring may be advanced at an angle to the desired subsurface elevation, directed along the completion path using a steerable drill head and a walkover radio-frequency (or other) guidance system, and then angled upward to exit the ground. Following completion of the pilot hole, the boring is cut to the final diameter using reamers. Rock holes may be advanced using a steerable tungsten carbide bit with a downhole air hammer, air rotary, or mud motor assembly. Drilling fluids, consisting of water, air, bentonite slurries, or polymeric solutions, are typically recycled through a closed-loop system to remove cuttings from the borehole. Well screen, casing, risers, filter fabric and/or pre-packed filter media are assembled at the exit end of a continuous hole and pulled into place behind the reamer. Pre-packed stainless steel screens have been selected for wells requiring a filter pack, but less expensive materials, including PVC, HDPE, steel, and fiberglass have also been used for well screen. Similar to conventional water wells, horizontal well screen and filter pack sizes are designed to optimize well yield and limit fine particle entry. Much greater compressive and tensile strength are required of horizontal well materials, however, to prevent failure during emplacement or wellbore collapse. Pre-packed filter materials are used due to the difficulty of placing sand, plugs, and grout in a horizontal well bore. Horizontal wells may be developed by pumping, swab/surging, and jetting. For blind wells, a washover bit and pipe are used to allow horizontal well construction within a temporary casing.

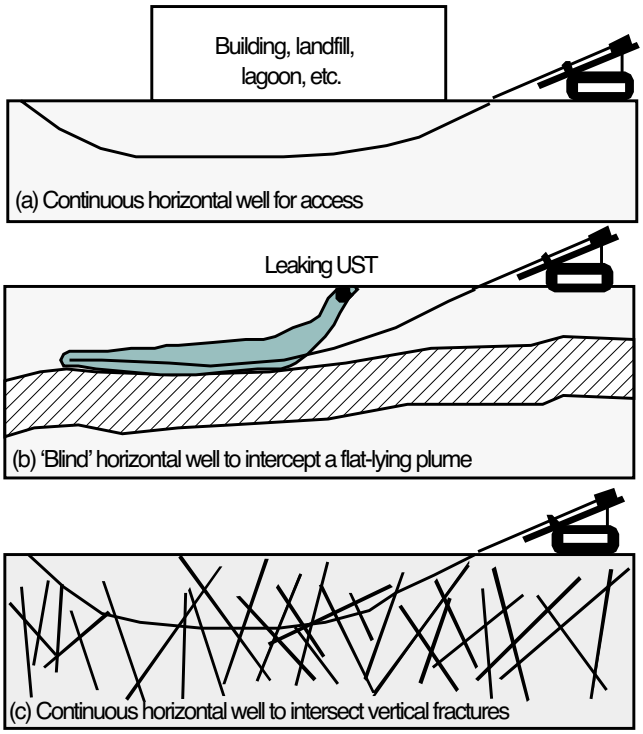

Figure 18. Several applications of horizontal wells (modified from U.S. EPA, 1994b).

Trench Drain Systems

Trench drain systems are typically constructed perpendicular to the direction of ground-water flow to cut off and contain contaminant migration by creating a continuous hydraulic sink (Figure 19). A trench drain installed along the plume axis, however, will provide more effective contaminant mass removal (but may not provide complete containment). Designers should assess the potential for downgradient mounding of ground water transmitted along the length of a drain system, particularly if the drain is not oriented perpendicular to the natural flow direction. It may be appropriate to construct segmented drains to restrict flow along the drain length.

Trench drains are typically constructed using a backhoe to shallow depth in heterogeneous, low permeability media where many wells would be needed to obtain the required yield for capture of a specific area, but may also be suitable in moderate and high permeability soil. Although the depth limit for conventional excavation techniques is about 20 feet, specialized equipment can be used to install trench drains as deep as approximately 70 feet or deeper. The saturated zone of the trench is backfilled with a highly-permeable granular material such as sand or gravel. Geotextile filter fabric is placed around the permeable backfill to prevent fine particles from clogging the drain system. The upper few feet of the trench should be backfilled with low permeability material to reduce infiltration. Ground water that enters the granular backfill flows through the fill, and/or through perforated pipe installed near the trench bottom, to an extraction sump or sumps pumped to maintain a hydraulic sink along the drain.

Consideration should be given to pipe cleanout access and the installation of monitor wells along the drain length. At some locations, it may be advantageous to install an impermeable synthetic membrane on the downgradient side of a cutoff trench to prevent fluid bypass. Trench drain systems can also be used to inject treated or clean water to create pressure ridges and

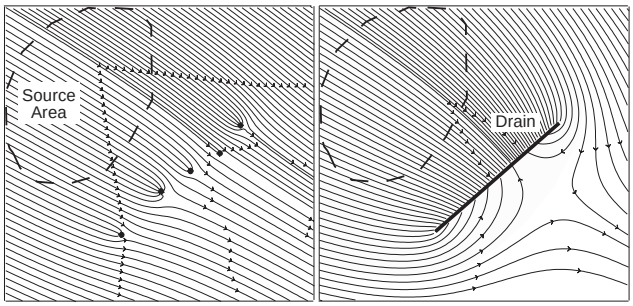

Figure 19. A trench drain constructed perpendicular to the direction of ground-water flow may provide more effective containment than extraction wells (e.g., for shallow contamination in heterogeneous, low-permeability media).

thereby enhance hydraulic containment and flushing rates. Drain depth, spacing, location, and other design criteria can be assessed using the computational tools described in Table 1 and various analytical solutions (Cohen and Miller, 1983).

The cost of excavating drains into bedrock is usually prohibitive. Drain construction also may be impractical due to access restrictions, building stability concerns, and costs associated with excavating large quantities of contaminated materials. Potential excavation stability problems can be addressed by using a trench box or other shoring methods, minimizing both the time that excavated sections are kept open and the length of open sections, and/or by use of guar guam or other gels (U.S. EPA, 1992c). Alternatively, 'one pass' trenching techniques may be applicable. For example, a 'one-pass' trencher can be used to excavate a 12-inch wide trench to a maximum depth of 22 feet, install a HDPE perforated collection pipe, and place granular backfill in a simultaneous operation (Gilbert and Gress, 1987). This method minimizes contaminant exposure during trenching, quantities of contaminated material requiring disposition, and stability problems. Additional information on trench drain systems is provided by Repa and Kufs (1985), Meini et al. (1990), Day (1991), and U.S. EPA (1991b, 1994b).

Treatment Technology Selection

Ground-water treatment technologies rely on physical, chemical, and/or biological processes to reduce contaminant concentrations to acceptable levels. Presumptive treatment technologies include use of: air stripping, granular activated carbon (GAC), chemical/UV oxidation, and aerobic biological reactors for dissolved organic contaminants; chemical precipitation, ion exchange/adsorption, and electrochemical methods for treatment of metals; and a combination of technologies to treat ground water containing both organic and inorganic constituents (U.S. EPA, 1996). Widely-used ground-water treatment technologies that are available as package plants are described in Appendix B .

The evaluation and selection of treatment alternatives for a particular P&T system is based on technical feasibility and costs (capital and operational) of achieving remediation goals. Key parameters that influence treatment design and efficacy include flow rate, ground-water constituents requiring treatment (including naturally occurring dissolved metals that may foul or interfere with a treatment system), influent concentrations, and discharge requirements. Relationships between these parameters and treatment design are discussed briefly below, and in more detail by AWWA (1990), Nyer (1992), U.S. EPA (1994a), WEF (1994), and Noyes (1994).

The treatment flow rate, influent concentrations, and desired effluent concentrations influence the applicability of potential treatment methods. Flow rate is usually based on a projection of the pumping rate needed to achieve remediation goals. Treatment plant capacity may need to be increased where effluent is reinjected or where aggressive P&T is employed to hasten cleanup. The degree of contaminant concentration reduction required for each constituent is crucial to treatment design. For example, although GAC adsorption may reduce the concentration of a particular contaminant more than air stripping, depending on the discharge requirements, air stripping may be utilized as the sole technology, as pretreatment to GAC, or not at all. The discharge requirements often depend on the final disposal method for the treated water. Options include discharge to surface water, reinjection, discharge to another treatment system, or direct use. Regulations may preclude some options due to effluent concentrations, flow rate, or potential impacts to the ground water. Discharge to an existing treatment system (POTW or industrial treatment system) is generally the least restrictive option, but each system will have specific flow rate and concentration requirements. Effluent discharge to surface water and reinjection below the water table require permits.

The first step in selecting a treatment strategy is to exclude methods that are not implementable based on contaminant type, concentrations, flow rate, and site characteristics. Where multiple contaminants are present, some technologies may be excluded as complete solutions, but considered as a pretreatment or polishing step in a 'treatment train'. Thus, to effectively use air stripping for volatile organic contaminants, it may be necessary to pretreat the influent by chemical precipitation to remove dissolved metals that could foul the stripping unit. Examples of unit processes and sequences in ground-water treatment trains are listed in Table 4. At some sites, it may be beneficial to split ground water that is extracted from different areas into more than one treatment train (e.g., highly contaminated water from a source area may be treated differently than dilute downgradient ground water).

The technically implementable methods are then assessed with regard to effectiveness, relative implementability, and cost. An evaluation of effectiveness should consider the projected rate and duration of flow, the level of treatment required for each constituent, and the reliability of each method. Reliability may be difficult to assess for innovative technologies based on readily available data. In the absence of adequate performance data, treatability and pilot-scale testing should be conducted to yield critical data for use in technology selection, design of full-scale facilities, estimating costs, and identifying potential problems. The time element of treatment can be addressed during pilot studies by appropriate scaling of treatment units, flow rates, and concentrations (e.g., smaller capacity GAC units can be used to determine constituent breakthrough times more quickly). An evaluation of relative implementability should consider technical and administrative aspects, including permits, space limitations, storage and disposal options, availability of equipment, availability of skilled workers to implement the technology, visual impacts, and community relations. Cost estimates should include capital costs, annual costs, and an estimate of treatment duration; and cost comparisons should incorporate a discount rate for future costs and a cash flow analysis.

Treatment strategies should be designed and implemented in a manner that will accommodate changing conditions over the life cycle of a P&T project. At many sites, modifying treatment capacity or methods to match changing influent chemistry or flow rate over time can improve system performance and reduce cost. As with pumping, treatment optimization requires ongoing monitoring.

Proposed designs (e.g., extraction/injection well construction and placement, piping diagrams, treatment system design) should be presented in drawings and accompanied by detailed text discussion with appropriate tables. Discussion should include such topics as materials selection, proposed processes, and installation procedures. Rationale for design choices should also be discussed with supporting calculations presented and supporting data presented or referenced.

Technology Integration

Under favorable conditions (Figure 4), P&T technology can achieve clean-up goals. However, most, if not all, remedial methods will have difficulty rapidly restoring ground-water quality to meet low concentration standards in the presence of highly sorbing contaminants, NAPL, and heterogeneous media. In these cases, remedial performance may be improved by integrating P&T operation with other clean-up technologies. This integration can occur spatially (e.g., where P&T is applied to the dissolved plume and other technologies are applied to source areas) and temporally (e.g., where multiple technologies are applied in series).

Remedial technology integration has occurred at many sites contaminated with petroleum product LNAPLs. Although mobile LNAPL may be pumped via extraction wells, immobile product will remain in the subsurface. Excavation is a candidate technology to remove shallow LNAPL. Due to their volatility and degradability, many petroleum products, such as gasoline, can also be remediated using SVE and enhanced bioremediation. Alternatively, natural attenuation may be demonstrated to be an effective petroleum contaminant management strategy at some sites.

Table 4. Common Treatment Train Unit Processes [1] and Sequence (modified from U.S. EPA, 1996)

Ground-Water Treatment Train Unit Processes

Solid or Liquid Separation Technologies	*Primary Treatment Technologies*	*Effluent Polishing Technologies[2]*	*Vapor Phase Treatment Technologies[3]*
• Oil/grease separation[4] • Filtration[5] • Coagulation or flocculation[5] • Clarification or sedimentation[5]	For Organics: • Air stripping • Granular activated carbon • Chemical/UV oxidation • Aerobic biological reactors For Metals: • Chemical precipitation • Ion exchange/adsorption • Electrochemical methods	• Activated carbon • Ion exchange • Neutralization	• Activated carbon • Catalytic oxidation • Thermal incineration • Acid gas scrubbing • Condensation

General Sequence of Ground-Water Treatment Train Unit Processes

Sequence	*Unit Treatment Process*	*Treatment Stage*
Begin	Equalize inflow	Pre-treatment
	Separate solid particles	Pre-treatment
	Separate oil/grease (NAPLs)	Pre-treatment
	Remove metals	Treatment
	Remove volatile organic contaminants	Treatment
	Remove other organic contaminants	Treatment
	Polish organics[2]	Post-treatment
	Polish metals	Post-treatment
End	Adjust pH, if required	Post-treatment

Notes: [1] Technologies that may be required for treatment residuals, such as spent carbon, are not listed.
[2] Effluent polishing technologies are used for the final stage of treatment prior to discharge, and can include pH adjustment (neutralization) as well as additional removal of aqueous constituents.
[3] Vapor phase contaminants released during water treatment may need to be contained and treated. These include organic contaminants volatilized during air stripping, from biological treatment, or other gases released from chemical oxidation, reduction, or biologic processes (e.g., hydrochloric acid, hydrogen sulfide, methane, etc.).
[4] Methods for separating oil and/or grease from water include, but are not limited to, gravity separation and dissolved air floatation. These methods can be used to remove NAPLs from extracted water.
[5] These technologies can be used to remove solid particles at the start of the treatment train or to remove other solids resulting from chemical precipitation, chemical/UV oxidation, or biological treatment.

These same technologies (extraction, excavation, SVE, air sparging and, to a lesser extent, bioremediation) have also been applied to DNAPL source areas where the chemicals have the appropriate properties. Additional technologies are being evaluated for NAPL recovery (i.e., surfactant flushing, steam flushing, alcohol flooding, hot water flooding, and surfactant-enhanced solubilization). Except for excavation, however, there are no proven technologies to remove sufficient DNAPL to fully restore a DNAPL-contaminated aquifer (U.S. EPA, 1992a). Therefore, hydraulic containment will remain an important management option for the DNAPL-contaminated portion of the subsurface.

Away from source areas, bioremediation also can be combined with P&T. Various solutions, including dissolved oxygen and nutrients, can be injected upgradient or within the contaminant plume to enhance biodegradation. At some sites, natural attenuation may be used in conjunction with or following ground-water extraction.

Natural attenuation refers to natural biological, chemical, and physical processes that reduce contaminant concentrations and mass. Also known as intrinsic remediation, it includes destructive chemical transformation processes (radioactive decay, biodegradation, and hydrolysis) and nondestructive partitioning and dilution processes (sorption, volatilization, and dispersion). At many sites, contaminant plume growth is restricted by biodegradation, partitioning, and/or dilution. For example, the limited mobility of many soluble petroleum hydrocarbons, such as BTEX compounds, in ground water due to biodegradation has been particularly well-documented (e.g., Barker et al., 1987).

Natural attenuation processes may be significant factors in contaminant removal and limitations to aqueous-phase contaminant migration at many sites. Field evaluation of such processes and rates is an area of continuing research. Proposed methodologies for evaluating natural attenuation of fuel contaminants are discussed in Wiedemeier et al. (1995) and McAllister and Chiang (1994).

Potentially cost-effective, innovative enhancements and alternatives to P&T (NRC, 1994) are being pilot-tested at many contamination sites. Permeable treatment walls using the funnel-and-gate approach are leading candidate remedial technologies (Starr and Cherry, 1994). These systems are designed to reduce contaminant concentrations in ground water that is passively funneled through a permeable reaction wall, which contains abiotic or biologically reactive media, an air sparge system, or some other enhancement.

Design of Operations and Maintenance

Detailed plans for evaluation of maintenance requirements should be established prior to installation. Establishment of the plan during the design stage allows for incorporation of features to simplify maintenance procedures (e.g., access ports for cleaning distribution piping in infiltration galleries). Maintenance such as pump replacement and well development may be performed on an as needed basis. The required frequency will depend on site conditions and equipment. Equipment manuals may be consulted regarding maintenance requirements for specific system components.

The major causes of decreased well performance include reduction in yield due to incrustation or biofouling of the screen or adjacent materials, formation plugging by fine-grained materials, corrosion or incrustation resulting in increased water velocity and sand pumping, structural failure of the casing or screen, and pump damage (Driscoll, 1986). Periodic monitoring of total depth, pumping rate, drawdown, specific capacity, and efficiency may be used as indicators of maintenance requirements for extraction or injection wells. Injection wells and galleries are particularly susceptible to blockage or fouling and may require frequent maintenance. Maintenance schedules should be sufficiently frequent so as not to compromise system performance with respect to the established design objectives (e.g., maintain capture, maintain specified pore volume flushing rates). Additional discussion of operation and maintenance issues is provided in Driscoll (1986) and Bureau of Reclamation (1995).

Performance Monitoring

P&T performance is monitored by measuring hydraulic heads and gradients, ground-water flow directions and rates, pumping rates, pumped water and treatment system effluent quality, and contaminant distributions in ground water and porous media. These data are evaluated to interpret P&T capture zones, flushing rates, contaminant transport and removal, and to improve system operation. Detailed guidance on methods for monitoring P&T performance is provided by Cohen et al. (1994).

Restoration progress can be assessed by comparing the rate of contaminant mass removal (e.g., plotted as cumulative mass removed) to estimates of the dissolved and/or total contaminant mass-in-place. If the rate of contaminant mass extracted approximates the rate of dissolved mass-in-place reduction, then the contaminants removed by pumping are primarily derived from the dissolved phase. Conversely, a contaminant source (i.e., NAPL, sorbed contaminant, or a continuing release) is indicated where the mass removal rate greatly exceeds the rate of dissolved mass-in-place reduction. Site hydrogeology and contaminant properties should be evaluated to determine if source removal or containment, or P&T system modifications, could improve P&T performance.

The time needed to remove dissolved mass-in-place can be projected by extrapolating the trend of the mass removal rate curve or the cumulative mass removed curve. Future concentration tailing, however, may extend the extrapolated clean-up time. If the mass removal trend indicates a significantly greater clean-up duration than estimated originally, system modification may be necessary. The effect (or lack of effect) of P&T system modifications will be evidenced by the continuing mass removal rate and cumulative mass removed trends.

Progress inferred from mass removal rates can be misleading, however, where NAPL and solid phase contaminants are present (e.g., the mass removed will exceed the initial estimate of dissolved mass-in-place). Interpretation suffers from the high degree of uncertainty associated with estimating NAPL or solid contaminant mass-in-place. Stabilization of dissolved contaminant concentrations while mass removal continues may be an indication of NAPL or solid phase contaminant presence. Methods for evaluating the potential presence of NAPL are provided by Feenstra et al. (1991), Newell and Ross (1992), and Cohen and Mercer (1993).

Mass removal rates are also subject to misinterpretation where dissolved contaminant concentrations decline rapidly due to:

(1) mass transfer rate limitations to desorption, NAPL or precipitate dissolution, or matrix diffusion; (2) dewatering a portion or all of the contaminated zone; (3) dilution of contaminated ground water with clean ground water flowing to extraction wells from beyond the plume perimeter; or (4) the removal of a slug of highly contaminated ground water. Contaminant concentration rebound will occur if pumping is terminated prematurely in response to these conditions.

The projected restoration or clean-up time is site specific and varies widely depending on contaminant and hydrogeologic conditions and the clean-up concentration goal. Estimating clean-up time is complicated by difficulties in quantifying the initial contaminant mass distribution and processes that limit cleanup. Guidance for estimating ground-water restoration times using batch and continuous flushing models is provided by U.S. EPA (1988b). The batch flushing model is based on a series of consecutive discrete flushing periods during which contaminated water in equilibrium with adsorbed contaminants is displaced from the aquifer pore space by clean water. Values of contaminant concentration in soil and water are calculated after each flush. An example of an analogous method (and corrections) to this batch flushing model are provided by Zheng et al. (1991, 1992). The batch and continuous models assume that: (1) zero-concentration influent water displaces contaminated ground water from the contamination zone by simple advection with no dispersion; (2) the clean ground water equilibrates instantaneously with the remaining adsorbed contaminant mass; (3) the sorption isotherm is linear; and (4) chemical reactions do not affect the sorption process. Care must be taken to avoid relying on misleading estimates of restoration time that may be obtained by using these simplified models. Although more sophisticated modeling techniques are available (i.e., contaminant transport models), their application often suffers from data limitations, resulting in uncertain predictions. Nevertheless, clean-up time analyses are useful for assessing alternative remedial options and determining whether or not clean-up goals are feasible.

Disclaimer

The U.S. Environmental Protection Agency through its Office of Research and Development partially funded and collaborated in the research described here under Contract No. 68-C4-0031 to Dynamac Corporation. It has been subjected to the Agency's peer and administrative review and has been approved for publication as an EPA document. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

Quality Assurance Statement

All research projects making conclusions or recommendation based on environmentally related measurements and funded by the Environmental Protection Agency are required to participate in the Agency Quality Assurance Program. This project did not involve physical measurements and as such did not require a QA plan.

Appendix A

Limitations for Conventional P&T Technology

Widespread experience with P&T systems during the past 15 years indicates that their ability to reduce and maintain dissolved contaminant concentrations below clean-up standards in reasonable time frames is hindered at many sites due to complex hydrogeologic conditions, contaminant chemistry factors, and inadequate system design (Keely, 1989; Mercer et al., 1990; U.S. EPA, 1993a; NRC, 1994; and Cohen et al. 1994). Hydrogeologic conditions that confound ground-water cleanup include the presence of complex sedimentary deposits, low permeability formations, and fractured bedrock. Chemical processes that cause contaminant concentration tailing and rebound during and after P&T operation, respectively, and thereby impede complete aquifer restoration, include: (1) the presence and slow dissolution of nonaqueous phase liquids (NAPLs); (2) contaminant partitioning between ground water and porous media; and (3) contaminant diffusion into low permeability regions that are inaccessible to flowing ground water. These limitations may render restoration using only conventional P&T technology impracticable at some sites.

NAPL Dissolution

NAPLs that are denser than water (DNAPLs), in particular, exacerbate ground-water restoration efforts. This is due to their prevalence at contamination sites, their complex subsurface migration behavior and distribution, their low aqueous solubility, and limits to DNAPL removal using available technologies (U.S. EPA, 1992a; Grubb and Sitar, 1994; and Pankow and Cherry, 1995). Greater success has been achieved remediating petroleum hydrocarbon LNAPLs using conventional methods and enhanced technologies such as soil vapor extraction, bioremediation, and air sparging.

Subsurface NAPL trapped as ganglia at residual saturation or contained in pools can be a long-term source of ground-water contamination, as illustrated in Figure 8-d, due to its limited aqueous solubility that may greatly exceed drinking water standards. At many sites, NAPL pools will continue to contaminate ground water long after residual fingers and ganglia have dissolved completely (Cohen and Mercer, 1993). If NAPLs are not removed (e.g., by excavation) or contained (as depicted in Figure 2), then tailing and rebound will occur during and after P&T operation, respectively, in and downgradient of the NAPL zone. Above residual saturation, NAPL will flow unless it is immobilized in a stratigraphic trap or by hydrodynamic forces. NAPL movement can greatly expand the subsurface volume where restoration is impractical. A critical element of site characterization, therefore, is to delineate the nature and extent of mobile and residual NAPL so that these source areas can be removed or contained. Detailed guidance on NAPL site characterization is provided by American Petroleum Institute (1989), U.S. EPA (1992a), Cohen and Mercer (1993), and Newell et al. (1995).

Contaminant Sorption and Desorption

Sorption/desorption also cause tailing, concentration rebound, and slow ground-water restoration. As dissolved contaminant concentrations are reduced by P&T operation, contaminants sorbed to subsurface media desorb from the matrix and dissolve in ground water. The volume of ground water that must be passed through a contamination zone to attain clean-up standards increases with contaminant sorption and kinetic limitations to the rate of desorption.

Equilibrium contaminant partitioning between porous media and ground water can be described by the Langmuir or Freundlich isotherms (Figure A-1). For the linear isotherms (N = 1) and for limited ranges of C_w (particularly at low concentration) where N $\neq$ 1, the Freundlich constant, K_f, can be identified as a soil-water distribution coefficient, K_d:

$$K_d = C_s / C_w \qquad \text{(A-1)}$$

where C_s and C_w are the equilibrium contaminant concentrations in soil and water, respectively.

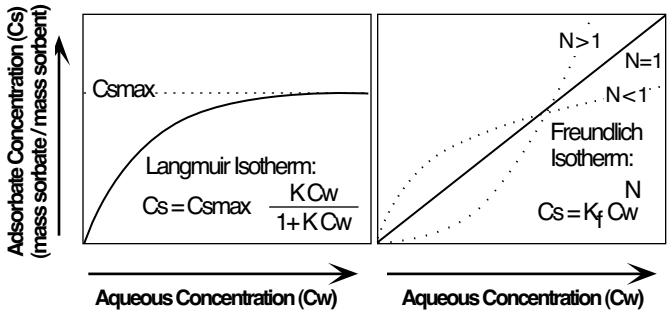

Figure A-1 The Langmuir and Freundlich adsorption isotherms (modified from Palmer and Fish, 1992).

Contaminant K_d values must be characterized to predict ground-water restoration times for different P&T schemes or for natural ground-water flushing. By assuming that sorption is instantaneous, reversible, and linear, K_d values can be used to estimate: (1) the retardation factor, R,

$$R = 1 + K_d \rho_b / n \qquad \text{(A-2)}$$

and (2) the equilibrium distribution of contaminant mass between the solid and aqueous phases

$$f_w = C_w V_w / [(C_w V_w)+(C_s M_s)] = V_w / (V_w + K_d M_s) \quad \text{(A-3)}$$

where ρ_b is the dry bulk density of the media, n is the media porosity, V_w is the volume of water in the total subject volume, M_s is the mass of solids in the total subject volume, and f_w is the fraction of mass residing in the aqueous phase.

Although the ratio of bulk density to porosity is typically within a range of four to six, K_d values for different contaminants vary over orders-of-magnitude (e.g., Montgomery and Welkom, 1990). Thus, contaminant velocity and P&T restoration time are particularly sensitive to soil-water partitioning (K_d values) of ground-water contaminants.

The nonlinearity of contaminant desorption and difficulty of contaminant removal appear to increase with the duration of contaminant presence in the subsurface (Brusseau, 1993). Thus, old plumes are likely to exhibit significant nonideal behavior. Conversely, ground-water cleanup may be simplified if remedial efforts are undertaken quickly after the occurrence of a contaminant release.

Sorption and retardation values vary between different contaminants at a given site and between different sites for a given contaminant (Mackay and Cherry, 1989). As depicted in Figure 8, desorption and retardation increase the volume of ground water that must be pumped to attain dissolved contaminant concentration reductions. Tailing and rebound effects will be exacerbated where desorption is slow relative to ground-water flow and kinetic limitations prevent sustenance of equilibrium contaminant concentrations in ground water (Bahr, 1989; Brogan, 1991; Haley et al., 1991; and Palmer and Fish, 1992). This concept is illustrated in Figure A-2.

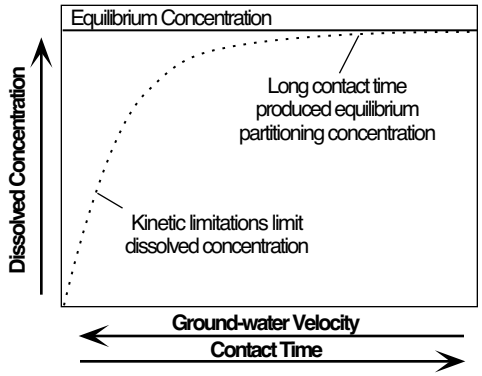

Figure A-2. Relationship between ground-water velocity and the concentration of dissolved contaminants that (a) desorb from porous media, (b) dissolve from precipitates, or (c) dissolve from NAPL (modified from Keely, 1989). Kinetic limitations to dissolution exacerbate tailing.

Solids Dissolution

Important physicochemical processes that affect the solubility, reactivity, mobility, and toxicity of inorganic contaminants include: (1) chemical speciation, (2) oxidation/reduction, (3) dissolution/ precipitation, (4) ion exchange and sorption, and (5) particle transport (Palmer and Fish, 1991). Inorganic contaminants occur in many different chemical forms or "species." Knowing the total concentration of an inorganic element in ground water or soil, as commonly provided by laboratory analysis, may be of little value (alone) in assessing its subsurface behavior. Rather, it is often more important to determine contaminant speciation which depends on several factors including pH, Eh, ion and gas concentrations, and temperature. For example, metal cations combine with different anions to form aqueous complexes that increase the solubility, mobility, and risk associated with potentially toxic metals such as chromium and arsenic.

Given the complex interaction between solid minerals, inorganics, and environmental factors (such as Eh-pH relations), computer codes are used to assess the solubility and geochemical behavior of inorganic species in ground water. Codes used to evaluate mineral solubility, saturation, and chemical speciation include WATEQ (Truesdell and Jones, 1974), SOLMINEQ88 (Kharaka et al., 1988) and mass transfer codes, such as PHREEQE (Parkhurst et al., 1980), EQ3/EQ6 (Wolery, 1979), and MINTEQ (Felmy et al., 1984), that can also be used to deduce equilibrium chemical reactions. Data requirements for these codes typically include field analysis of ground-water samples for pH, temperature, Eh or dissolved oxygen, and alkalinity, and a complete inorganic chemical analysis for all major and minor ions and all metals and anions under investigation.

Besides conducting thorough chemical analyses for speciation studies, investigations should be conducted to delineate inorganic contaminant plumes and estimate plume migration rates. Mineralogical characterization efforts can be used to identify solid phases (e.g., clay minerals and Fe and Mn oxyhydroxides) that control inorganic contaminant partitioning (EPRI, 1989). Sorption-desorption and other tests can be conducted to assess inorganic contaminant partitioning, solubility, and mobility as a function of pH and other factors, and the potential for aquifer restoration. Additional information relevant to assessing inorganic ground-water contamination is given by EPRI (1989), Domenico and Schwartz (1990), Palmer and Fish (1991), Stumm (1992), Fetter (1993), Runnells (1993), and Allen et al. (1993).

Ground-Water Velocity Variation

Tailing and rebound also result from variable travel times associated with different flowpaths taken by contaminants to extraction wells. Ground water at the edge of a capture zone travels a greater distance under a lower hydraulic gradient than ground water closer to the center of the capture zone. Travel times also vary as a function of initial contaminant distribution and hydraulic conductivity differences. If pumping is stopped, rebound will occur wherever the resulting flowpath modification diminishes contaminant dilution. Permeability and contaminant distributions should be characterized to facilitate analysis of ground-water stagnation and velocity variations that would be induced by alternative pumping schemes.

Matrix Diffusion

As contaminants advance through relatively permeable pathways in heterogeneous media, concentration gradients cause diffusion of contaminant mass into the less permeable media and thereby retard solute velocity relative to ground water (Gillham et al., 1984). During a P&T operation, dissolved contaminant concentrations in the relatively permeable zones may be quickly

reduced by advective flushing relative to the less permeable zones. This causes a reversal in the initial concentration gradient and the slow diffusion of contaminants from the low to high permeability media. This slow process can cause long-term tailing and rebound after the termination of pumping.

Matrix diffusion may dictate the time necessary for complete remediation, particularly in heterogeneous and fractured media where transport via preferential pathways results in large concentration gradients (Grisak and Pickens, 1980; McKay et al., 1993; and Parker et al., 1994). For example, consider a sand aquifer with clay lenses that was contaminated for a long time before commencing P&T operation. Advective transport induced by pumping may quickly reduce contaminant concentrations in the sand. Concentrations in the clay lenses, however, will decrease slowly as contaminants slowly diffuse from the clay to the sand. The areal extent of the clay is such that an approximation of one-dimensional diffusion out of each lens can be used to estimate the time needed to reduce contaminant concentrations in the clay. If (C_o) is a uniform initial contaminant concentration in a clay lens of thickness m, and that P&T maintains a very low concentration in the sand, then the time required for diffusion to reduce the average relative contaminant concentration (C/C_o) in a clay lens can be estimated by (Carslaw and Jaeger, 1959, p. 97):

$$\frac{C}{C_0} = \frac{8\,C_0}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \exp\left(-\frac{D^0}{\alpha R m^2} (2n+1)^2 \pi^2 t \right) \qquad \text{(A-4)}$$

where R is the retardation factor, α is tortuosity (typically = 1.6 to 1.3 in granular media; Bear, 1972), D^o is the free water diffusion coefficient, and t is time. Considering typical free water diffusion coefficients for organic contaminants (1×10^{-5} to 1×10^{-6} cm ^{2}/sec), changes in C/C_o in clay lenses of different thickness are shown as a function of time in Figure A-3, and indicate that matrix diffusion can greatly increase aquifer clean-up time.

The potential for matrix diffusion to cause tailing and rebound can be assessed based on (1) knowledge of the contaminant concentration history in the subsurface, (2) site stratigraphy, (3) chemical analyses conducted on vertical core samples taken from low-permeability matrix material, (4) diffusion modeling, and (5) review of P&T monitoring data. Estimates of water diffusion coefficients for various contaminants and media are available in the literature (Parker et al., 1994) or can be, but rarely are, measured in a laboratory (Myrand et al., 1992).

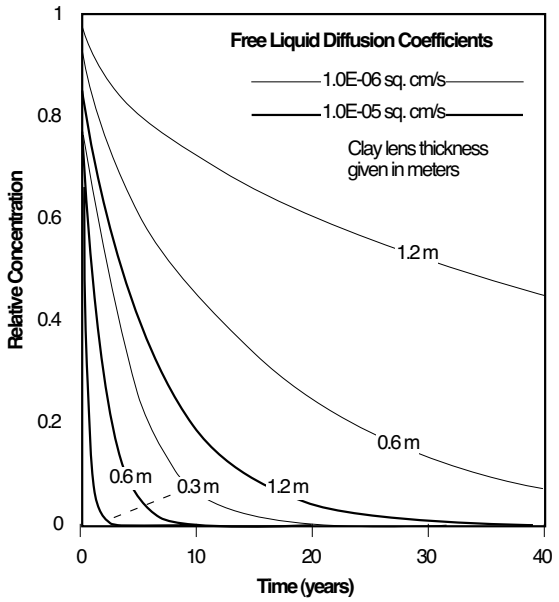

Figure A-3. Changes in average relative contaminant concentration in clay lenses of specified thickness due to diffusion to adjacent clean zones during P&T (based on typical diffusion coefficient and tortuosity values).

Appendix B

Selected Ground-Water Treatment Technologies Available as Package Plants

(modified from U.S. EPA, 1994a; Boulding, 1995)

Method	*Process Description*	*Package Plant Components and Sizes* *(Dimensions are for overall plant envelope)*	*Advantages and Limitations*
Air Stripping Widely used to remove volatile contaminants from ground water.	Volatile contaminants are transferred from water to gas phase by passing air or steam through water in a tall packed tower, shallow tray tower, or stripping lagoons. The air stream containing volatile contaminants may require treatment (e.g., with vapor-phase carbon). Stripping with steam may be cost-effective for water containing a mix of relatively nonvolatile and volatile compounds, particularly at industrial facilities where steam is readily available.	Package plants include tall packed tower or compact low profile diffuser tray units, feed pump, air blower, and effluent pump. Flow meters for influent and air flow are required. An influent throttle valve and blower damper are required to adjust the air/water ratio. Acid or chlorine is used to wash the tower packing (e.g., of Fe precipitates). Heights are for packed tower units. 1-10 gpm — 4'x4'x20' — 2 HP 10-50 gpm — 6'x8'x25' — 5 HP 50-100 gpm — 7'x10'x30' — 8 HP 100-400 gpm— 8'x12'x40' —20 HP	Effective for VOCs. Equipment is relatively simple. Startup and shutdown can be accomplished quickly. Modular design is well-suited for contaminant P&T. Package systems widely available. Dissolved Fe and Mn can be precipitated and foul the packed media resulting in headloss and reduced system effectiveness. Pretreatment (oxidation, precipitation, sedimentation) of influent may be required. Biological fouling may also occur (requiring cleaning via chlorination or a biocide). Sensitive to pH, temperature, and flow rate. May be cost-prohibitive at temperatures below freezing (may need to heat). May need GAC polishing of water effluent and treatment of air stream.
Granular Activated Carbon (GAC) Adsorption Widely used to remove metals, volatile and semi-volatile organics, pesticides, PCBs, etc. from ground water and leachate.	Aqueous contaminants are sorbed to GAC or synthetic resin packed in vessels in parallel or series. Used sorbent is regenerated or replaced. Extent of adsorption depends on strength of molecular attraction, molecular weight of contaminants, type and characteristics of adsorbent, pH, and surface area.	Package systems include 1 to 3 pressure vessels on a skid, interconnecting piping, a feed pump, optionally a backwash pump, pressure gauges, differential pressure gauges, influent flow meter, backwash flow meter, and control panel. Spent adsorbers are disconnected and sent to regeneration centers or landfills. 1-10 gpm - 12'x8'x8' - 2 HP 10-50 gpm - 14'x8'x8' - 7 HP 50-100 gpm - 20'x10'x8' - 10 HP 100-200 gpm - 20'x20'x8' - 20 HP	Effective for low solubility organics. Useful for a wide range of contaminants over a broad concentration range. Not adversely affected by toxics. High O&M costs. Intolerant of suspended solids (will clog). Pretreatment required for oil and grease greater than 10 mg/L. Synthetic resins intolerant of strong oxidizing agents.
Chemical Precipitation, Flocculation, Sedimentation Widely used to remove metals from contaminated ground water and landfill leachate.	Metals are precipitated to insoluble metal hydroxides, sulfides, carbonates, or other salts by the addition of a chemical (e.g., to raise pH), oxidation, or change in water temperature. Flocculent aids may be added to hasten sedimentation.	Package plants include a rapid-mix tank, flocculation chamber, and settling tank. Inclined plate gravity separation or circular clarifiers are used for settling. Typical equipment includes a rapid mixer, flocculator and drive, feed pump, sludge pump, acid and caustic soda pumps for pH control, and a polymer pump. 1-10 gpm - 8'x4'x9' - 3 HP 10-50 gpm - 10'x4'x13' - 5 HP 50-100 gpm - 11'x6'x14' - 7 HP	Useful for many contaminated ground-water streams, particularly as a pretreatment step. Effectiveness limited by presence of complexing agents in water. Precipitate sludge may be a hazardous waste.

Appendix B (continued)

Method	Process Description	Package Plant Components and Sizes (Dimensions are for overall plant envelope)	Advantages and Limitations
UV Oxidation Used increasingly to remove organic contaminants from ground water and other wastewaters.	Ultraviolet (UV) oxidation involves adding an oxidant, such as hydrogen peroxide, to contaminated water and then irradiating the solution with UV light. This splits the hydrogen peroxide, producing hydroxyl radicals which react with organic contaminants, causing their breakdown to non-toxic products (e.g., low weight aldehydes, carbon dioxide and water).	An oxidant (hydrogen peroxide) is injected upstream of the reactor vessel and mixed with the contaminated water in line. The fluid then flows sequentially through 1 or more reactors containing UV lamps where treatment occurs. 1x10 kW - 2'x6'x6' 1x30 kW - 4'x4'x8' 4x30 kW - 12'x5'x8'	UV oxidation can treat a broad range of soluble organics and is particularly effective for destroying chloroalkanes such as TCE and vinyl chloride and aromatic compounds such as benzene and toluene. Pretreatment may be needed to remove suspended solids, NAPL, and iron concentrations > 100 mg/L. Treatability studies needed.
Filtration Widely used to remove fine suspended solids from ground water and landfill leachate.	A fixed or moving bed of media traps and removes suspended solids from water passing through the media. Monomedium filters usually contain sand, while multimedia filters include granular anthracite over sand possibly over very fine garnet sand. Filters are used upstream of other treatment processes.	Package filters consist of one or more pressure vessels on a skid. A feed pump, backwash pump, piping, and valves complete the system. 1-10 gpm - 10'x4'x8' - 2 HP 10-50 gpm - 14'x6'x8' - 3 HP 50-100 gpm - 18'x8'x8' - 5 HP 100-250 gpm - 24'x10'x8' - 15 HP	Reliable and effective means of removing low levels of solids. Equipment is readily available and easy to operate and control. Filters clog if suspended solids concentration is high. Backwash water requires further treatment.
Ion Exchange Widely used to remove metal cations, TDS, and anions (e.g., nitrate, sulfate, chromate) from drinking water and for various other applications.	Ion exchange is an adsorption process that uses a resin media to remove dissolved ion contaminants (by exchanging sorption sites held by harmless ions). Cation resins adsorb metals while anion resins adsorb such contaminants as nitrate and sulfate. Systems consist of pressure vessels containing beds of resin pellets and strainers to retain the pellets. The resin bed is regenerated by flushing with acid and/or caustic soda.	Package plants include resin-filled pressure vessels, regeneration chemical tanks, and waste brine storage tanks. Acid and caustic soda solution pumps are provided to regenerate the resin. Resins can be selected that are ion-specific. 1-10 gpm - 8'x3'x6' - 3 HP 10-50 gpm - 14'x5'x8' - 10 HP 50-100 gpm - 17'x6'x10' - 12 HP	Removes a broad range of ionic species. Units are compact and not energy intensive. Must monitor effluent for contaminant breakthrough. High concentrations of Fe and Mn, hardness cations (Ca and Mg), suspended solids, and certain organics will foul ion exchangers. These constituents are often present at much higher concentration than the targeted contaminants. One option is to use ion-specific resins to remove heavy metals in the presence of Ca and Mg.
Reverse Osmosis (RO) Widely used for removing dissolved solids from drinking water and other applications.	RO is a separation process that uses selective semipermeable membranes to remove dissolved solids from water. A high-pressure pump forces the water through a membrane, overcoming the natural osmotic pressure, to divide the water into a dilute (treated) stream and a concentrated (residual brine) stream.	RO package plants include cartridge prefilters, a high-pressure feed pump, RO modules, pressure vessels, and a backpressure valve. 1-10 gpm - 8'x3'x6' - 13 HP 10-50 gpm - 12'x6'x6' - 35 HP 50-100 gpm - 14'x12'x8' - 85 HP	Can reduce both inorganic and organic dissolved solids. Some brine must flow out of the RO module to remove concentrated contaminants. This rejected flow may be 10% to 50% of the feed flow. Units are subject to chemical attack, fouling, and plugging. Pretreatment needs (e.g., to remove Fe, Ca, Mg) may be great.

Appendix B (continued)

Method	Process Description	Package Plant Components and Sizes (Dimensions are for overall plant envelope)	Advantages and Limitations
Fluidized Bed Biological Reactor (FBR) Widely used to remove soluble organics (e.g., BTEX, aromatics, halogenated aliphatics, etc.) from ground water, but not landfill leachate.	An aerobic FBR is a fixed-film biological treatment technology using microbes grown on GAC or sand media. Dedicated pumps provide desired fluidization and control the reactor internal flux. Influent enters the reactor bottom. The media bed expands as the biofilm grows thicker and reduces the media density. An internal growth control system intercepts the rising bed at a desired height, removes most biomass from the media, and returns the media to the reactor. Aerobic GAC FBR integrates biological removal with GAC sorption.	Package plants include an enclosed vertical cylindrical vessel, influent pump, air compressor or blower, air diffuser, effluent recycle pump, and media/biomass separation tank. 1-10 gpm - 12'x7'x15' - 7 HP 10-50 gpm - 18'x10'x15' - 10 HP 50-100 gpm - 18'x12'x15' - 12 HP 100-400 gpm - 18'x16'x15' - 40 HP	Expected to have a high process and mechanical reliability. Single or dual reactor design provides on-line flexibility. GAC FBR provides stable performance under fluctuating loading conditions. NAPL may pass through or cover the biofilm surface. Iron levels > 20 mg/L may require pretreatment to avoid plugging. Ca and Mg may cause scaling problems. Not designed for removing suspended solids. GAC FBR is not efficient for low-yield, nonbiodegradable organics because it is often operated as a high loading system with a short retention time.
Activated Sludge System Widely used to remove biodegradable organic contaminants and inorganic nutrients (e.g., N and P) from landfill leachate, but not from ground water.	This is a suspended-growth, biological treatment system that uses aerobic microbes to biodegrade organic contaminants. Influent is pumped into an aeration tank, mixed with bacteria, and kept in suspension. In the presence of oxygen, nutrients, organic compounds, and acclimated biomass, organic contaminants are biodegraded. After a treatment period, the fluid and biomass are passed to a settling tank, where cells are separated from treated water. A portion of the settled cells are recycled to the next treatment batch and the remaining sludge is disposed.	Package plants include cylindrical or rectangular aeration tanks and clarifiers, positive displacement blower, air diffusers, sludge recycle pump, sludge waste pump, chemical feed pumps, and control panel. 1-10 gpm - 23'x12'x12' - 5 HP 10-50 gpm - 45'x24'x12' - 15 HP 50-100 gpm - 45'x50'x12' - 25 HP 100-200 gpm- 45'x100'x12'- 47 HP	Effective and reliable if there are no shock loads. Technology is highly developed. Can tolerate higher organic loads than most biological treatment processes. High degree of flexibility. High capital costs. Generates sludge that may be high in metals and refractory organics. Sensitive to high concentrations of heavy metals or toxic organics. Fairly energy intensive. Has difficulty with low concentrations of contaminants, relatively long time needed for organism acclimation. Long detention times for some complex contaminant degradation.
Sequencing Batch Reactor (SBR) Widely used to remove biodegradable organics and inorganic nutrients from LF leachate, but not from ground water.	The SBR is a periodically operated, suspended growth, activated sludge process. It is different from the continuous activated sludge process in that the treatment steps are carried out in a single reactor tank in sequential steps.	Package plants include 1 or 2 rectangular or cylindrical SBR tanks, blowers, air diffusers, influent pumps, waste sludge pump, effluent pump, and chemical pumps. A floating decanter removes clear water from the reactor water at the end of the treatment cycle. 1-10 gpm - 20'x10'x12' - 7 HP 10-50 gpm - 30'x15'x14' - 40 HP 50-100 gpm - 40'x20'x14' - 80 HP	See above. By using a single tank, SBR saves land requirements and provides flexibility in changeable time and mode of aeration in each stage.

Abstract Three groundwater tracer tests using deuterium-labelled benzene, toluene, xylene and naphthalene (BTXN), trichloroethene (TCE) and munitions compounds (e.g. trinitrotoluene—TNT) were carried out in Australia to determine sorption, biodegradation and other transport parameters for contaminant plumes. The BTXN and TCE tests were natural gradient tests in an anaerobic sand aquifer, and the third munitions tracer test was a forced gradient test in a fractured basalt aquifer. Sorption coefficients, biodegradation rates and dispersion coefficients were estimated from multi-depth and location monitoring and modelling. The use of deuterium-labelled tracers is shown to be viable and attractive, although difficulties with in-field operations and environmental policy may limit application of such a technique.

INTRODUCTION

Quantifying the natural attenuation of hazardous chemicals in groundwater environments is non-trivial (Wiedemeier *et al.*, 1999). Direct *in situ* estimates of sorption coefficients, biodegradation rates and dispersion coefficients are needed to assess natural attenuation, and to parameterize models of contaminant fate. Laboratory-derived estimates are often not representative of field conditions. Summary results of three in-field groundwater tracer tests using deuterium-labelled compounds are presented and compared to laboratory and other estimates. The advantages and difficulties of the technique are also discussed. One tracer test involved the injection of deuterium-labelled benzene, toluene, xylene and naphthalene (BTXN) compounds into a gasoline plume in anaerobic sulphate-rich groundwater. The second tracer test involved the injection of deuterium-labelled trichloroethene (TCE) into a TCE plume, and the third tracer test involved injection of deuterium-labelled munition compounds (e.g. trinitrotoluene—TNT) into a mixed contaminant plume in a fractured basalt aquifer.

BTXN TRACER TEST

Fully deuterated BTXN were used with bromide as groundwater pollutant tracers inside a plume of gasoline components to determine *in situ* retardation (R) and biodegradation rates ($t_{½}$) for a sand aquifer (Thierrin *et al.*, 1995). The benzene plume at the site was greater than 420 m long while the toluene and *o*-xylene plumes were typically 100–200 m. Variable attenuation was apparent for individual BTEX components (Davis *et al.*, 1999). Sulphate reduction was also observed. The tracer test was carried out over 17 m in the mid-region of the plume. Monitoring occurred at 19 stainless steel multi-port boreholes. Prior to injection, the deuterated BTXN and bromide were mixed into 400 l of groundwater pumped from the injection well under anaerobic conditions. The injected mass of bromide, benzene-d_6, toluene-d_8, *p*-xylene-d_{10}, and naphthalene-d_8, was 82.8, 2.1, 1.83, 1.55 and 0.5 g, respectively, with mass recoveries of 68, 69, 48, 56 and 15%. The total injected mass of 6 g compared with 100 kg dissolved in the plume.

Depth-averaged $t_{½}$ and R values were calculated (Table 1) from the breakthrough curves (Fig. 1). The data show increasing retardation from benzene, to toluene, to *p*-xylene, to naphthalene. R values from laboratory batch tests (Table 1) were much greater than tracer test values. Except for naphthalene, tracer test estimates of $t_{½}$ were comparable to simple whole-of-plume modelling (Thierrin *et al.*, 1993). The additional mass loss of naphthalene was possibly due to nonlinear sorption or biodegradation. The latter seems unlikely (Wiedemeier *et al.*, 1999). Also, tracer test dispersivity estimates of 0.0034–0.026 m, indicating limited dilution due to dispersion.

Table 1 Half-lives (days) from the tracer test and whole-of-plume modelling (assuming first-order rates), and R values from the tracer test and laboratory batch tests.

Parameter	Tracer test (half-life in days)	Modelling (half-life in days)	Tracer test (R)	Batch test (R)
Benzene	>800	>800	1.02 ± 0.04	1.3
Toluene	90 ± 30	120 ± 25	1.04 ± 0.02	1.9
p-xylene	225 ± 75	–	1.12 ± 0.10	–
m- and *p*-xylene	–	170 ± 10	–	2.0
o-xylene	–	125 ± 10	–	1.9
Naphthalene	33 ± 6	160 ± 20	1.32 ± 0.14	2.6

TCE TRACER TEST

The transport characteristics of a TCE plume in anaerobic, ammonium and sulphate-rich groundwater were determined through a small-scale (13 m) natural-gradient tracer test using deuterium-labelled TCE (TCE-d_1) and bromide (Benker *et al.*, 1997). The plume was approximately 100–150 m wide and 3–9 m thick, with TCE, ammonium and sulphate concentrations up to 1300 µg l^{-1}, 90 and 470 mg l^{-1}, respectively. Dichloroethene was detected. The tracer test was carried out in the plume ~600 m downgradient of the source area. The tracer solution, consisting of 400 l of groundwater spiked with 30 g of KBr and 42.5 µl of TCE-d_1 (plume mass was 60–100 l of TCE), was injected at a rate of 80 l min^{-1}, 15–16 m below ground (mid-

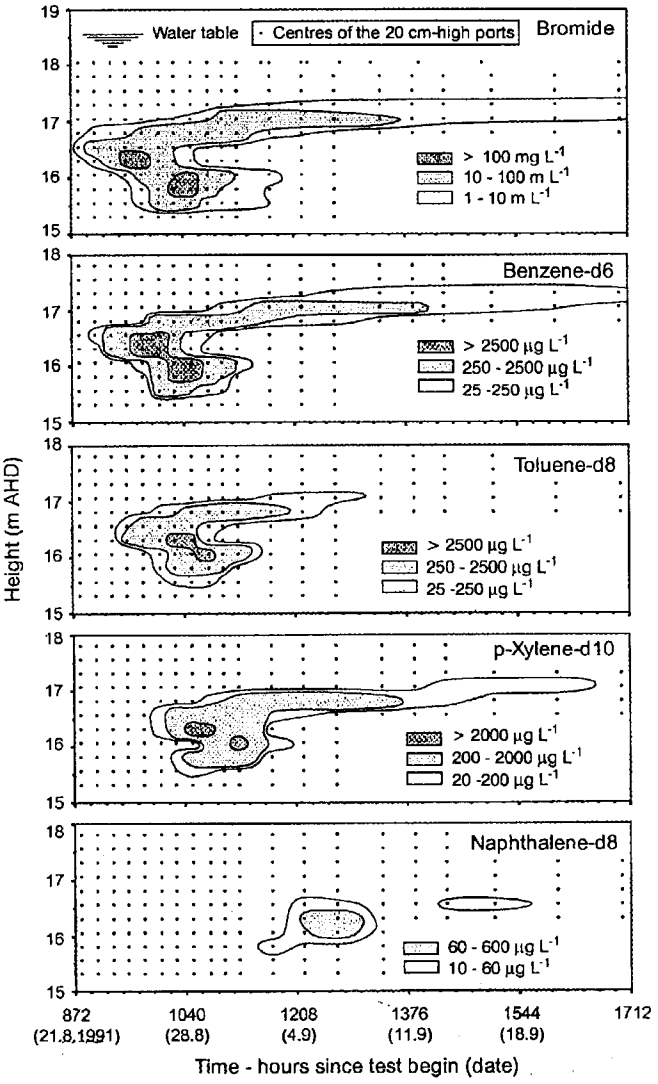

Fig. 1 Tracer test data depicted as depth–time contour plots (after Thierrin *et al.*, 1995).

plume). Monitoring occurred in seven multi-port bores, each with nine 0.2 m long screens placed vertically 0.1 m apart, 14.3–16.9 m below ground.

The field experiment showed TCE-d_1 to be stable and non-retarded (Fig. 2). Commonly used correlation equations (Benker *et al.*, 1998) overestimated R values for TCE. Batch experiments were more accurate but still overestimated TCE sorption. Column experiments were most suitable for predicting TCE sorption. Tracer test modelling also indicated a longitudinal dispersivity of 0.005 m. The tracer test indicated that TCE within the aquifer moves conservatively, is highly mobile, and that high concentrations will be preserved to substantial distances downgradient of the source.

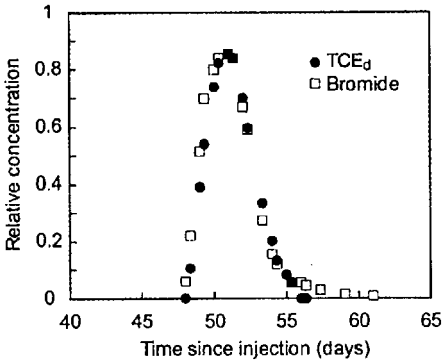

Fig. 2 Bromide and TCE-d_1 breakthrough 13 m from the injection location.

MUNITIONS TRACER TEST

A forced-gradient tracer experiment using deuterated munition compounds (2-nitrotoluene-d_7, 2-NTd_7; 4-nitrotoluene-d_7, 4-NTd_7; 2,6-dinitrotoluene-d_6, 2,6-DNTd_6; 2,4-dinitrotoluene-d_6, 2,4-DNTd_6; 2,4,6-trinitrotoluene-d_5, TNTd_5; and hexahydro-1,3,5-trinitro-1,3,5-triazine-d_6, RDXd_6) and bromide was conducted to determine *in situ* retardation and biodegradation rates in a fractured basalt aquifer at a munitions factory in Melbourne Victoria (Toze *et al.*, 1997). The tracers were mixed into 400 l of groundwater pumped from the injection bore T1 under anaerobic conditions. Bore T14, 24 m downgradient of T1, was pumped (at 3.8 m^3 h^{-1}) prior to injection to stabilize groundwater flows and drawdowns (0.17 m in T1, 0.37 m in T14). The tracers were injected into T1 (12–14 m below ground) over 35 min. Groundwater was sampled from T1 and six other bores each with 2–5 sampling ports, 11.5–15.5 m below ground.

Table 2 Injected concentrations of bromide and deuterated munitions compounds at bore T1, and calculated *R* values from the tracer test and laboratory soil columns.

Compound	Injected concentration ($\mu g\ l^{-1}$)	Field *R* values	Laboratory *R* values
bromide	1 120 000	–	–
2-NTd_7	2 400	1.1	1.0
4-NTd_7	1 200	1.0	1.4
2,6-DNTd_6	470	1.1	1.5
2,4-DNTd_6	1 460	1.2	8.2
TNTd_5	750	–	8.8
RDXd_6	690	–	2.1

Injected concentrations are shown in Table 2. The tracers moved laterally and vertically, e.g. 2-NTd_7 took up to 70 h to peak at T1-5 (500 $\mu g\ l^{-1}$), possibly due to density effects of the added bromide (T1-5 indicates port 5). Deuterated munition compounds were detected almost immediately in three bores ~2 m away from T1, and after about 3 h, peak 2-NTd_7 concentrations were 710, 930 and 1600 $\mu g\ l^{-1}$ in these bores. The tracers were detected at two bores 6 m away (e.g. Fig. 3), although TNTd_5 and RDXd_6 were not detected. Peak 2-NTd_7 concentrations (65 $\mu g\ l^{-1}$ and 50 $\mu g\ l^{-1}$)

occurred after 42 and 50 h at these 6-m bores. No significant degradation of the deuterated munitions compounds could be inferred. The R values determined from breakthrough curves at bore T9-4 (Fig. 3) were generally significantly less than laboratory-derived R values (Table 2; Patterson *et al.*, 1996). The greater values of R may be due to fresh basalt surfaces from packing of columns. The contaminated plumes have the potential to travel significant distances off-site from the initial source areas.

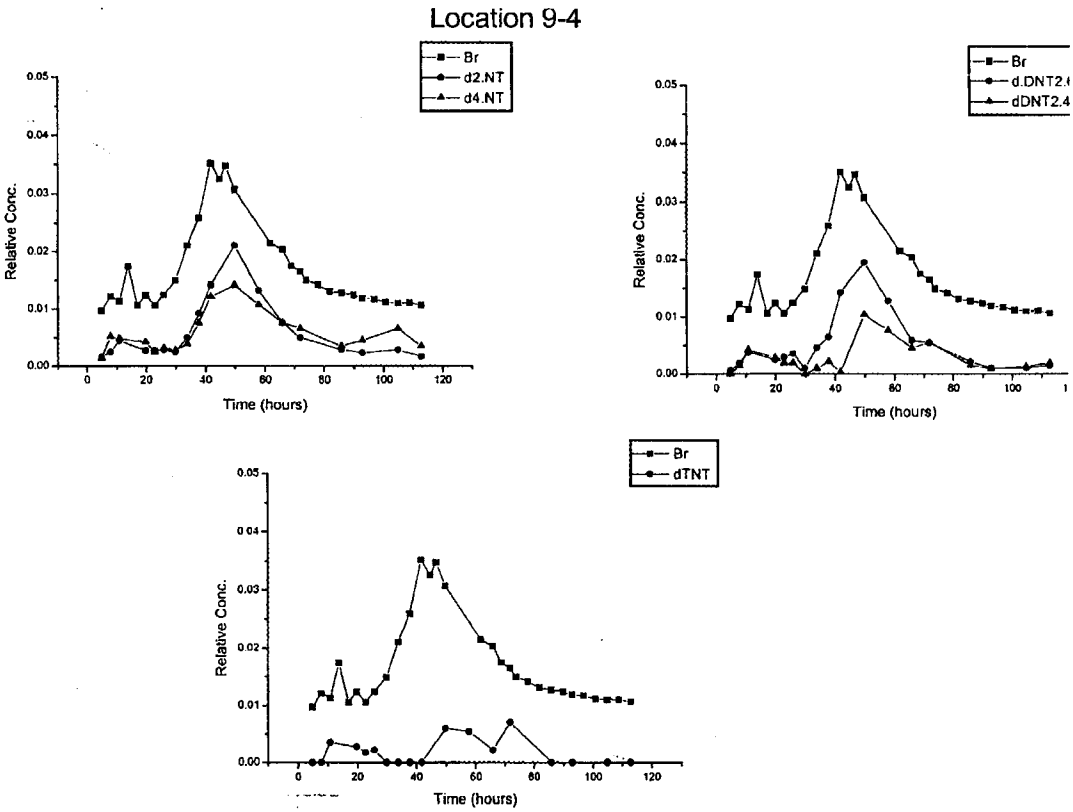

Fig. 3 Breakthrough curves at sampling port 4 of borehole T9 (6 m from T1).

ADVANTAGES AND DISADVANTAGES

In each tracer test, key contaminants (benzene, TCE and munitions) were shown not to be degrading significantly, however, the munitions experiment was inconclusive. *In situ* measurement of sorption and biodegradation avoids *ex situ* variability and disturbance in laboratory experimentation, as exemplified by the comparison between batch, column and tracer scale estimates (Tables 1, 2 and Benker *et al.*, 1998). A difficulty however, is preserving groundwater geochemical (inorganic and organic) conditions when extracting groundwater for mixing of tracers and re-injection, especially where anaerobic conditions and volatile constituents need to be preserved.

Defining the shape and zone of radius of the injected tracer volume is also difficult—this may lead to mis-estimation of some of the transport parameters. Groundwater hydraulic changes during tracer tests may confuse analysis. Prior to the BTXN tracer experiment, a bromide tracer test was carried out to define flow directions and velocities. Between the end of the bromide tracer test and the start of the BTXN tracer test, the flow direction changed by 20°, complicating monitoring bore locations and the frequency of monitoring.

The stability of deuterated compounds is also a concern, and how well the deuterated compounds mimic the actual compounds of interest. The munitions compounds were tested to determine their hydrogen/deuterium exchange rates under various pH conditions (pH values of ~4.5, 6.8–7.0 and ~9.1). Analysis of characteristic ions indicated no change in isotope ratios (and hence no deuterium/hydrogen exchange) under acidic, neutral or basic conditions for all the compounds apart from TNT. For TNT, exchange occurred under neutral and basic conditions (Fig. 4). The NTs and DNTs are less acidic than TNT with fewer nitro groups to share a negative charge, and so are less prone than TNT to hydroxide ion attack. Despite the instability of the $TNTd_5$ under basic and neutral conditions, all the deuterated compounds were able to be used confidently because of the slightly acidic nature of the groundwater at the site.

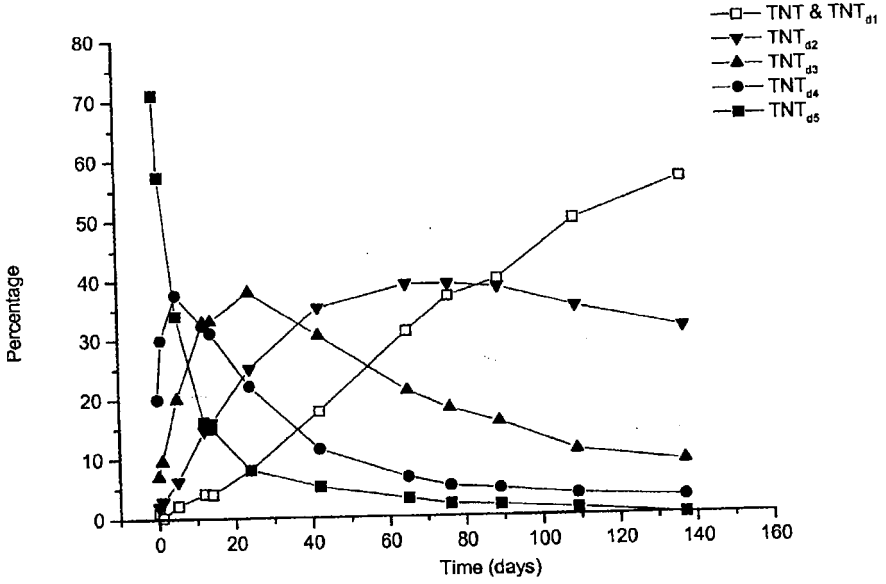

Fig. 4 Transformation of deuterated TNT under basic conditions.

The value of *in situ* deuterium-labelled tracer tests for measuring transport and natural attenuation characteristics far outweighs the disadvantages, especially when contending with the uncertainties of conventional measurements on disturbed samples in batch, column and microcosm experiments. A greater limitation however, may be the prohibition in some countries of the injection of any amount of hazardous compounds into the subsurface, regardless of benefit/impact ratios.

Dispersivity Estimates from a Tracer Experiment in a Sandy Aquifer

by Dirk Mallants[a,c], Armando Espino[a], Marijke Van Hoorick[a], Jan Feyen[a], Noel Vandenberghe[b], and Walter Loy[b]

Abstract

The success or failure of transport models in predicting the migration of a contaminant plume in ground water depends to a large extent on the quality of flow and transport parameters used. In this study, we investigate the spatial variability in the tracer velocity and dispersivity in a shallow sandy aquifer in northern Belgium. Based on hydraulic conductivity measurements on cores sampled along a vertical profile, the aquifer was found to be mildly heterogeneous, i.e., with the variance of the log-transformed conductivity K, $\sigma^2_{\ln K}$, equal to 0.22. By means of a natural gradient tracer experiment, transport of a chloride tracer was investigated in a three-dimensional network of multilevel point samplers (MLS). Least squares fitting of a two-dimensional transport model to the individual breakthrough curves resulted in an average longitudinal dispersivity that was 10 times larger than the transverse dispersivity. The results further showed the existence of a dispersion-scale effect whereby the depth-averaged longitudinal dispersivity increases with increasing travel distance. The average longitudinal dispersivity corresponding to a travel distance of 10 m was equal to 0.2 m. We finally show that theoretical expressions for the macroscopic dispersivity tensor, which require input on hydraulic conductivity heterogeneity, could be used here to approximate the observed dispersive behavior. These conceptually simple models are useful to estimate macroscopic dispersivities when no tracer data are available.

Introduction

Prediction of subsurface contaminant spreading requires information on the site-specific mixing behavior. The process of dispersive mixing in the direction of mean ground water flow is characterized by the longitudinal dispersivity parameter, whereas transverse dispersion is governed by the transverse dispersivity. Common methods to estimate the dispersivity at a particular site are based on the analysis of controlled field-scale tracer tests (e.g., Freyberg 1986; Garabedian et al. 1988; Jensen et al. 1993) or on uncontrolled migration events such as large contaminant plumes (e.g., van der Kamp et al. 1994; Engesgaard et al. 1996).

The analysis of tracer data from small and large plumes has revealed that the longitudinal dispersivity increases with increasing transport distance (e.g., Gelhar et al. 1992). This so-called dispersion-scale effect may be explained by considering a contaminant plume that encounters a large number of small-scale heterogeneities within a sedimentary unit of the aquifer. These heterogeneities cause spatial variations of fluid velocities, which in turn are responsible for mixing of solutes (Freeze and Cherry 1979).

Several theoretical models have been developed that predict the scale dependence of the dispersivity parameter on the basis of more easily measurable properties, such as the variance and the correlation scale of the hydraulic conductivity (Gelhar and Axness 1983; Dagan 1989). These stochastic models are useful in that they provide estimates of the field-scale dispersivity where direct determination in the field is impossible. However, there is a continuous need to evaluate the predictive capacity of such models for different sediments.

The objectives of the present study are: (1) to map the hydraulic conductivity heterogeneity in the top layer of a sand aquifer; (2) to determine the dispersivity-scale relationship on the basis of a field tracer test; and (3) to test several theoretical models of dispersivity using the field data of the first two objectives.

Materials and Methods

Description of the Experimental Site

The experimental site is located in the northern part of the province of Antwerp, close to the village of Mol, Belgium (Figure 1). At the study site the top 20 m of the aquifer are mainly composed of well-sorted fine, white quartz sands, generally referred to as the Mol sands. The underlying Kasterlee sands (20 to 32 m) contain glauconite-rich silt and clay lenses and are considered to behave as an aquitard (Patijn 1981). The stratigraphy of the top of the sandy aquifer was determined from particle size analysis and the presence of specific minerals such as tourmaline and zircon. Contiguous core sampling (56 cores in total) along a vertical pro-

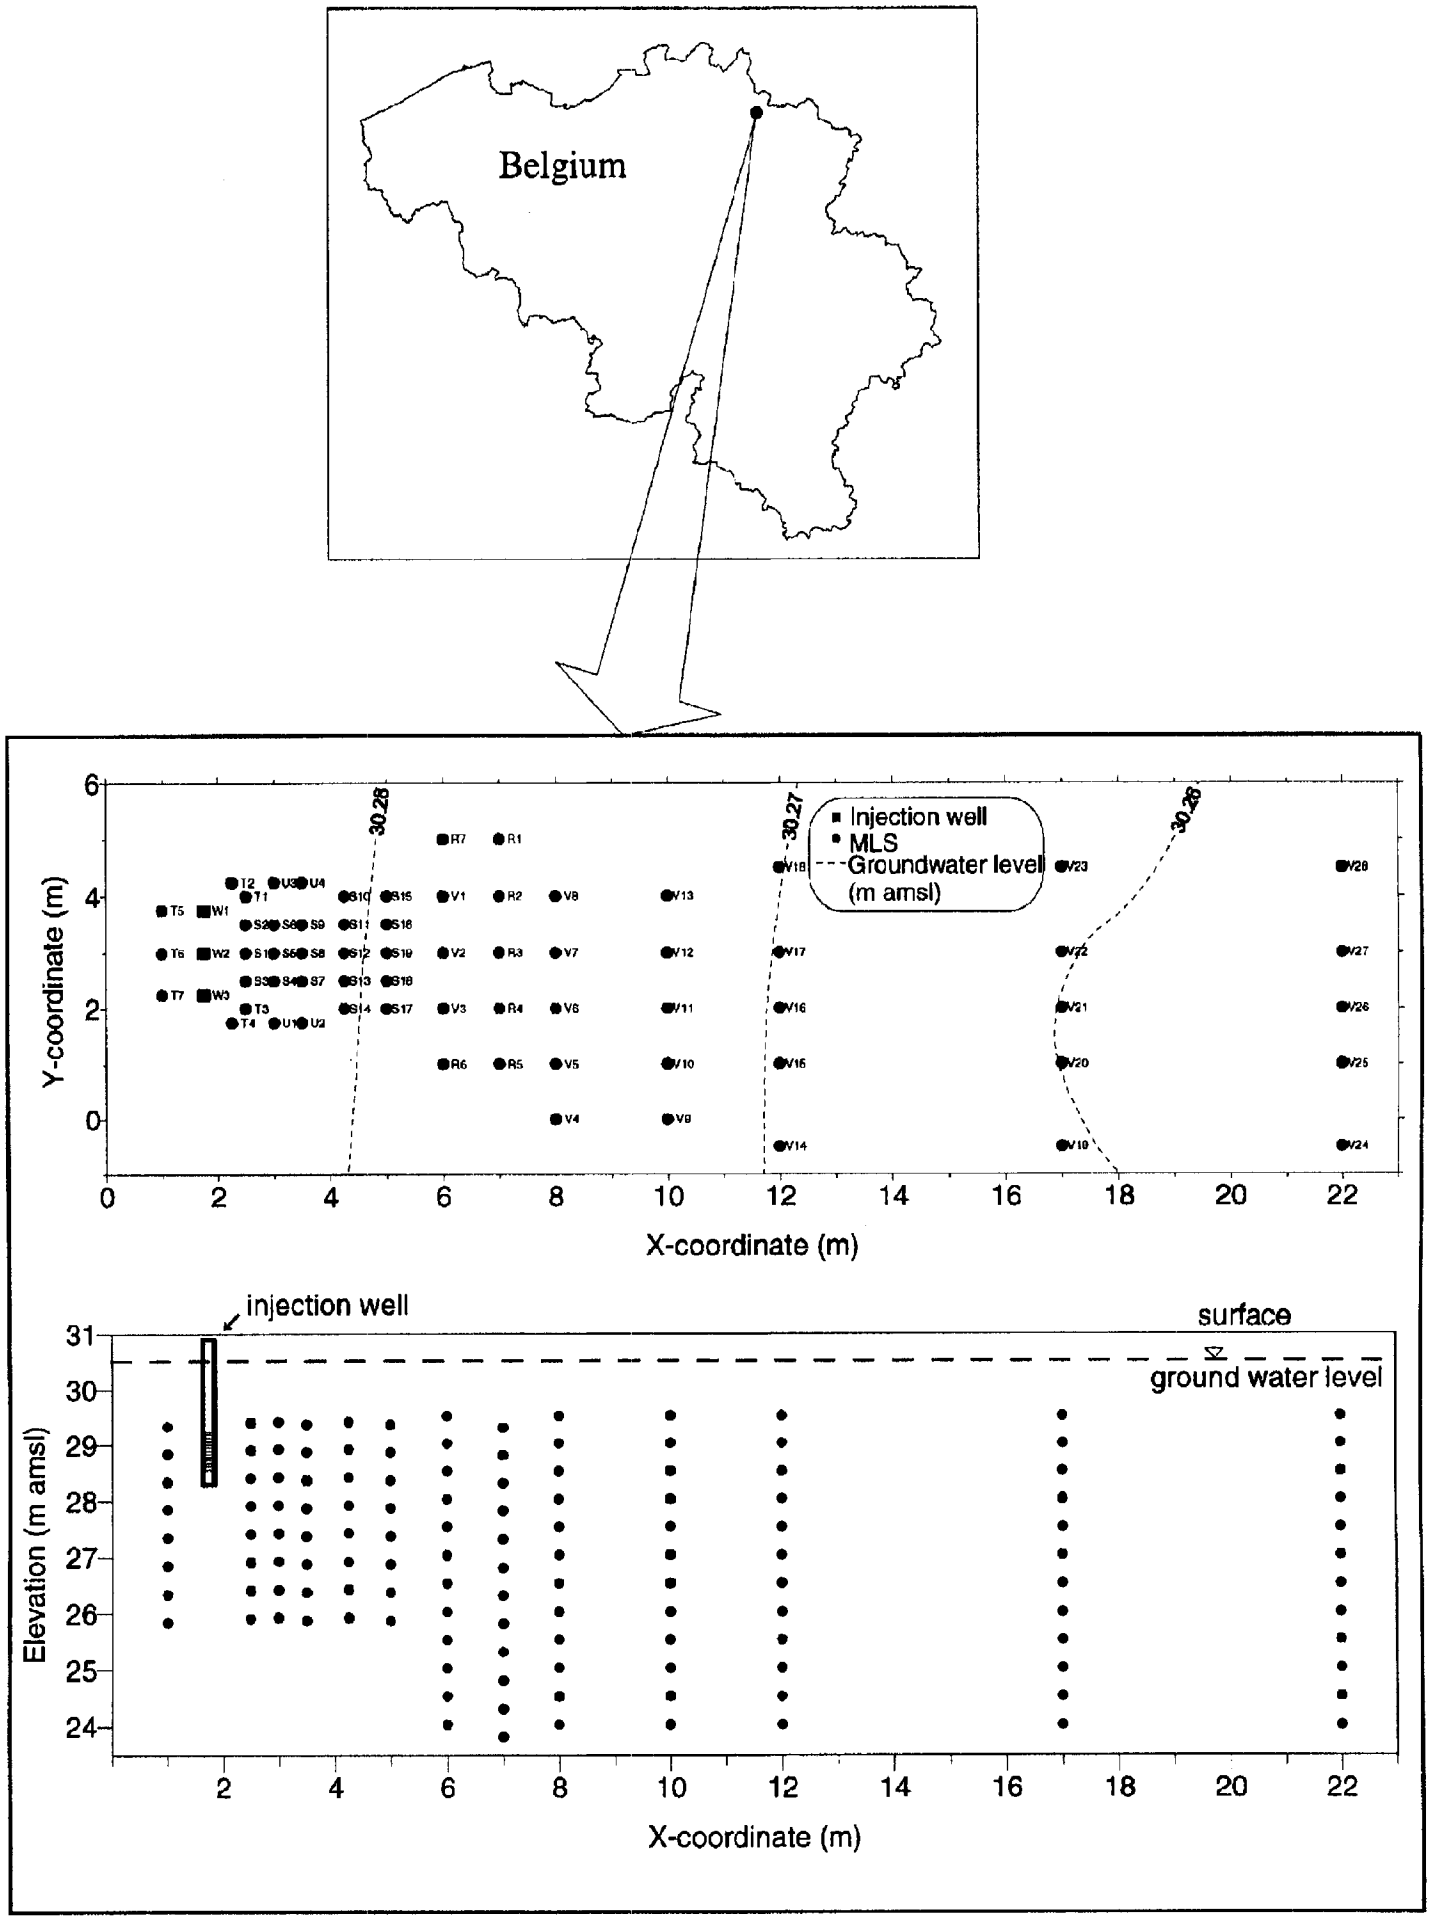

Figure 1. Location of experimental site (top), MLS-network (middle) and cross section of aquifer with sampling ports indicated as closed circles.

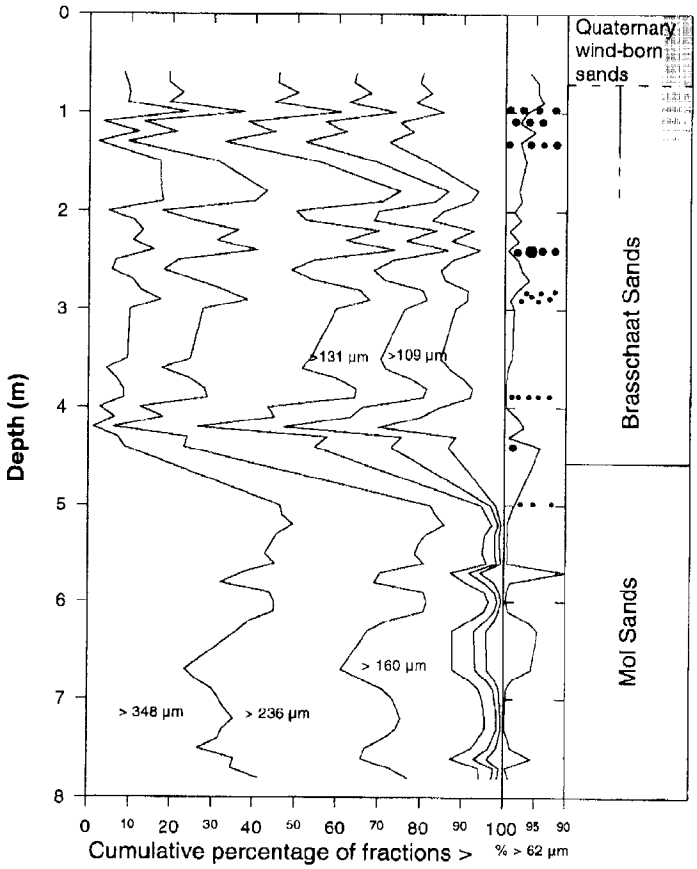

Figure 2. Particle size distribution and stratigraphic analysis of core samples. The left part shows all fractions, whereas the middle part shows only fractions larger than 62 µm. Closed circles represent small stones.

file of 8 m depth and particle size analysis allowed us to construct continuous particle size distribution curves (Figure 2). The cumulative percentage of particles larger than 62 µm is consistently above 90% and, at most depths, even larger than 95%. Between 4 and 5 m, the deeper sands become coarser compared with the shallow ones, with a relatively sharp boundary between the two sediments. Also of importance to the tracer experiment are the Brasschaat sands (from 0.6 to 4.5 m depth) overlying the Mol sands. The former are of Quaternary age (early Pleistocene) and will be referred to hereafter as sediment 1; whereas the latter are marine deposits of Tertiary age (Pliocene), referred to hereafter as sediment 2. The Brasschaat sands are covered by Quaternary wind-borne sands.

Prior to the determination of the particle size and the porosity, we determined the hydraulic conductivity, K, on the same 56 undisturbed core samples. K was measured using a laboratory constant head permeameter. Vertical variability in K is given in Figure 3, together with porosity and estimated transport velocity, v (to be discussed later). The increase in K with increasing depth is consistent with the sands becoming coarser at greater depths, i.e., when moving from sediment 1 to sediment 2. Geometric mean values of K (variance of ln K between parenthesis) for sediment 1 and 2 are, respectively, 7.64×10^{-5} m/s (0.60) and 2.89×10^{-4} m/s (0.33). The global K value for both sediments was 1.83×10^{-4} m/s and the overall variance of ln K was 0.22. The horizontal correlation length for hydraulic conductivity, L, was determined on additional cores collected within the Brasschaat sands (at a depth of approximately 1.5 m). Variogram analysis revealed a value of L = 1 m. Absence of detailed data on the horizontal variability in

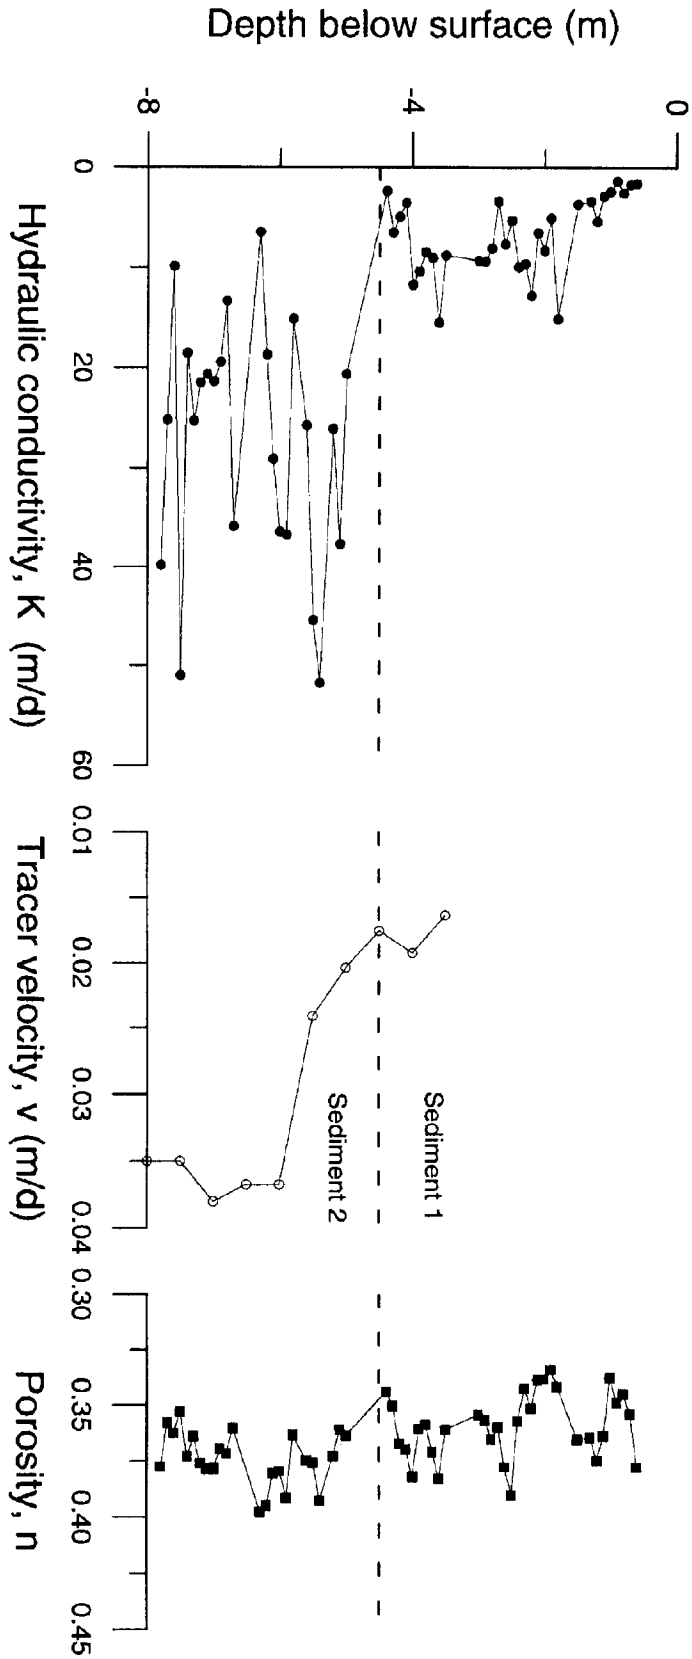

Figure 3. Vertical variability in hydraulic conductivity, K, estimated tracer velocity, v, and porosity, n. Dashed line indicates boundary between sediment 1 and 2.

hydraulic conductivity for the lower layer necessitated the use of data from the upper layer as being representative for the lower one. This may be justified because the spatial structure of sedimentary aquifers is usually controlled by large-scale depositional processes that can be expected to generate a larger continuity in the horizontal

than the vertical direction (Koltermann and Gorelick 1996). It is reasonable to assume that for this mildly heterogeneous sedimentary aquifer the horizontal spatial structure will not change dramatically within a few meters. Values for porosity determined on the same core samples ranged between 0.33 and 0.40, with an average of 0.37.

Tracer Experiment

An array of 65 multilevel samplers was installed to monitor the migration of a tracer (Figure 1). Each MLS had sampling ports every 0.5 m and the ground water was sampled between 1.5 and 7 m beneath the water table. The sampling ports were similar in design to the ones described by Domenico and Schwartz (1998).

A 540 L chloride solution (1.5 g/L) was injected in three injection wells over 17 hours. By means of the spatial arrangement of the three injection wells on a line, the initially contaminated volume of the aquifer may be approximated by a parallelepiped. The spacing of 0.75 m between the injection wells was considered to be close enough to achieve an overlap of the injected tracer volume before the first samplers would be reached. The estimated size of the parallelepiped was $0.72 \times 1 \times 2.2 = 1.58$ m^3. The injection wells were screened from 1 to 1.5 m below water level. There was no noticeable increase in water level at the time of injection. Sampling of the MLS started immediately after injection and continued for more than 200 days. Chloride concentrations were determined by means of potentiometric titration. The central line of MLS (S1-S5-S8-etc.) was sampled most frequently, whereas snapshots of the three-dimensional plume behavior were taken approximately every month. The average hydraulic gradient for the entire sampling period ranged between 0.0024 and 0.0035 (Figure 1).

Dispersion Models

Chloride breakthrough curves were constructed for sampling ports that had been monitored almost weekly. Transport parameters were obtained by fitting a two-dimensional transport model to the individual breakthrough curves. For a two-dimensional uniform flow field and an instantaneous injection of a tracer, the model is given by Bear (1979):

$$C(x,y,t) = \frac{M}{4\pi nbt(D_L D_T)^{0.5}} \exp\left(-\frac{(x - vt)^2}{4D_L t} - \frac{y^2}{4D_T t}\right) \quad (1)$$

where C is concentration, M is the injected mass, n is porosity, b is the thickness of the aquifer, v is flow velocity in x direction, D_L and D_T are the local scale longitudinal, respectively transverse dispersion coefficient owing to small-scale velocity variations, x and y are spatial coordinates, and t is time since start of injection. The velocity in the y direction is assumed to be zero, and the x axis is oriented in the direction of flow.

Several solutions to the advection-dispersion equation exist. For instance, Sudicky et al. (1983) and Moltyaner and Killey (1988a, 1988b) applied an analytical solution describing the movement of a contaminant released as a rectangular parallelepiped. Others such as Leland and Hillel (1982) have applied the solution for an instantaneous point injection to a tracer test similar in layout to ours. All these analytical solutions are based on the assumption of unidirectional and uniform flow. Regardless of the analytical model applied, it will provide only an approximate description of the transport and dispersion process. As a result, dispersivities thus obtained may be considered only approximate. Furthermore, when the size of the injection volume is small relative to the sampled part

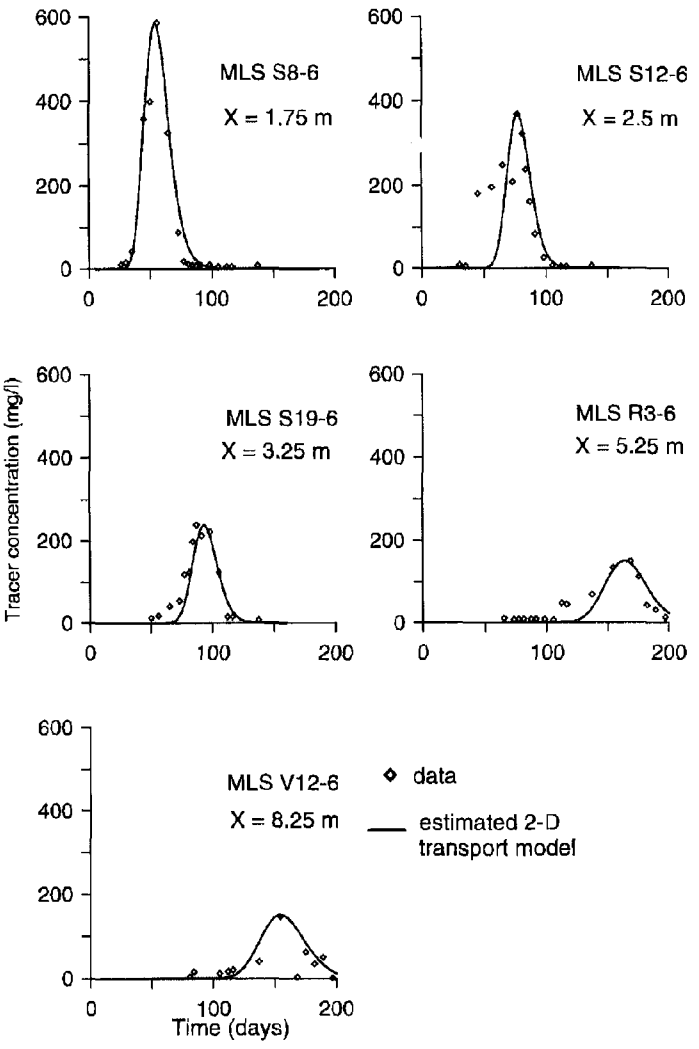

Figure 4. Observed and estimated tracer concentrations in five MLS located on a central line in the direction of ground water flow (at a depth of 4 m below surface). MLS S8-6, MLS12-6, etc., indicates the code of each sampler (for location, see Figure 1), with the second number referring to the sampling port (in this case the sixth). Distance from injection well is also indicated.

of the aquifer, the solution to the two-dimensional transport model for an instantaneous point injection given by Bear (1979) may be used to a parallelepiped source. Finally, because the 17-hour injection time is still small relative to the travel time to the different samplers, we considered the injection to be effectively instantaneous.

The parameter estimation code of Sauty and Kinzelbach (1988) was used to obtain the flow velocity and the longitudinal and transverse dispersion coefficients by minimizing the differences between the calculated and observed tracer concentrations. Application of Equation 1 further assumes a uniform vertical solute concentration. On the basis of the depth distribution of the hydraulic conductivity (Figure 3) it was evident that a more conductive layer was underlying the top layer starting approximately at 4 m below surface. This vertical inhomogeneity in hydraulic conductivity suggested that an injected tracer could migrate differently (i.e., faster) in the lower layer compared with the upper one. Therefore, the multilevel samplers were used to obtain a profile of estimated pore water velocities and dispersivities across the vertical dimension of the aquifer. Accordingly, rather than fitting Equation 1 to vertically averaged breakthrough curves, we first used Equation 1 to describe transport at different depths and then averaged the dispersivities with

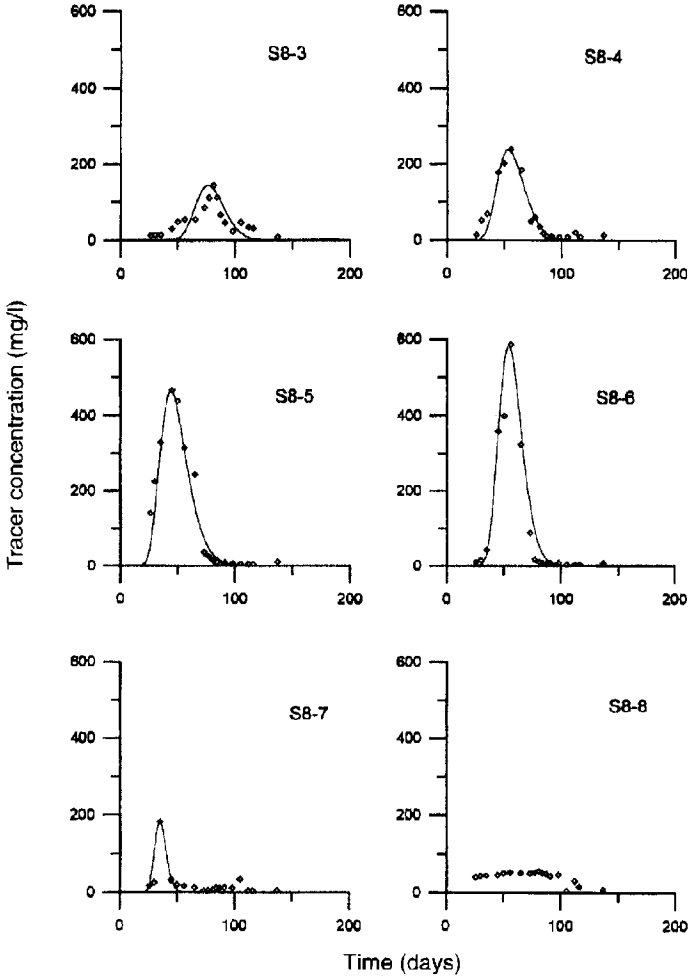

Figure 5. Observed and estimated tracer concentrations in MLS S8 located at 1.75 m from the injection wells. Distance between depth intervals is 0.5 m, with S8-3 at 2.5 m below surface.

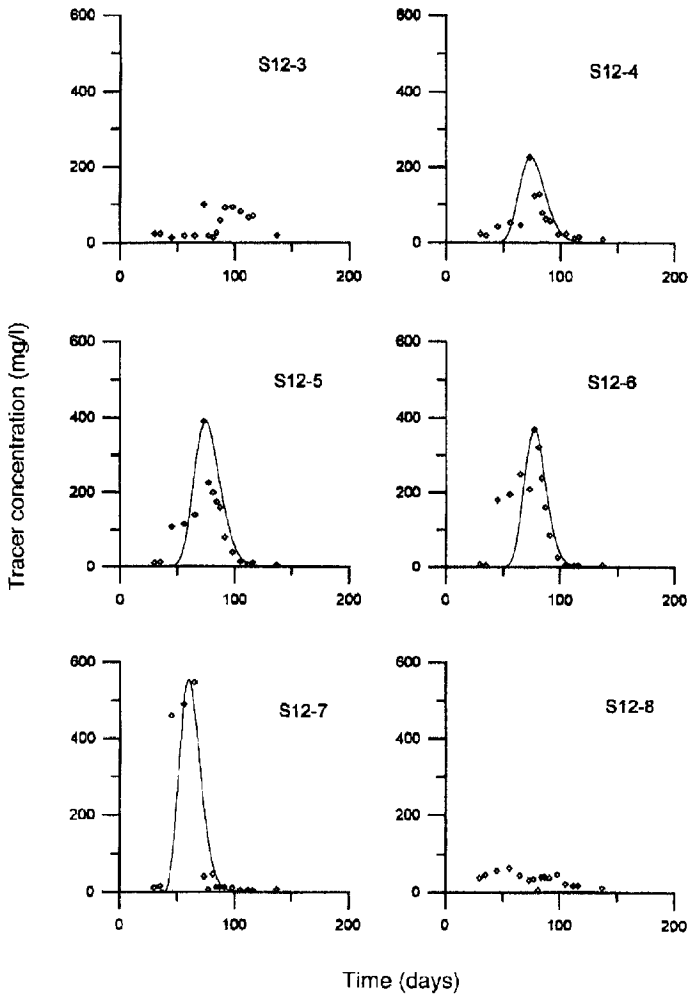

Figure 6. Observed and estimated tracer concentrations in MLS S12 located at 2.5 m from the injection wells. Distance between depth intervals is 0.5 m, with S12-3 at 2.5 m below surface.

depth.

The depth b = 30 m and the porosity n were adjusted dependent upon depth (Figure 3). From the estimated dispersion coefficients, D_L and D_T, we calculated the longitudinal and transverse dispersivities, α_L and α_T, as

$$\alpha_L = \frac{D_L}{v}$$
$$\alpha_T = \frac{D_T}{v} \qquad (2)$$

Results and Discussion

Estimating Dispersivity Parameters

Typical breakthrough curves measured at a depth of 3 m below the water table are given in Figure 4, with the fitted two-dimensional model. All five multilevel samplers are located on one line in the direction of the main flow, with the first one at a distance of x = 1.75 m from the middle injection well. The vertical distribution of the pore water velocities that were estimated by fitting of Equation 1 to the breakthrough curves is shown in Figure 3. Each value represents the average of all values estimated at that particular depth. As could be expected from the hydraulic conductivity distributions with depth, v also increases with increasing depth: from 0.016 m/d at 4 m to 0.035 m/d at 8 m depth. Note that although the average hydraulic conductivity of sediment 2 is almost four times larger than that of sediment 1, the pore water velocity in sediment 2 is only twice as large as that of sediment 1. This discrepancy may indicate the presence of a vertical flow component not accounted for in the model, leading to an underestimation of the true velocity and/or an overestimation of the measured K values because of the use of small diameter samples that may have exhibited flow along the core wall. Additional explanations could be the uncertainties due to the parameter optimization approach and the use of straight line distances from the injection wells to the different samplers in calculating the velocities.

Observed and fitted breakthrough curves at different depths along the same vertical line for two multilevel samplers (MLS S8 and MLS S12) are shown in Figure 5 and 6, respectively. For multilevel sampler S8, at 1.75 m from the injection wells, the center of the plume is somewhat in between sampling port 5 and 6. The maximum concentration occurs at sampling port 6, approximately 4 m below surface. At 2.5 m from the injection wells (MLS S12), the center of the plume has slightly stretched in the vertical direction and now also includes sampling port 7, where the tracer maximum is. These observations suggest that there is a small but noticeable vertical movement between the depth intervals, possibly the combined result of density effects, short-circuiting between different

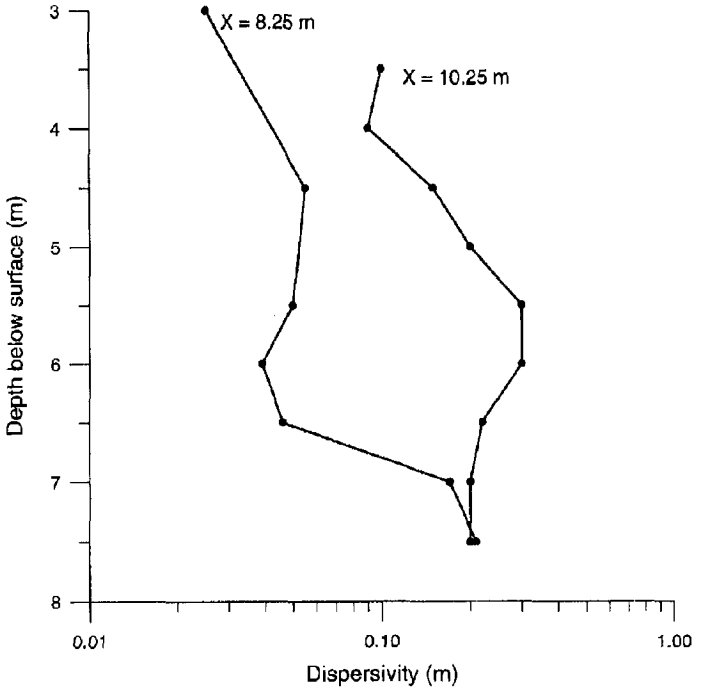

Figure 7. Longitudinal dispersivity versus depth below surface (based on data for MLS V12 and V17).

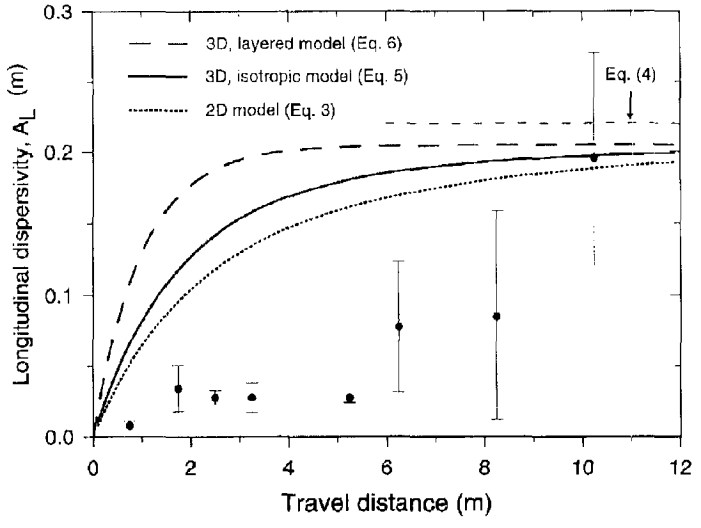

Figure 8. Behavior of dispersivity with increasing travel distance. Average observed longitudinal dispersivities are indicated as closed circles (error bars are one standard deviation). Theoretical models are based on Equations 3 through 6.

depth intervals as a result of higher permeabilities around the multilevel samplers, or some other reason. The effect of this vertical movement on the estimated transport parameters is small, i.e., an increase in dispersivity with increasing depth was found to exist but it was small and not systematic. For instance, Figure 7 shows the vertical variability in the dispersivity parameter for two multilevel samplers at 8.25 and 10.25 m, respectively, from the injection wells. In the first profile at x = 8.25 m, the dispersivity varies between 0.03 m at 3 m depth and 0.05 m at 6.5 m depth. A significant increase occurs at the 7 and 7.5 m depths, where a maximum value of 0.20 m was found. The second profile shows a somewhat different behavior, with an increasing dispersivity from 0.1 m at 4 m depth to 0.3 m at 5.5 and 6 m depth. At greater depths, it decreases again to 0.2 m. From these data it is clear that the dispersivity behaves rather erratically with depth, presumably caused by variability in hydraulic conductivity in both vertical and horizontal directions. Since the purpose of the study was to investigate the effects of small-scale heterogeneities on flow and transport parameters, the analysis was done using the individual breakthrough curves rather than composite curves calculated as the average of the concentrations measured at all depths of a particular sampler. The latter tend to average out the effect of small-scale heterogeneities.

A statistical analysis of the transport parameters v, α_L, and α_T revealed a lognormal probability density function for all three parameters. The mean (and standard deviation) values were v = 0.025 (0.014) m/d, α_L = 0.09 (0.093) m, and α_T = 0.0085 (0.047) m, respectively. The ratio α_L/α_T is approximately equal to 10, which is well within the range of five to 100 proposed by de Marsily (1986).

All calculated dispersivities with approximately the same distance traveled from the source were averaged. These values are shown in Figure 8 with their standard deviation. The average dispersivity increases from 0.01 m for x = 0.75 m to 0.2 m for a travel distance of 10.15 m. According to the compilation by Gelhar et al. (1992) of dispersivity values taken from the literature, observed dispersivities for a travel distance of 10 m range from 0.01 to 10 m. From Figure 8 we further note the presence of a dispersion scale effect, but there is insufficient data to conclude whether or not the plume traversed sufficient heterogeneities such that the dispersion would remain constant.

Testing of Macro-Dispersion Models

The property of the aquifer that characterizes the macrodispersive spreading owing to spatial variations of macroscopic pore water velocities is the macro-dispersivity, A. These velocity variations are caused primarily by hydraulic conductivity heterogeneities, although they also may be attributed in part to spatial variability in effective porosity or the transient nature of flow directions (this mainly affects the transverse macro-dispersion [Rehfeldt and Gelhar 1992]). Because spatial variability in hydraulic conductivity is generally orders of magnitude larger than variability in porosity (Koltermann and Gorelick 1996), the effect of the latter is often neglected. Considering our data set, the coefficient of variation CV for hydraulic conductivity was 0.49, whereas that for total porosity was 0.04. From Figure 3, we further note that differences in total porosity across the boundary between layer one and two are small. For sandy materials, total porosity is nearly identical to effective porosity (de Marsily 1986). Therefore, the observed variability in total porosity presumably contributes little to the dispersion process.

Several theoretical models exist to predict the macro-dispersion. Most of these models make use of the variability of the hydraulic conductivity (in terms of the variance of lnK, σ^2_{lnK}) and the correlation length of lnK, L, the latter being the distance for which the spatial correlation between K values becomes zero. In case of two-dimensional ground water flow in an isotropic aquifer (the assumption is that the correlation length in the x and y directions is the same), the following models may be used to predict the longitudinal macro-dispersivity A_L for intermediate travel distance (Sposito and Barry 1987):

$$A_L = L\,\sigma^2_{lnK_s}[1 - 3(2x/L)^{-1} - 3(x/L)^{-2}\exp(-x/L) + 3(x/L)^{-3}(1 - \exp(-x/L))] \quad (3)$$

and long travel distance ($x \rightarrow \infty$) (Gelhar 1993):

$$A_L = \sigma^2_{lnK_s} L$$

(4)

In case of three-dimensional ground water flow and an intermediate travel distance, the following model exists for an isotropic aquifer (Gelhar 1993):

$$A_L = \frac{L\,\sigma^2_{\ln K}}{\gamma^2}[1 - 4(x/L)^{-2} + 24(x/L)^{-4} - 8[(x/L)^{-2} + 3(x/L)^{-3} + 3(x/L)^{-4}]\exp(-x/L)] \quad (5)$$

where $\gamma = \exp(\sigma^2_{\ln K}/6)$.

The model for a stratified aquifer (the horizontal correlation length is much larger than the vertical) is

$$A_L = \frac{L\,\sigma^2_{\ln K}}{\gamma^2}(1 - \exp(-x/L)) \quad (6)$$

The theoretical behavior of A_L was calculated for all four models using the previously determined values of $\sigma^2_{\ln K} = 0.22$ and L = 1 m (Figure 8). The two-dimensional model for long travel distance clearly is an asymptotic model, which only slightly overestimates the average measured dispersivity. Moreover, the value for A_L predicted by the long-distance model (i.e., 0.22 m) is close to the measured one, i.e., 0.2 m. The two-dimensional model for intermediate distance overpredicts the measured values at intermediate distance, but it is nearly identical to the measured value at x = 10.15 m. The three-dimensional models also overpredict the measurements at early and intermediate distance, but their behavior at x = 10.15 m is close to the data. The difference between the two- and three-dimensional models at long travel distance is that the latter reach their constant value at x = 10 L (i.e., at x = 10 m, when L = 1 m), whereas the former becomes constant only after approximately 60 correlation lengths (i.e., at x = 60 m, when L = 1 m; Dagan 1989).

Although the theoretical dispersivity models use only data on hydraulic conductivity heterogeneity, their predictions are within a factor of 2 to 3 from the measurements for distances larger than 5 m. Closer to the origin, differences are larger, probably owing to the small distance traveled and the relatively small number of heterogeneities encountered by the solute plume. Nevertheless, the power of the theoretical models to predict macro-dispersivities in the absence of tracer data warrants further development and testing under different hydrogeological conditions.

Conclusions

A ground water tracer test was conducted in which the solute plume traveled through fairly homogeneous sandy sediments where the lower part was more permeable than the upper part. The results revealed a vertical distribution of the tracer velocity, which showed the same trend as the vertical variability of hydraulic conductivity measurements. However, the average tracer velocity for the lower sediment was only twice as large as that of the upper sediment, whereas the average conductivity for the lower sediment was four times larger than that of the upper. Based on a two-dimensional transport model, average estimated values for the longitudinal and transverse dispersivity were 0.09 and 0.0085 m, respectively. At the maximum travel distance of 10.15 m the average dispersivity was 0.2 m. Theoretical macro-dispersion models that use the variance and correlation length of hydraulic conductivity measurements as inputs predicted the dispersivity at x = 10.15 m fairly well. For shorter travel distances, the predictions were less accurate. This study illustrates how important good estimates of hydraulic conductivity are in contaminant transport research.

Field Test for Effective Porosity and Dispersivity in Fractured Dolomite, the WIPP, Southeastern New Mexico

D. D. Gonzalez

H. W. Bentley
Hydro Geo Chem, Inc., Tucson, Arizona 85716

Introduction

The Waste Isolation Pilot Plant (WIPP), a demonstration facility 26 mi (41.6 km) east of Carlsbad, New Mexico, used to store transuranic waste in Permian-bedded salts, has been under field investigation since 1975. Hydrologically, the area is characterized by a typical semiarid environment underlaid by four confined aquifer systems whose transmissivities range from 10 to 10^{-5} ft^2/d (1 to 10^{-6} m^2/d).

Previous local hydrogeologic investigations show a fractured dolomite, whose thickness and depth of burial range from 22 to 24 ft (6.7 to 7.3 m) and 498 to 897 ft (152 to 274 m), respectively, as the most likely groundwater vehicle to transport waste to the biosphere in the event such a repository is breached. To describe adequately and to predict solute transport, certain hydraulic characteristics of the transporting medium need to be estimated along a hypothetical flow path. Effective porosity and dispersivity are two parameters which are most difficult to predict, particularly in fractured rock exhibiting low transmissivities. This paper describes the results of the first of a series of two-well recirculation tracing tests to be performed. The recirculation tests were performed using an extraction-injection well couplet similar to that described by Grove and Beetem [1971]. Test duration was

270 days and resulted in a well-defined breakthrough curve. Specific test configurations are described in detail in a later section of this paper.

H-2 Site Description

The regional hydrogeology of the WIPP area has been described by Hiss [1976], Powers et al. [1978], and Mercer and Orr [1979]. Hydrologic testing at the H-2 site has concentrated on the three liquid-bearing zones above the proposed waste repository horizons. These are the Permian Rustler-Salado contact and the two beds within the Rustler Formation: the Culebra and the Magenta Dolomite members.

The H-2 wells were drilled by the U.S. Geological Survey (USGS) and Sandia National Laboratories in 1977. H-2A was completed to the Magenta at a depth of 563 ft (172 m). H-2B was drilled to the Culebra at 661 ft (202 m), then perforated in the Magenta, and completed as a dual-observation well. H-2C was drilled to the Rustler-Salado contact at 743 ft (227 m), perforated in the Culebra, and also completed as a dual-observation well [Mercer and Orr, 1979]. Figure 1 shows the three-well configuration, the zones each is open to, and their general orientation.

The three liquid-bearing zones were cored and analyzed by the USGS. A description of these cores, taken from Mercer and Orr [1979], is given in Tables 1a - 1c.

Hydrologic testing of the Rustler-Salado contact and of the Magenta Dolomite Member consisted of bailing each well dry and observing the recovery response. Estimates of transmissivity in the Rustler-Salado contact were between 10^{-1} and 10^{-4} ft^2/d (1 and 10^{-5} m^2/d). The transmissivity in the Magenta averaged about 0.1 ft^2/d (0.01 m^2/d) [Mercer and Orr, 1979].

Three aquifer tests with observation wells were made to determine hydraulic properties of the Culebra. The average transmissivity from these tests is 0.6 ft^2/d (0.06 m^2/d); storage coefficient is about 1.3×10^{-5} [Bentley and Walter, 1983].

773.5-795.6	light pink to light red-orange polyhalitic halite, minor clay partins, with brown halitic clay at base

Rustler-Salado cored interval: 743-795 ft; top of Rustler-Salado contact: 764 ft.

Tracing Test Configuration

Test 1

The pumping and injecting system for test 1 included H-2B as the pumping well and H-2C as the injecting well (Figure 1). Pumping was begun on February 13, 1980, to allow the aquifer to approach steady state flow conditions. Injection of sodium benzoate (SBA), pentafluorobenzoate (PFB), and a suite of halocarbon tracers (CCl_4, $CFCl_3$, and CF_2Cl_2) was begun at 2330 hours on February 22, 1980, at

which time the water flow rate through the system was 1140 ml/min. Injection continued until some time between 1200 hours on February 24 and 1200 hours on February 25, when the tracer injection line ruptured and the remainder of the tracers were lost.

Pumping continued in an attempt to complete the test successfully; however, sediment accumulation affected the injection system and the performance of the injection well, H-2C, until the test was terminated June 18, 1980.

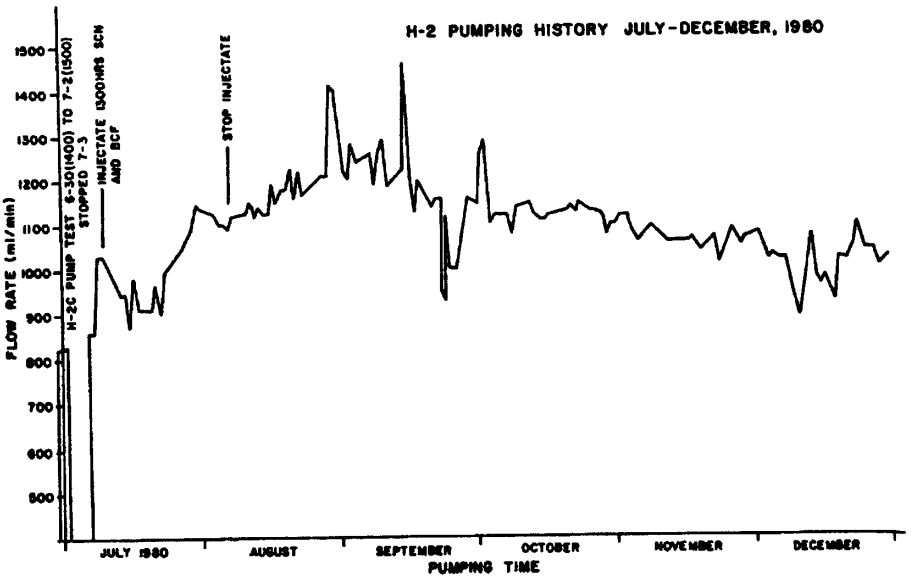

Fig. 2. H-2 pumping history July-December 1980.

Test 2

After the abortion of test 1 the site was reconfigured with H-2C as the pumped well and H-2B as the injection well. A combination of in-line filters and a settling tank alleviated almost all problems with sedimentation. After pumping to steady state, tracer injection was begun on July 10, 1980, with sodium thiocyanate (SCN) and bromochlorodifluoromethane (BCF) and continued for 28 days at rates of 1.9 ml/min for SCN and 0.75 ml/min for BCF.

Pumping of H-2C continued for 274 days until the test was terminated when the data suite was completed on April 7, 1981. The discharge from H-2C varied from 930 to 1460 ml/min, as shown in Figure 2.

Tracer Injection

Analysis of the two-well recirculating test [Grove and Beetem, 1971] depends on a constant concentration of tracer having been injected for a significant fraction of the test period. This constant injection was accomplished by the use of a MPL Micrometering Pump equipped with three pumping units capable of pumping at rates of 0.092 to 60 ml/min with 2% accuracy. In the case of the volatile tracers, which were dissolved in isopropanol, the potential changes in concentration due to volatilization or variable head space were eliminated by injecting from a 40-gal. pressure tank equipped with an internal neoprene diaphragm. Figure 3 is a schematic of the tracer injection system. Recirculation and injection was accomplished by a 3/4-in. (1.9 cm) pipe string connecting the pumping well and the injection well. At the injection well the pipe was connected to a 1/2-in. (1.3 cm) polyethylene tubing which was run down to the well perforations at the Culebra. Thus the volatiles were introduced at a maximum water depth, which minimized losses. Both the volatile and anion tracers were injected into the formation with little dilution by the water stored in the well bore.

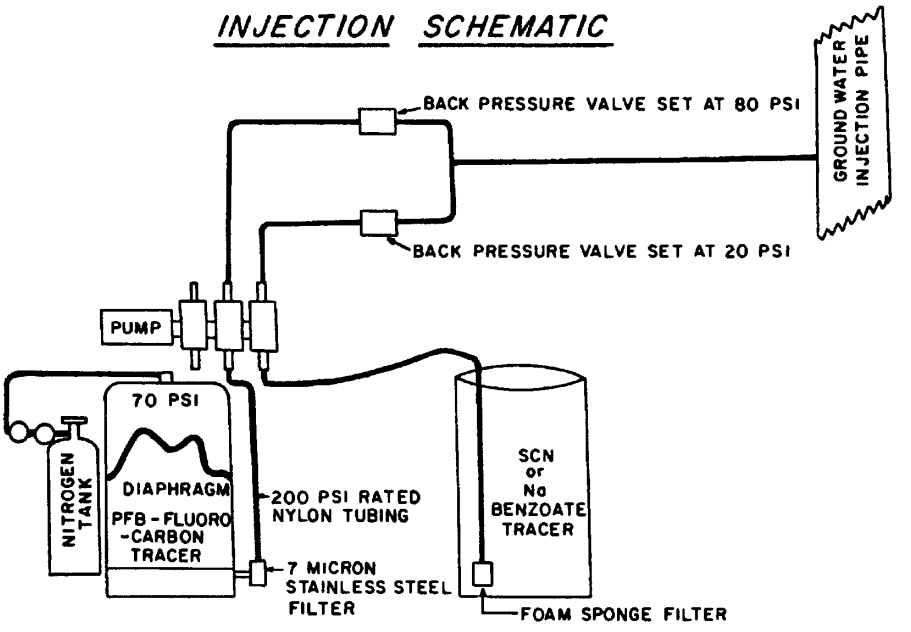

Fig. 3. Schematic of tracer injection circuit.

Tracer Collection

Anion tracers were collected from a faucet at the pumping head and stored in 250-ml polyethylene bottles and, later, in 30-ml plastic scintillation counting bottles. Volatiles were collected in 30-ml melt seal vials which were sealed within 5 min with a butane torch.

Tracer Analysis

Volatile tracer injectate concentrations were estimated at the site by direct injection into a Varian 3000 gas chromatograph equipped with a 6-ft (1.8 m) Carbopak 1/8-in. (0.3 cm) column and an electron capture detector. These analyses were qualitative, made only to establish that the tracers were in the proper range, approximately 1 mg/l. No subsequent analyses of these tracers were made. Anion tracer injectate concentrations were analyzed by

Injection July 10, 1980; average concentration 721 $\pm$ 27 mg/l.

high performance liquid chromatography (HPLC). HPLC was used onsite for the first tracing test for PFB and SBA tracer injection. Average injection well concentrations were 721 $\pm$ 27 mg/l for SCN^-, 650 mg/l for SBA, and 213 mg/l for PFB.

As the tracing test proceeded, tracer samples were sent to the Hydro Geo Chem laboratory in Tucson, Arizona, for further analysis. Laboratory analysis included HPLC measurement of SCN^- and PFB.

Table 2 shows the SCN^- results. Table 3 represents the PFB data. Standards were analyzed every fifth to tenth chromatogram, and two analyses were made for each sample. If the results did no agree within 2% or less, a third analysis was performed.

Tracer Stability

Both SCN^- and PFB appear to be refractory in the Culebra. Moreover, neither has shown any degradation at mg/l levels in Culebra H-2

water when stored in the laboratory for several months. PFB was first injected at H-2C on February 13, 1980, recovered in August 1980, and analyzed in September 1981, with no apparent losses occurring in the formation or in the laboratory. Studies with mixtures of barnyard soils and water yield similar results [H.W. Bentley, personal communication, 1983].

Results and Interpretation of H-2 Recirculation Test 2

A numerical analysis of the H-2 recirculation test was performed using the Grove and Beetem [1971] model. The model consists of a recharging-discharging well pair with a pattern of streamlines and treats the aquifer as uniform and isotropic and pumping as constant. To calculate the movement of the tracer, the model approximates the infinite number of streamlines by a finite number

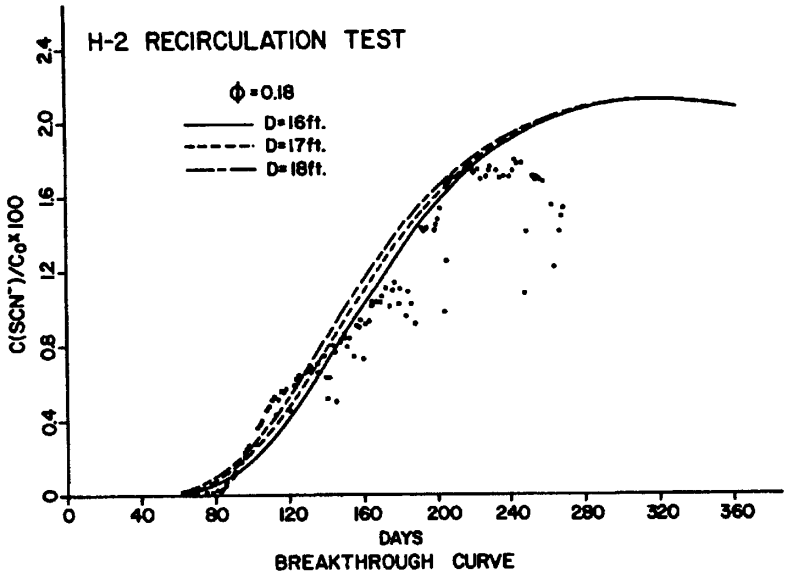

Fig. 4 Two-well recirculation SCN^- tracing test at the H-2 well pad, WIPP, SE New Mexico. Lines are output from the Grove and Beetem [1971] model with porosity ϕ fixed and varying dispersivities α.

of crescents. Each crescent is treated as a one-dimensional flow tube with only longitudinal dispersivity defined. This model uses the one-dimensional solution to the convective-dispersive equation for a finite column:

$$\frac{\partial c}{\partial t} = - v \frac{\partial c}{\partial x} + D \frac{\partial^2 c}{\partial x^2}$$

as presented by Brenner [1962]. The boundary conditions used by Brenner are

$$qC_o = vc - D \frac{\partial c}{\partial x}$$

at $x = 0$ borehole surface of injection well and

$$\frac{\partial c}{\partial x} = 0$$

at $x = L$ borehole surface of extraction well, where $x = 0$ and $x = L$ are the coordinates of the injection and pumping wells, respectively, and

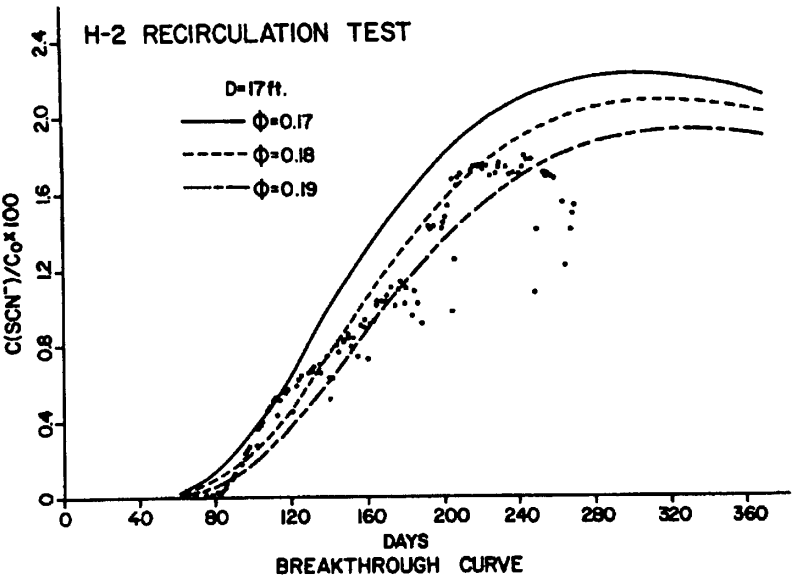

Fig. 5. Two-well recirculation SCN^- tracing test at the H-2 well pad, WIPP, SE New Mexico. Grove-Beetem curves show effects of changes in porosity ϕ by 0.01 with dispersivity α fixed at 17 ft.

q Darcy velocity, L/T;

C_o initial concentration, M/L^3;

v seepage velocity, L/T;

c observed concentration, M/L^3;

D coefficient of hydrodynamic dispersion, L^2/T;

x distance, L;

α dispersivity;

D αv.

The boundary condition used by Brenner at the extraction well implies no dispersive flux. Although this boundary condition has often been used to represent finite length columns, its physical validity is questionable.

An attempt was made to fit the observed data from the H-2 recirculation test with the Grove and Beetem model using a range of porosities, ϕ, and dispersivities, α. The result of variations in

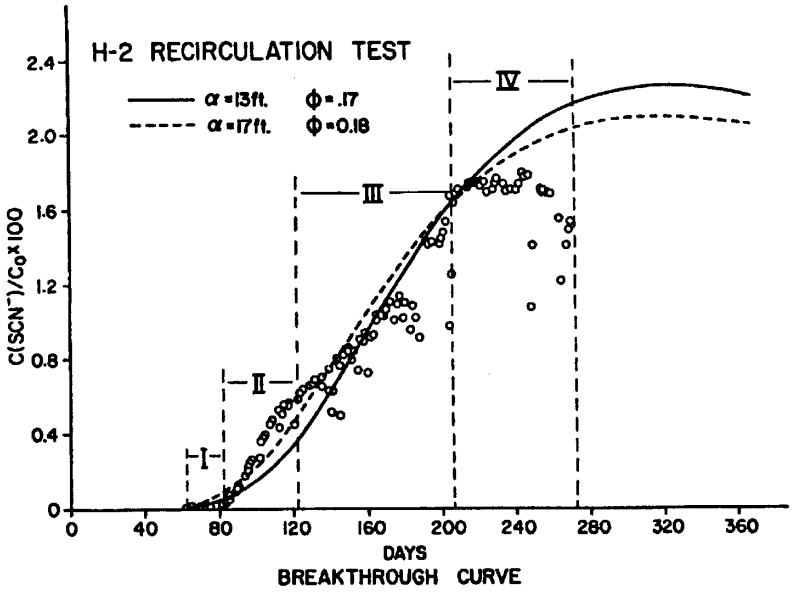

Fig. 6. Attempts to fit various parts of the SCN^- tracer breakthrough curve with varying dispersivity α and porosity ϕ.

α with a given ϕ is shown in Figure 4. Increases in α displace the curves toward earlier times. However, they have little effect on the curve slope or maximum.

Figure 5 demonstrates the variation in curves when α is fixed and ϕ is allowed to change. The porosity variations produce much larger effects in the first appearance time, slope of limb, peak time, and value of peak. For the values of α and ϕ shown, changes in porosity have a much larger effect on the breakthrough curve than changes in dispersivity.

Simplifying, the observed breakthrough curve was divided into four segments, as shown in Figure 6. Segment I extends from about 60 to 80 days after injection during which time the tracer first reached detectable concentrations. Segment II extends from 80 to 120 days during which time the concentration rose rapidly. Segment III includes that portion of the curve between 120 and 200 days where the curve is concave upward. Finally, segment IV begins at

200 days when the tracer curve becomes convex, reaches a maximum, and finally declines.

Two curves are shown in Figure 6 corresponding to α = 13 ft (4 m) with ϕ = 0.17 and α = 17 ft (5.2 m) with ϕ = 0.18. The solid line for α = 13 ft (4 m) and ϕ = 0.17, fits segment I and the early part of segment IV reasonably well but does not fit segments II and III. The dashed line in Figure 6, corresponding to α = 17 ft (5.2 m) and ϕ = 0.18, is considered to be the best fit for the first three segments of the breakthrough curve. Although this curve also matches the very early portion of segment IV, it does not match the late time data. The Grove-Beetem model cannot be used to generate a breakthrough curve matching the decline in concentration after about 220 days. Given the shape of the observed breakthrough curve in segments II and III, neither the Grove-Beetem model nor any other solution to the two-well problem that treats the formation as uniform and discharge as constant can be expected to represent accurately the observed breakthrough curve.

Conclusions

As a result of tracer performance and simplicity in handling and analysis, the anions PFB and SCN are the tracers of choice for use in evaluating aquifer parameters in dolomites at the WIPP.

Porosity and dispersivity at H-2 have been estimated at 18% and 17 ft (5.2 m), respectively. The data obtained from recirculating tests are valuable in establishing the flow and solute transport regime in the Culebra Dolomite of the Rustler Formation in the vicinity of the H-2 location. The type curves generated by the Grove-Beetem model fit the early portions of the data, however, do not match late-time data. The model cannot match the decline in concentrations without modification to include anisotropy, variable pumping rates and boundary conditions, and solute retardation in terms of matrix permeability.

A site specific numerical model is indicated, utilizing both recirculation and convergent flow tracer test for calibration. At

H-2, for instance, convergent flow tracer tests and aquifer tests for anisotropy should be performed. These results coupled with the H-2 recirculating tests will provide the basis to generate a model which describes these local phenomena and will provide guidance in establishing the field operations plan. Presently, anisotropy and tracer tests are planned at six hydropads along a hypothetical flow path originating at the center of the WIPP proposed facility and leading towards the discharge area near the Pecos River, 17 mi (27.4 km) away. Hydropad modeling will serve as the basis for a regional flow and solute transport model.

Ground Water Flow in a Fractured Carbonate Aquifer Inferred from Combined Hydrogeological and Geochemical Measurements

by L. Zanini[a], K.S. Novakowski[b], P. Lapcevic[c], G.S. Bickerton[a], J. Voralek[c], and C. Talbot[c]

Abstract

A conceptual model for ground water flow is presented for a fractured Silurian dolomite in the Niagara Escarpment area of southern Ontario. Such a model is necessary to facilitate remedial efforts of a PCB-contaminated site located in Smithville, Ontario. Both physical and chemical hydrogeological observations obtained from field investigations were used to deduce the structure of the ground water flow system in the fracture network. The field study was conducted using observations obtained from six boreholes drilled in the vicinity of the town of Smithville. The boreholes were diamond cored through the entire thickness of the dolomite formation (approximately 45 m), hydraulically tested using a 2 m packer spacing and then completed using multipacker casing strings. Measurements of hydraulic head were obtained on a weekly basis over a period of two years, and ground water from each borehole interval was collected for geochemical analyses for inorganic and isotopic composition. Transmissivity measurements indicate that the dolomite is divided into two ground water flow systems separated by an extensive unit of low transmissivity that is pervasive throughout the region. The upper flow system is characterized by water enriched in Mg^{2+} and SO_4^{2-}. Below the low transmissivity zone, ground water increases in salinity and is enriched in Ca^{2+} and SO_4^{2-}. Based on the geochemistry, the rate of ground water migration in the lower flow system is surmised to be much less than that in the upper system. Measurements of hydraulic head in conjunction with the results of the analyses of the environmental isotopes ($\delta^{18}O$ and δ^2H) suggest that ground water flow is mainly horizontal and likely governed by enlarged bedding plane fractures. The isotope geochemistry and topographical features further suggest that ground water recharge is occurring approximately 2 km to the north of Smithville.

Introduction

The Niagara Escarpment is an extensive geological structure that extends along the western shoreline of Lake Ontario (Figure 1). This feature is composed of a stratigraphic sequence of dolostone and shale units that includes the Lockport Formation as the cap rock (Tesmer 1981). The Lockport Formation is an important source of water for many of the farming communities in the Niagara region. It also underlies numerous industrialized cities and towns. As a result, chlorinated solvents have contaminated the ground water at several locations (Masalia and Johnson 1984; Yager et al. 1997).

During the late 1970s and early 1980s a PCB management site was operated on the outskirts of the town of Smithville, located approximately 15 km south of Lake Ontario, on the Niagara escarpment (Figure 1). In 1985, it was discovered that PCB oils and associated solvents had penetrated the overburden and pervaded the upper horizons of the Lockport Formation. This resulted in the closure of a local water supply well, which used ground water from this aquifer. The full impact of the PCB contamination into the lower horizons is yet to be resolved. However, it was determined that a conceptual model for ground water flow in the region was necessary to develop a remedial strategy for the site.

The primary purpose of this study is to use both physical and geochemical hydrogeological observations in the construction of the conceptual model. Physical hydrogeological observations include measurement of the distribution of transmissivity and measurement of hydraulic head at selected depth intervals in the Lockport Formation. Geochemical observations include measurements of the inorganic ionic content, stable isotopic ($\delta^{18}O$, δD) and tritium (^3H) composition of the ground water, as well as determination of the chemical composition of the rock units. The inorganic composition of the ground water is used in conjunction with hydraulic measurements to determine preferential flowpaths in the fracture network. Trends in the concentrations of dissolved inorganic compounds are used to define differing ground water flow regimes. Isotopic composition is used as an indicator of ground water recharge. Thus, the geochemical data provides information on the ground water flow system that cannot be deduced using hydraulic information alone. Recent application of a similar approach was used in the development of a conceptual ground water flow model for granitic rock in Aspo, Sweden (Smellie et al. 1995) and for the fractured Chalk Aquifer in the United Kingdom (Hisock et al. 1996).

Site Geology and Hydrogeology

The contaminated site is just north of the town of Smithville, Ontario (Figure 1). The surface topography in the area (Figure 1) indicates the presence of a swale oriented in the east-west direction, located approximately 1.5 km to the north of the site. A river (20

Mile Creek), flowing from the northwest to the southeast, is approximately 1 km to the south of the site. The topographical gradient in the vicinity of the site has a slight inclination of approximately 10 m/km to the south. Approximately 5 to 10 m of glaciolacustrine clay and clay till underlies the site (Figure 2). The overburden is of minimal permeability (K is approximately equal to 10^{-9} to 10^{-11} m/s) although pervaded by sparse vertical fractures, some of which may be fully penetrating (Golder Associates 1995). The Lockport Formation (Figure 2) underlying the clay till is composed of four geological members consisting of fine to medium grained dolostone that dip in a southeasterly direction at an angle of 0.5 degrees (Golder Associates 1995). The upper member (Eramosa) of the Lockport Formation is 10 to 20 m in thickness and contains a fairly uniform distribution of vertical fractures (Lapcevic et al. 1996). Transmissivity of the fractures can be as high as 10^{-2} m^2/s (Golder Associates 1995). The Vinemount member, which underlies the Eramosa, is characterized by a weathered vuggy zone (1 to 4 m thick) and a zone of unfractured rock of relatively low transmissivity (3 to 4 m in thickness). The lower members (Goat Island and Gasport) are 6 to 7 m and 8 to 10 m in thickness, respectively. Fracture frequency in these units is sparser, although transmissivity is no less than that observed in the Eramosa member. The Lockport Formation is underlain by an impermeable shale (the Rochester Formation) of up to 17 m in thickness and is considered a regional aquitard (Golder Associates 1995).

Ground water flow in the fracture system is generally to the southeast, following the stratigraphic dip of the geological units (Golder Associates 1995). Based on previous studies of the Lockport Formation conducted at this site and elsewhere in the region, it is inferred that ground water flow is primarily governed by bedding plane fractures that are laterally extensive and have limited vertical interconnection (Novakowski and Lapcevic 1988; Riechart 1992; Golder Associates 1995). Thus, it was initially assumed that ground water flow in the Lockport Formation underlying the contaminated site is primarily in the horizontal direction, controlled by bedding plane fractures of unknown lateral extent and unknown vertical interconnectivity. Previous site investigations (Golder Associates 1995) indicate that some fractures, at least in the upper Lockport members, are laterally connected over a distance of 1 km as evidenced by the downgradient transport of aqueous-phase contamination emanating from the PCB source. Hydraulic gradients in these members have been estimated to be 0.02 with initial estimates of ground water velocity ranging 20 to 6000 m/a. Hydraulic gradients in some of the lower dolostone members were estimated at values ranging from 0.001 to 0.007 m/a (Golder Associates 1995).

Field Investigation

To conduct the field study, six 76 mm diameter boreholes were drilled in the vicinity of the site (Figure 1) using a diamond core and triple-tube wireline techniques. The boreholes were drilled to penetrate the entire thickness of the Lockport Formation; a depth of approximately 55 m below ground surface. Five of the boreholes are inclined at angles ranging from 55 to 57 degrees with respect to the ground surface, and one borehole (borehole 65) is vertical. Boreholes were drilled at an angle in order to intercept vertical fractures.

Once drilling was completed, hydraulic tests using the constant-head injection method (Novakowski 1988) were performed on each borehole to obtain measurements of transmissivity over continuous 2 m depth intervals. Because the majority of the testing was conducted in inclined boreholes, an inherent error is imparted to the interpretation of the hydraulic testing results. This is because the actual flow around the borehole is slightly elliptical, rather than radial as assumed for the analysis. The degree of error accrued was calculated to be no more than a few percent. Standard sliding-head packers with steel-reinforced glands were used for the testing. Periodic leak and inflation tests were conducted to ensure that the packers were obtaining a competent seal against the borehole wall. Minimum and maximum values of transmissivity ranging between 10^{-10} m^2/s and 10^{-2} m^2/s can be determined using the constant-head method.

After completion of the hydraulic testing, the boreholes were instrumented with a series of permanently emplaced packer systems (Black et al. 1987). There are five to nine isolated intervals with respect to depth in each borehole. Values of hydraulic head in each interval were calculated from pressure measurements obtained using a pressure transducer. Measurements of hydraulic head were obtained on a weekly basis over a two-year period.

A total of 31 rock samples, collected from each of the stratigraphic units of the Lockport Formation, were submitted for mineralogical analyses. The samples were prepared by crushing the sample to a powder (less than 100 μm size fraction) using a ceramic ball mill. Samples were analyzed for mineral content using X-ray diffraction (XRD).

Ground water samples were collected in November 1997 from zones isolated using the permanently emplaced packer systems. The samples were collected using a stainless-steel sampling chamber (volume of 500 mL) connected to an electronic actuating device that draws ground water from the isolated zone outside the borehole casing. Ground water in the borehole annulus is subject to mixing and diffusional processes that equilibrate the geochemical parameters with those of the surrounding ground water. Since ground water is not sampled from within the borehole casing, the need to purge the borehole of standing water is eliminated (Black et al. 1987).

After drawing the sample to ground surface, electrical conductivity, Eh, and pH were measured in the field on unfiltered samples in enclosed containers. Electrical conductivity was measured using a conductivity probe. A combination electrode with an Ag/AgCl internal reference, calibrated against the buffers 4 and 7 were used to determine pH. Eh was measured using a combination platinum redox and Ag/AgCl reference electrode. Alkalinity was measured immediately following sample collection by titrating a known volume of filtered sample with 0.16N sulfuric acid using a HACH digital titrator. Ground water samples collected for the analyses of inorganic ions and dissolved organic carbon (DOC) were filtered in the field using a 0.45 μm nylon filter. Samples submitted for cation analyses were preserved at the time of collection with ultrapure HCl.

Analyses for metals were performed at the National Laboratories for Environmental Testing in Burlington, Ontario, Canada, using inductively coupled plasma spectroscopy (ICP-MS). Anions (Cl^-, SO_4^{2-} and SiO_2) were determined using ultraviolet photometry (COBAS). Concentrations of ammonia (NH_3-N) and nitrate (NO_3-N) were analyzed using a Bran+Luebbe TRAACS-800 continuous flow analyzer. Analyses for DOC were performed using ultraviolet digestion. Charge imbalances for the inorganic ions are less than 10% with the exception of two samples.

In July and November of 1997, ground water samples were also collected for stable isotope analyses (^{18}O and ^{2}H). Analyses were performed at the National Hydrology Institute in Saskatoon, Saskachewan, Canada, using standard CO_2/water and H_2/water

equilibration techniques. $\delta^{18}O$ and $\delta^{2}H$ data were normalized to VSMOW/SLAP and are reported relative to VSMOW with reproducibility of ±0.1 and ±2.0, respectively. Samples were analyzed for ^{3}H at the University of Waterloo, Waterloo, Ontario, Canada, by using direct scintillation methods obtaining a detection limit of 6TU, with a reproducibility of ±8TU. Eleven samples were reanalyzed for enriched ^{3}H analyses in order to refine the estimate of concentration of ^{3}H in the ground water at a few locations. The enriched 3H analyses have a reproducibility ranging between ±0.6 to ±1.3 TU.

Saturation indices of various mineral phases were calculated using ground water chemistry and the geochemical speciation program PHREEQC (Parkhurst 1995). Thermodynamic data used for these calculations were provided in the PHREEQC database.

Results

Mineralogy

X-ray diffraction analyses (Table 1) indicate that the three principal minerals present in the units are dolomite (86 to 98 wt%), quartz (2 to 15 wt%), and gypsum (3 to 8 wt%). However, none of the samples from the Eramosa member are observed to contain any measurable gypsum.

Water Chemistry

The ground water underlying the Smithville site (Table 2) is mainly reducing (Eh < 0) at depths greater than 20 to 30 m below ground surface (approximately < 170 meters above sea level [masl]). At shallow depths, conditions are more aerobic (Eh > 0 mV). Increased concentrations of HS^- in solution and subsequent decrease in Fe^{2+} concentrations suggest that redox conditions change from iron reducing to sulfate reducing with increasing depth. The pH of the ground water is near neutral (6.8) to slightly alkaline (7.6). Temperature of the ground water ranges from approximately 10°C to 11°C. Concentrations of Ca^{2+}, N^{a+}, K^+, HS^-, Cl^-, and SO_4^{2-} increase with depth and Mg^{2+} and Fe^{2+} decrease with depth. Alkalinity also decreases slightly with depth.

Hydraulic Properties

The results of the constant head injection tests indicate that the transmissivity of the Lockport formation ranges between the testing limits of 10^{-10} m^2/s and 10^{-2} m^2/s with a few exceptions. Highest transmissivities measured at the maximum level (10^{-2} m^2/s) of the transmissivity test (3% of the total number of tests) are observed in boreholes 61, 63, and 65 at approximately 165, 155, and 170 masl, respectively. Nine percent of the zones tested had transmissivities below the minimum testing limit (10^{-10} m^2/s). Most of these zones are concentrated in the lower Vinemount and upper Rochester units. However, a few low transmissivity zones are observed at the top of the Goat Island (boreholes 60 and 62) adjacent to the Vinemount/Goat Island bedrock contact. The Eramosa, upper Vinemount and Gasport units are characterized by high transmissivities ranging from 10^{-5} to 10^{-2} m^2/s, whereas many low transmissivity measurements (10^{-10} to 10^{-7} m^2/s) are observed in the lower Vinemount unit and the Rochester Formation.

Hydraulic head measurements range from 181 to 192 masl. The highest hydraulic head measurements are observed in the Eramosa member of boreholes 60, 62, and 63. In these boreholes, hydraulic head decreases sharply below the Eramosa member. Hydraulic head is observed to be almost uniform with depth in boreholes 53 and 65 with values ranging between 184 and 185 masl. In borehole 61, hydraulic head is observed to be highest at an intermediate depth (at 160 masl), reflecting an artesian condition.

Environmental Isotopes

In general, the stable isotopic composition of the ground water ranges widely from −9 to −14 ‰ and −50 to −110 ‰ for $\delta^{18}O$ and $\delta^{2}H$, respectively. The isotopic composition of the ground water is enriched (−9 to −11 ‰ and −50 to −80 ‰ for $\delta^{18}O$ and $\delta^{2}H$, respectively) and changes little with depth in boreholes 60, 61, 62, and 63 whereas values become significantly depleted at approximately 165 masl and below in boreholes 53 and 65. Tritium values vary from below detection to values greater than 25TU.

Discussion

Major ion analyses of the ground water indicate that three chemically distinct zones are present in the flow system (Table 2,

Table 2

Figure 3). At shallow depths (elevations greater than 170 masl) corresponding to the Eramosa and upper Vinemount units (Table 2, Figure 3, boreholes 53, 61, 62, 63, and 65), Mg^{2+} and SO_4^{2-} are observed to be the ions of highest concentration in solution. At elevations between approximately 150 to 170 masl, corresponding to the lower Vinemount, Gasport, and Goat Island members, Ca^{2+} and SO_4^{2-} ions dominate. At greatest depth (elevations less than 150 masl, Rochester Formation) in boreholes 53, 61, 63, and 65, the ground water chemistry approaches brine conditions, characterized by high concentrations of Na^+ and Cl^-.

The location of these chemical zones can be readily explained as a consequence of mineral dissolution/precipitation reactions and the interaction of the ground water with formation members. For example, calculated saturation indices (SI) (Figure 3) indicate that ground water in most boreholes is undersaturated (SI approximately −0.5 to −1.0) with respect to gypsum at shallow depths (Eramosa and upper Vinemount). At greater depths ground water is observed to be close to equilibrium with gypsum (SI is approx-

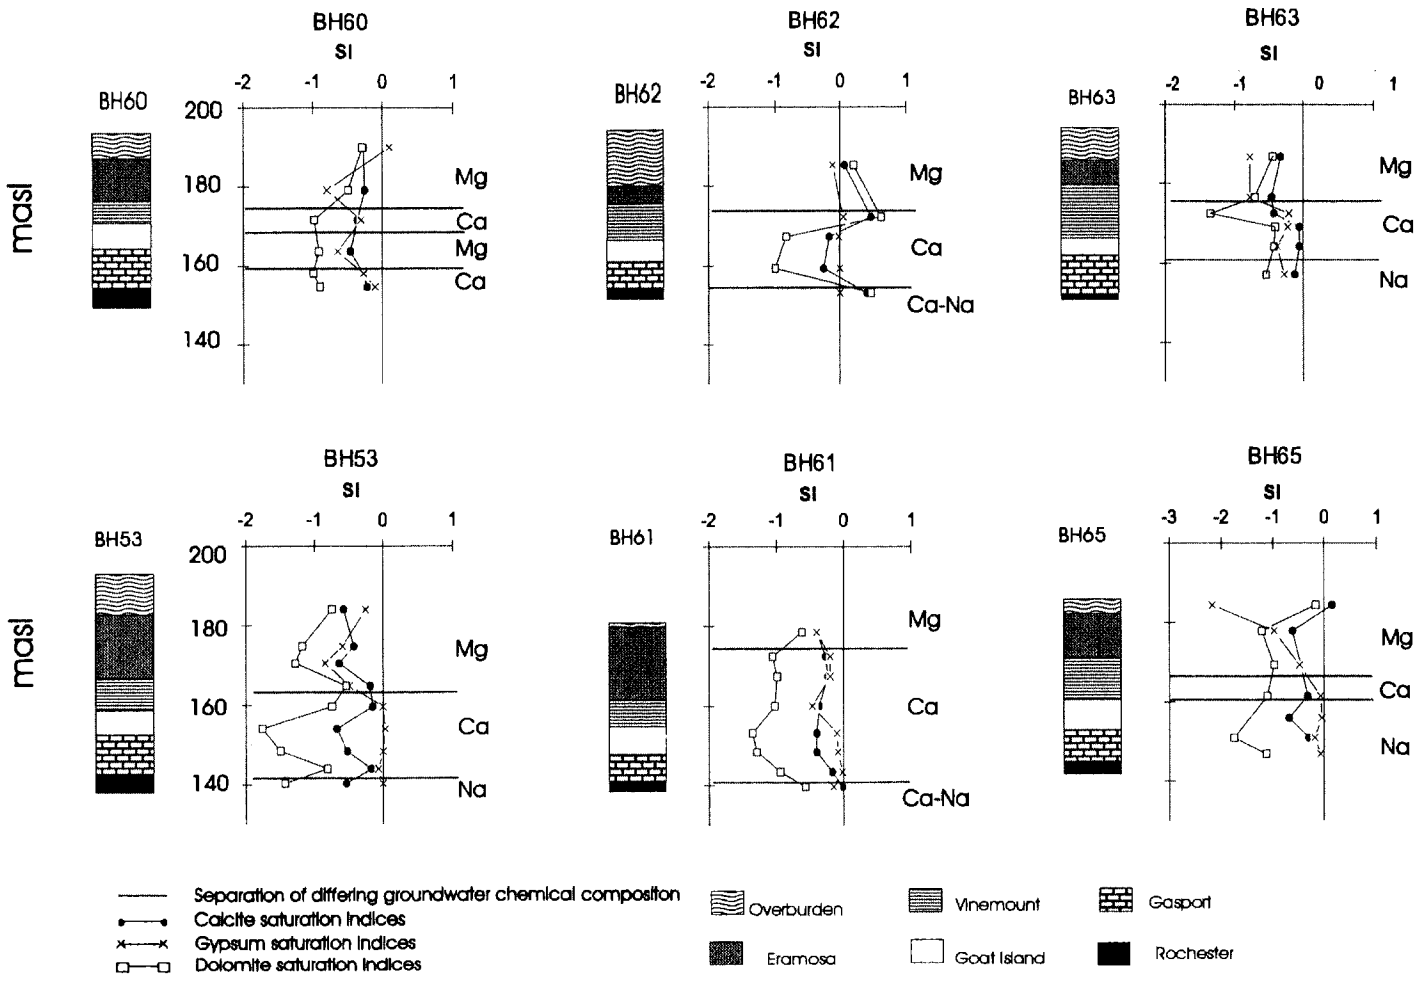

Figure 3. Calculated saturation indices (PHREEQC) for dolomite, gypsum, and calcite using chemistry from ground water samples collected at selected borehole depths in (a) boreholes 60, 62, and 63 upgradient from the PCB-contaminated site, and in (b) boreholes 53, 61, and 65 downgradient from the PCB-contaminated site.

imately 0) suggesting that the amount of Ca in the ground water is controlled by chemical equilibration reactions with gypsum observed to be present in the Vinemount, Goat Island, and Gasport members (Table 1). At elevations corresponding to the Rochester Formation, ground water tends to be undersaturated or near saturation with respect to both dolomite and calcite (Figure 3).

X-ray diffraction analyses indicate that almost all members of the Lockport Formation contain a small percentage of gypsum whereas no gypsum was observed in the Eramosa member. Thus, the dissolution of dolomite and calcite alone will control the amount of Ca concentrations in the ground water located in this member. The presence of gypsum in the lower formation members and the observation that ground water is in equilibrium with gypsum at depth in most boreholes, suggests that relative to ground water observed in the Eramosa, undersaturated water (i.e., recharge water) has not extensively reached this horizon. This is also evidenced by the diminished frequency of the vertical fractures observed in the lower members as compared to the Eramosa member (approximately three times lower frequency at depth; Lapcevic et al. 1996). The high Na concentrations and overall salinity observed in ground water at greater depth (elevations of approximately 150 masl or less; Figure 3, Table 2) also suggest high residence time and therefore sluggish ground water velocity.

The measured hydraulic parameters (transmissivity and hydraulic head) in each borehole are compared with measured geochemical parameters in Figure 4. The boreholes are arranged based on their position relative to the location upgradient (boreholes 60, 62, and 63; Figure 4a), in an area of possible ground water recharge, versus those located either immediately adjacent to the contaminated site (borehole 53, Figure 4b), or in possible areas of discharge along the river (boreholes 61 and 65; Figure 4b). Superimposed on these figures are the distribution of the three chemically distinct ground water zones previously discussed.

Upgradient Boreholes

Although the overburden is relatively thick in the vicinity of boreholes 60, 62, and 63 (Figure 4a), it was initially surmised that these boreholes are situated immediately downgradient from a potential zone of recharge. These boreholes are located approximately 1 km south of a swale that trends east-west. Due to a slight southward dip in the bedding planes, the thickness of the Eramosa member in these boreholes is less than that observed in the downgradient boreholes. The distribution of transmissivity follows the general observations (i.e., high transmissivity in the Eramosa, Goat Island, and Gasport members). Lower transmissivities are observed in the middle to lower Vinemount member. An exception to this is borehole 62, which exhibits lower transmissivity throughout the base of the Eramosa, Vinemount, and Goat Island members, with higher transmissivity evident only in the Gasport member.

The distribution of hydraulic head indicates a downward gradient with increasing depth in all three boreholes. In each case, the transition between higher and lower hydraulic head occurs at the

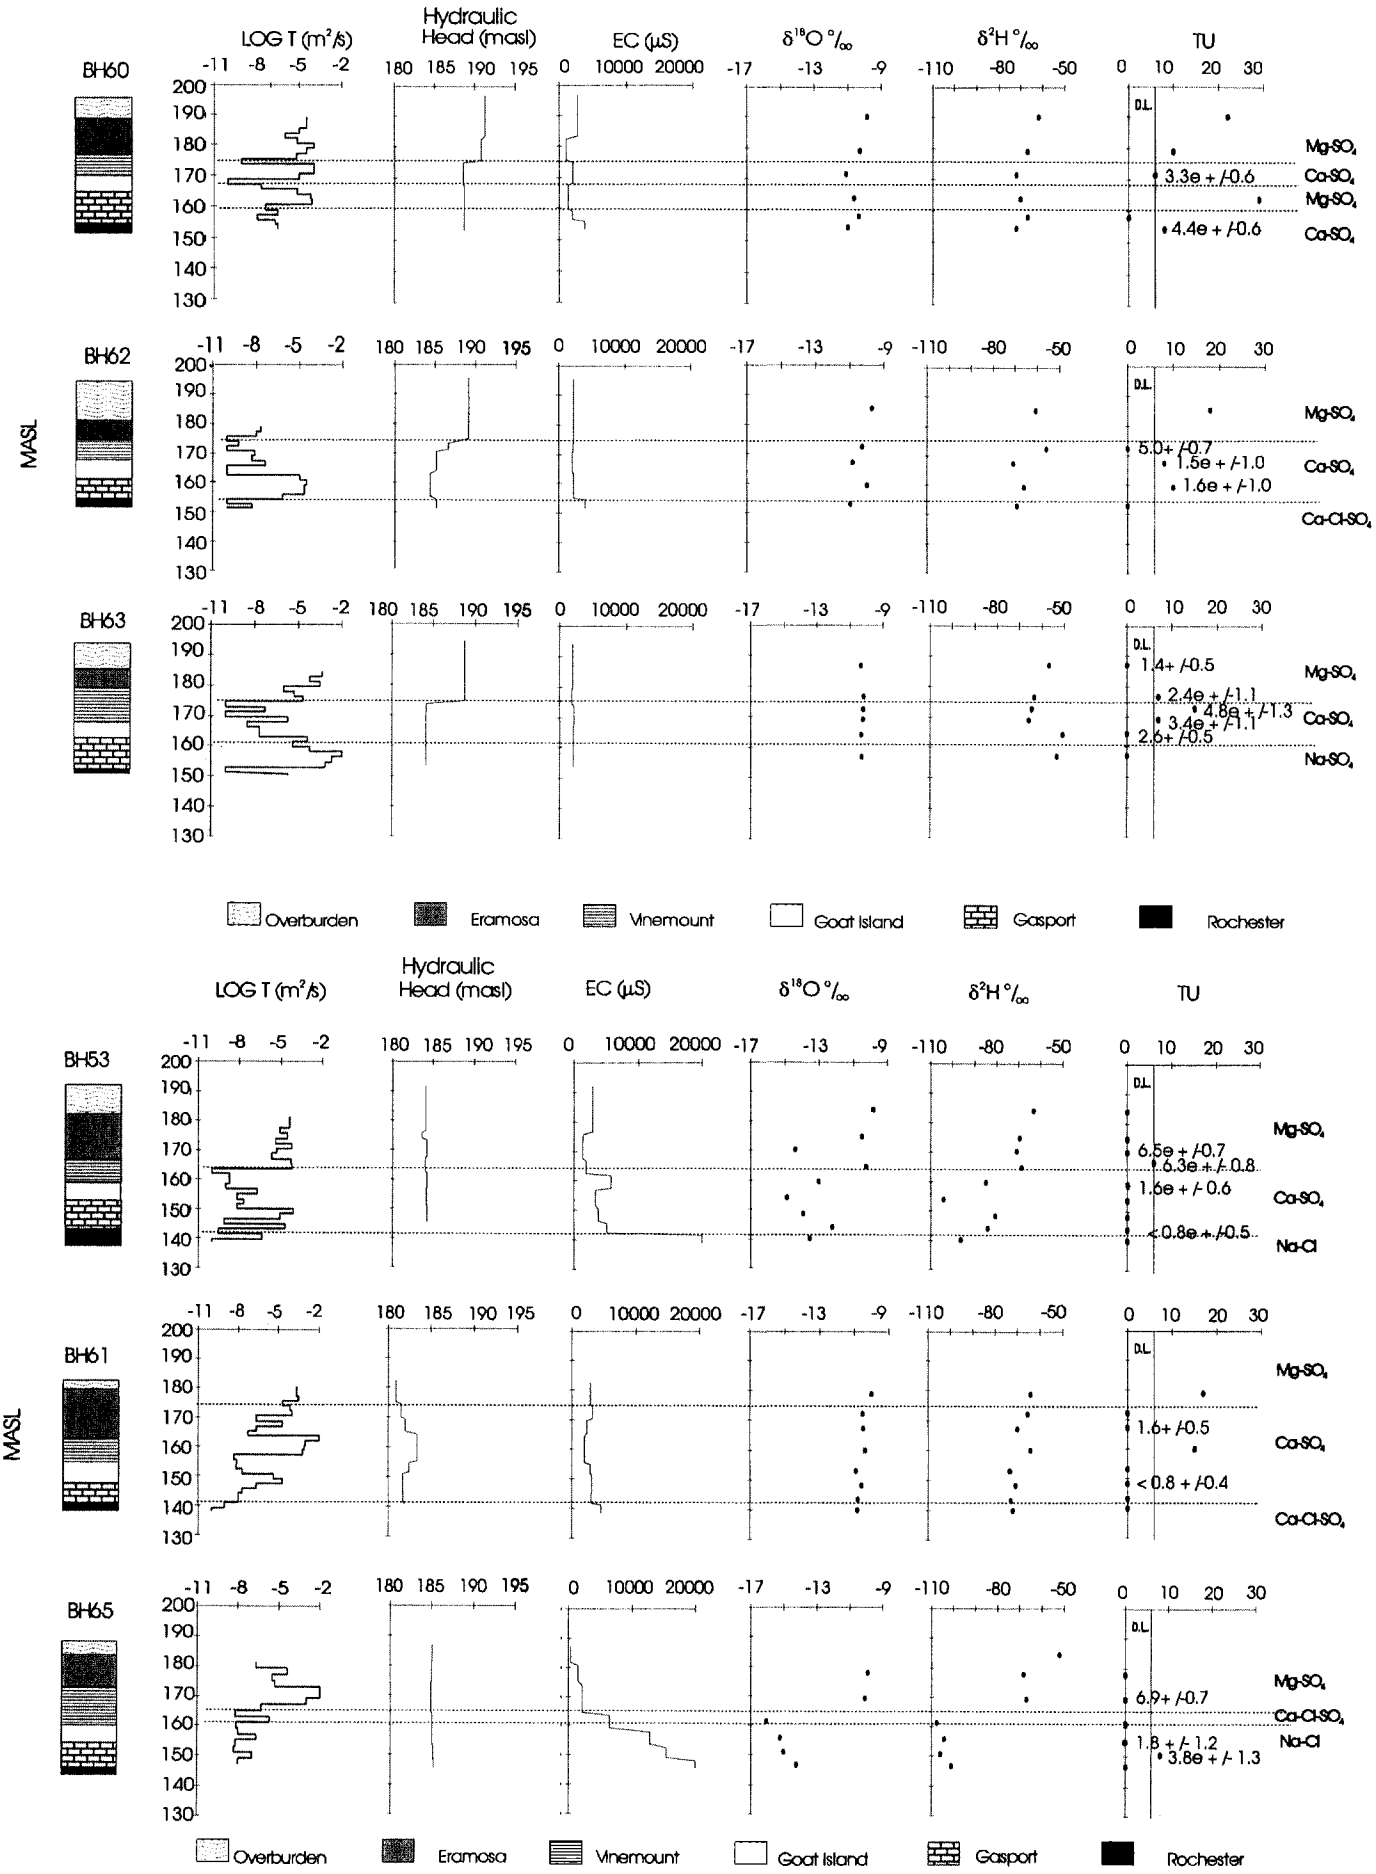

Figure 4. Composite diagram of measured parameters in (a) boreholes 60, 62, and 63 located upgradient from the PCB-contaminated site, and (b) boreholes 53, 61, and 65 located downgradient from the PCB-contaminated site.

base of the Eramosa member or top of the Vinemount member, across a discrete zone of low transmissivity. In the case of boreholes 60 and 63, the hydraulic head below the low transmissivity zone is uniform. The steady decrease in hydraulic head with depth (downward gradient) observed in borehole 62 may indicate weak vertical fracture connection through these units in the immediate vicinity of this borehole.

Electrical conductivity is relatively uniform with depth, ranging from approximately 2000 to 4000 µs. Similarly, the stable isotopic composition of the ground water is also uniform with depth, ranging from −9 ‰ to −11 ‰ and −60 ‰ and −80 ‰ for $\delta^{18}O$ and $\delta^{2}H$, respectively. Average $\delta^{18}O$ and $\delta^{2}H$ values in precipitation collected in Simco, Ontario, (located approximately 100 km to the east) during the period from 1975 to 1982, are approximately −10 ‰ and −70 ‰, respectively (IAEA/WMO 1988). Thus the ground water is of recent origin. In addition, many of the sampled zones contain measurable concentrations of ^{3}H indicating that ground water in these zones is of post WWII age. In boreholes 60 and 62, ^{3}H concentrations are highest in the shallow depths (elevations greater than 165 masl). However, high transmissivity zones in the lower Vinemount and Goat Island to upper Gasport also exhibit moderate to high ^{3}H concentrations.

The fact that there is little change in electrical conductivity and in the stable isotopic signature with respect to depth suggests that in the upgradient boreholes, ground water in both the upper Eramosa member and in the lower members are of a common origin. The presence of ^{3}H at various depths (i.e., shallow and deep) further indicates that younger water is infiltrating all depths of the flow system. On a local scale, recharge water may infiltrate through fractures in the thick overburden immediately above the boreholes. Alternatively, a large portion of recharge water may originate from the swale (Figure 1) and a bedrock ridge that lies immediately to the north of the site. The bedrock ridge has a topographic high of 10 to 15 m above the swale and is composed of Eramosa member rock, which outcrops in several places. Thus on a larger, more regional scale, the source of recharge water for the area most likely originates from exposed fractures in the ridge and swale areas.

Downgradient Boreholes

In general, the lithology logs for boreholes 53, 61, and 65 show a diminished overburden thickness and an increase in the thickness of the Eramosa member in the downgradient direction (Figure 4b). The elevation of the top of the Rochester Formation (the underlying aquitard) is 8 to 9 m below that of the upgradient boreholes.

The distribution of transmissivity in these boreholes is similar to that for the upgradient boreholes. Low transmissivity zones in the middle to lower Vinemount and high transmissivity zones in the Eramosa/Upper Vinemount, Goat Island, and Gasport members are observed. The exception is borehole 65, which has more sparsely distributed zones of limited transmissivity (10^{-7} to 10^{-8} m^2/s) in the Goat Island and Gasport members.

Contrary to the boreholes located upgradient, boreholes 53 and 65 have a relatively uniform distribution of hydraulic head with depth. The slightly lower hydraulic head observed at 175 masl (middle of the Eramosa member) in borehole 53 may be attributed to the ongoing pumping from a water treatment facility at the contaminated site that pumps ground water from only a few meters into the upper bedrock. The hydraulic head distribution in borehole 61 is dissimilar to all other boreholes in that the highest hydraulic head is observed in the high transmissivity feature that straddles the Eramosa-Vinemount member contact. This zone is artesian, resulting in vertically upward and downward gradients emanating from this horizon.

The electrical conductivity in boreholes located downgradient generally increases with depth (Figure 4b) with the exception of borehole 61. The most profound change in electrical conductivity is observed in boreholes 53 and 65, where measured values range from 1500 µs in the shallow zones to values greater than 20,000 µs in the deepest zones. Electrical conductivity in borehole 65 is observed to steadily increase with depth, whereas in borehole 53 electrical conductivity mainly increases below the Eramosa-Vinemount contact located at 162 masl. In borehole 61 electrical conductivity increases only slightly from approximately 2000 to 5000 µs.

In boreholes 53 and 65, $\delta^{18}O$ and $\delta^{2}H$ concentrations are relatively enriched in ground water located in the Eramosa and Upper Vinemount members (greater than 165 masl) with values ranging between −9 ‰ and −11 ‰ and −50 ‰ to −80 ‰, respectively. Below the Vinemount member, the isotopic signature becomes significantly more depleted with values ranging between −13 ‰ to −17 ‰ and −80 ‰ to −110 ‰ for $\delta^{18}O$ and $\delta^{2}H$, respectively. The change in isotopic signature occurs below the low transmissivity zone in the Vinemount member. In boreholes 53 and 65, ^{3}H (analyzed by direct methods) is not observed in any of the sampled ground water. However, enriched ^{3}H values obtained subsequently from borehole 53 indicate that the presence of ^{3}H (6.3TU ± 0.8TU) at 175 masl, close to the contact between the Eramosa and Vinemount units. The isotopic composition of the ground water in borehole 61 varies little with $\delta^{18}O$ and $\delta^{2}H$ ranging from −9 ‰ to −11 ‰ and −55 ‰ to −80 ‰ throughout the borehole depth. This signature is similar to that for the upgradient boreholes. As with the upgradient boreholes, substantial ^{3}H concentrations are also observed in borehole 61, particularly at the shallowest interval and the high transmissivity zone located in the middle of the Eramosa member. In borehole 65, a small amount of ^{3}H is observed at 150 masl. A second sample from this zone obtained five months later confirmed the presence of ^{3}H (3.8TU enriched ± 1.3TU). However, this zone is of low transmissivity (approximately 10^{-8} m^2/s), and it is likely that drill water was entrapped during installation of the permanent packer system.

The pronounced shift with depth in isotopic composition and electrical conductance observed in boreholes 53 and 65 suggests that two distinct flow systems are present. As with the upgradient boreholes, the low transmissivity zone in the Vinemount member appears to be the dividing horizon between the two individual flow systems.

Tritium, $\delta^{18}O$ and $\delta^{2}H$ concentrations in borehole 53 show the presence of recent water in the high transmissivity zone at the base of the Eramosa and the upper Vinemount. A value of 6.3 (± 0.8 TU) for enriched ^{3}H was obtained for this interval. The source for this water is likely through connection with the upgradient recharge area. Considering that ground water velocities in the fractures within the lower Eramosa range from 10 to 30 m/day (Radcliffe 1997) and matrix porosities range from 5% to 15% (unpublished data), transport of the ^{3}H from the recharge area in a horizontal flow system can be simulated. Using the Tang et al. (1981) solution, simulation of transport in a discrete fracture having an aperture of 500 µm, a velocity of 30 m/day and adjacent matrix porosity of 5% shows that ^{3}H concentrations as high as 15TU are possible at borehole 53 when input conditions at borehole 60 (i.e., 30TU) are employed.

The results for borehole 61 are complicated by the presence of the artesian hydraulic head in the high transmissivity zone in the

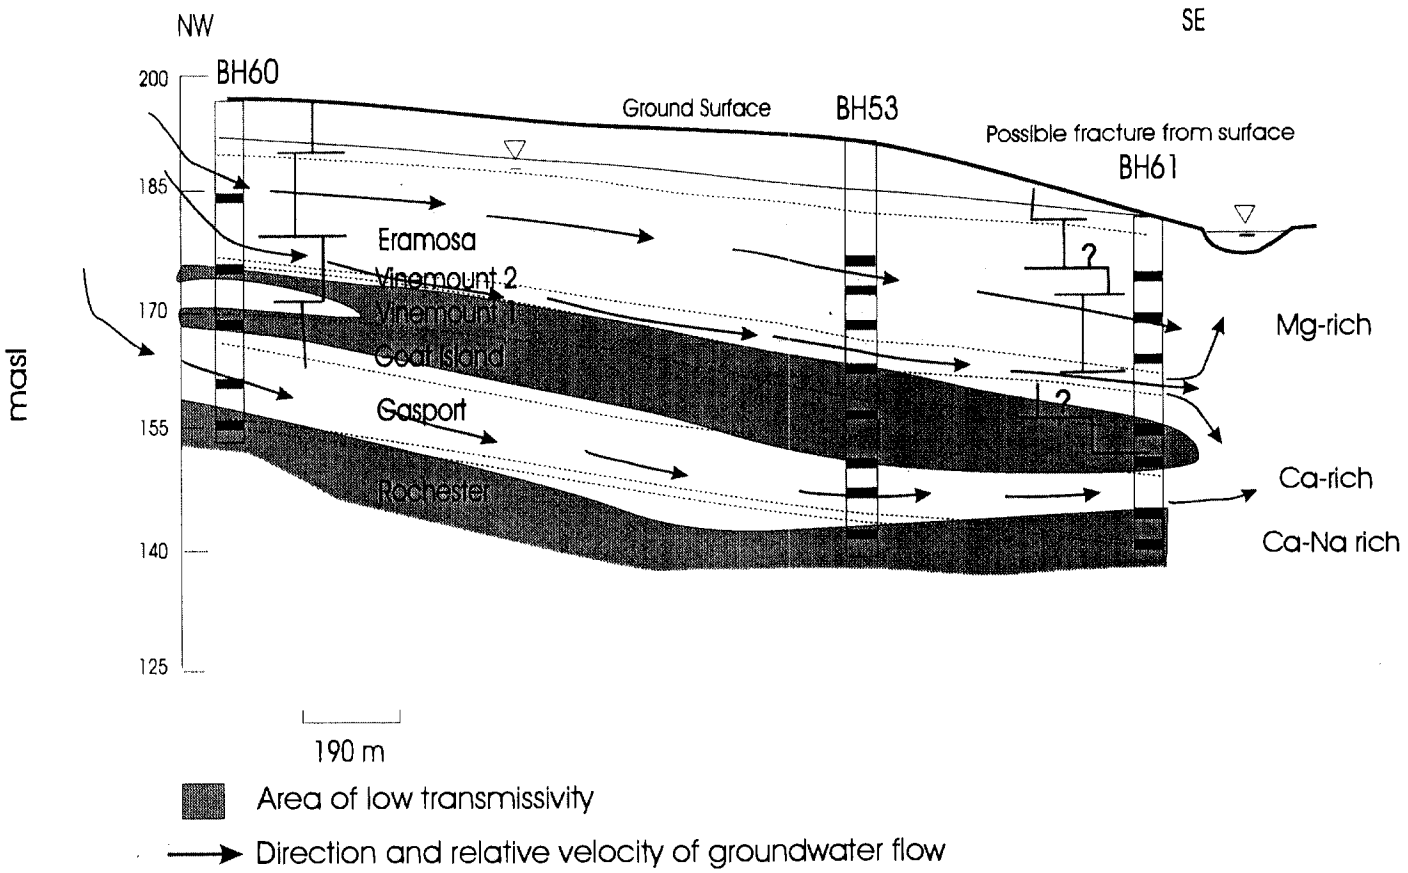

Figure 5. Conceptual model of two-dimensional flow at the Smithville site in the general direction of ground water flow (length of arrow indicates ground water velocity).

Lower Eramosa and Vinemount units. The water in this zone is observed to contain ^3H (15TU ± 8) and shows a similar isotopic signature to ground water located near the upgradient boreholes. The source of this water is uncertain. The strong discharging (upward gradients) observed in this highly transmissive zone suggests that the recharge is occurring from some distance away. Thus, hydraulic connection from the recharge area may be present. However, the upper Eramosa is exposed on the river bottom at several locations both upstream and downstream from borehole 61. Approximately 2 km upstream from borehole 61, river flow decreases with a significant volume discharging through the river bed. Thus, it is also possible that the source of recharge water in borehole 61 is through hydraulic connection with river water entering the subsurface at an upstream location.

Ground water in the stratigraphic intervals and below the artesian zone have stable isotopic signatures similar to that in the artesian zone. Although these waters do not contain measurable ^3H, it is likely that they originate from the artesian zone, through vertical connections, or are recharged at locations further up the river valley.

Conceptual Model and Conclusions

Since fracture networks are, in general, complex with the nature of fracture interconnection being uncertain, interpretation of ground water flow from borehole to borehole using hydraulic parameters is difficult. Indeed, the large variations in transmissivity values noted in all boreholes suggest that variability in ground water flow are common in the fracture system. The previous discussion supplements the hydrological data with geochemical data to provide evidence for hydraulic interconnection on a large scale. The conceptual model (Figure 5) represents a two-dimensional cross section, using three selected boreholes located in the direction of ground water flow (northwest to southeast).

Hydraulic head and measurements of transmissivity can provide only a general idea of ground water flow in the immediate vicinity of a particular borehole. For example, the uniform distribution of hydraulic head in boreholes 53 and 65 coupled with large variations observed in transmissivity measurements may indicate that ground water flow is primarily horizontal in the vicinity of these boreholes, with little interaction between the individual fracture planes. Alternatively, the uniformity of the hydraulic head distribution could imply that the horizontal fracture planes are extremely well connected such that vertical gradients are immeasurable. However, the chemistry and isotopic composition of the ground water in these boreholes shows the water above the Vinemount to be markedly different from that below, suggesting that little interaction between the water in these two horizons has occurred. We can also infer from the uniformity in hydraulic head that there are no local ground water sources (recharge zones) or drains (discharge zones) nearby.

Conversely, in the upgradient boreholes and borehole 61, transmissivity measurements are equally varied, yet distribution of hydraulic head with depth is not uniform. Evidence for predominantly horizontal flow is provided by the sharp change in hydraulic head distribution occurring at approximately 175 masl in the upgradient boreholes (60, 62, and 63) indicating that a unit of low permeability divides two separate flow systems. The uniform distribution of the geochemical parameters with depth and the presence of ^3H at depths below the low transmissive zone (e.g., borehole 60) suggests that on a small scale surrounding each borehole, local vertical hydraulic interconnections exist to allow for the penetration of recharge water across the low transmissive barrier.

In both the upgradient and downgradient vicinities, ground water flow is predominantly horizontal. Flow is likely controlled by

large bedding plane fractures that have been observed in the Lockport Formation (Tesmer 1981; Novakowski and Lapcevic 1988; Yager and Kappel 1998). The presence of bedding-plane partings is common in sedimentary rock sequences and is usually caused by stress changes. Enlarged bedding plane partings have been found to control ground water flow in the Lockport Formation at Niagara Falls Ontario, and in the Newark Basin, New Jersey (Novakowski and Lapcevic 1988; Michalski and Britton 1997).

The uniformity of the stable isotope composition with depth in the upgradient holes (60, 62, and 63) and the overall similarity to that of recent precipitation values suggest that ground water recharge is occurring just upgradient of these boreholes. Ground water recharge for the area likely occurs through fractures in the Eramosa unit from the swale and ridge located immediately north of the upgradient boreholes, where the Eramosa is observed to outcrop.

In all boreholes, a zone of low transmissivity is located in the middle to lower Vinemount member. This zone of low transmissivity varies in thickness yet appears ubiquitously. It is this horizon of low transmissivity that separates ground water flow into the upper and lower flow regimes in the region. The upper flow regime is present in the Eramosa member. The lower flow regime is present mainly in the Gasport and Goat Island members (Figure 5).

Inorganic ion concentrations of ground water and geochemical speciation modeling suggest that these regimes are physically and chemically related to the bedrock. Shallow ground water is found to be dominated by high Mg^{2+} concentrations due to equilibrium reactions with dolomite, which control the amount of Ca^{2+} and Mg^{2+} in solution. However, in the lower flow regime, ground water is dominated by high Ca^{2+} and SO_4^{2-} concentrations due to the higher amount of gypsum minerals present in the rocks.

Transmissivity measurements in the lower flow regime are observed to be just as high as that in the upper. Thus, calculations based on equivalent aperture width suggest that ground water velocity in both flow regimes are similar (Novakowski 1988). However, the high electrical conductivity and overall salinity observed at depth in the downgradient boreholes 53 and 65 suggest that ground water residence time in this zone may be greater than in the upper zone. Also, the observed depletion in stable oxygen and hydrogen isotopes at depth in these boreholes indicates that there is relatively less dilution from younger recharge water. As recharge is observed to penetrate all depths in the upgradient boreholes, it is therefore implied that fracture connectivity in the lower flow regime is less than that of the upper. This decrease in fracture connectivity allows for a greater period of time for recharge water to be transported downgradient (i.e., decreased velocity). Thus, the high transmissivity measurements observed in the lower flow regime are likely a result of increased fracture connectivity on a local scale only.

Ground water discharge from the flow system is less well defined. At borehole 65, located upstream of the town of Smithville along the banks of 20 Mile Creek, ground water in both the upper and lower flow systems appears to completely underflow the river. However, at borehole 61 located downstream from the town center, ground water appears to interact with the river water, at least within the upper flow system. In borehole 61, a high transmissivity zone in the Goat Island/Gasport exhibits the lowest hydraulic head at depth of any of the boreholes. This indicates significant underflow of the lower flow system.

Acknowledgments

Gratitude is extended to Kelly Millar, Susan Brown, and Andrea Brown for their assistance in the laboratory and the field. Also appreciated are editing suggestions from Jos Beckers and suggestions from Amy Sheldon in the interpretation of the tritium analyses. Funding for this research was provided by the Smithville Phase IV project.

GROUND-WATER RESOURCES OF THE CARRIZO AQUIFER IN THE WINTER GARDEN AREA OF TEXAS

ABSTRACT

The Winter Garden Area of Texas lies southwest of the San Marccos River and within the Guadalupe, San Antonio, Nueces, and Rio Grande basins. It consists of all or parts of Atascosa, Bexar, Caldwell, Dimmit, Frio, Gonzales, Guadalupe, Karnes, La Salle, Live Oak, McMullen, Maverick, Medina, Uvalde, Webb, Wilson, and Zavala Countie:;. Within the Winter Garden Area is found the Winter Garden District which includes Dimmit and Zavala Counties; and eastern Maverick County.

The Carrizo aquifer is the most continuous, permeable, and most developed (heavily pumped) water-bearing unit in the Winter Garden Area. Throughout most of the Winter Garden Area, the Carrizo aquifer yields ground water which is acceptable for most irrigation, public supply, and industrial purposes.

Recharge to the Carrizo aquifer enters by infiltration from rainfall and from streams which flow across the outcrop. The average rate of recharge to the Carrizo aquifer in the Winter Garden Area is about 100,000 acre-feet per year or 89 mgd (million gallons per day). In addition, leakage to the aquifer from other formations occurs in Dimmit, Frio, and Zavala Counties; an estimated 9,500 acre-feet per year (8.5 mgd) leaked into the Carrizo through confining beds and down uncemented well bores during the period 1963-1969. Average annual pumpage for the period 1963-1969 was approximately 272,000 acre-feet (243 mgd). Thus, for this period about 162,500 acre-feet per year (145 mgd) was removed annually from storage. These large annual withdrawals of ground water from storage have caused declines in Carrizo aquifer water levels, which directly affect the cost of pumping water and are also related to water-quality changes within the aquifer, particularly in the Winter Garden District (Dimmit, Zavala, and eastern Maverick Counties).

One of the primary objectives of this study was to simulate the Carrizo aquifer in the Winter Garden Area with a digital computer mathematical model. The simulations for the period 1970 through 2020 indicate the following: (a) in the heavily irrigated areas near Batesville and east of Carrizo Springs and Crystal City in Dimmit and Zavala Counties, water levels will continue to decline rapidly; (b) elsewhere in the Winter Garden Area, water levels will slowly decline if pumpage remains unregulated and occurs at predicted rates; (c) a firm water supply of 20,000 to 40,000 acre-feet per year (18 to 36 mgd) of ground water from wells can be developed in Wilson County for municipal use in the San Antonio region; (d) approximately 330,000 acre-feet per year (294 mgd) of ground water can be developed annually from the Carrizo aquifer and not lower water levels below a 400-foot level below land surface or below the top of the water-bearing sands until the year 2020, representing an increase of 58,000 acre-feet per year (52 mgd) over the withdrawals of 1963-l 969; and (e) the areas most favorable for development of additional ground-water supplies are in Wilson and Gonzales Counties.

GROUND-WATER RESOURCES OF THE CARRIZO AQUIFER IN THE WINTER GARDEN AREA OF TEXAS

INTRODUCTION

Purpose and Scope

Field study was begun in October 1967 to determine the ground-water resources of the Winter Garden Area of Texas with emphasis on the Carrizo aquifer. The primary objectives of this study were: (a) to determine the regional geohydrologic characteristics of the Carrizo aquifer; (b) to establish monitoring programs for pumpage, water levels, and water quality with respect to the Carrizo aquifer for continuous evaluation of ground-water availability and dependability on a regional basis; (c) to examine the feasibility of artificially recharging the Carrizo aquifer; and (d) to use a digital computer model of the Carrizo aquifer to evaluate the aquifer's response to pumping and the probable future ground-water conditions. Field work for this study was completed in the spring of 1970.

Volume I summarizes the results of this investigation, and contains information on the amounts of water that have been and can be produced from the Carrizo aquifer, its hydrologic characteristics, and the chemical quality of its water. The water-bearing strata of the Wilcox Group and other aquifers of the Claiborne Group are also discussed. Volume II contains supporting basic data: records of 3,214 water wells, records of water levels in 474 wells, and chemical analyses of water samples from 1,553 wells. Also available for reference in the files of the Texas Water Development Board are drillers' logs of 711 wells that were used in the study.

Location and Population

The area covered by this report, which will be referred to as the Winter Garden Area, is the area southwest of the San Marcos River in which the Carrizo aquifer contains fresh to slightly saline water. It consists of all or parts of Atascosa, Bexar, Dimmit, Frio, Gonzales, Guadalupe, Karnes, La Salle, Live Oak, McMullen, Maverick, Medina, Uvalde, Webb, Wilson, and Zavala Counties. Data were also collected east of the San Marcos River (Caldwell and eastern Guadalupe Counties), in order to minimize boundary effects of a computer simulation of the Carrizo aquifer. Although most of the maps in this report extend well east of the San Marcos River, all figures in the report concerning volume of ground water apply only to areas west of the San Marcos. The Winter Garden Area (west of the San Marcos River) consists of approximately 11,800 square miles and represents approximately 4.5 percent of the State's total area. Within the Winter Garden Area is the Winter Garden District, an irrigated region which produces vegetables in late winter and early spring in Dimmit, Zavala, and eastern Maverick Counties (Figure 1).

According to data in the 1970-71 Texas Almanac, the Winter Garden Area has a population of approximately 140,000, or about 1.2 percent of the State's population.

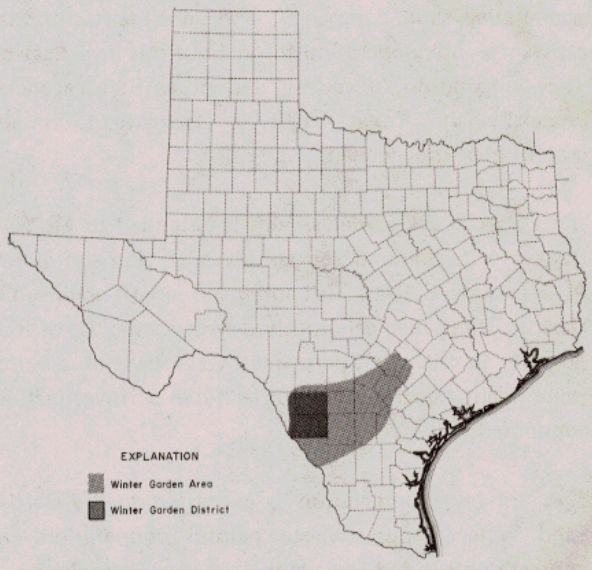

Figure 1.—Location and Extent of the Winter Garden Area and the Winter Garden District

Personnel

This report was prepared by the authors under the general direction of Lewis Seward, Principal Engineer-Project Development, and Robert Bluntzer, director, Water Availability Division. Tommy Barnes, geologist, assisted in assembling the data.

The digital computer mathematical model used to simulate the Carrizo aquifer was developed by George F. Pinder of the United States Geological Survey, and was modified by staff of the Board's Systems Engineering Division, under the direction of Lial Tischler and assisted by Al Austin, Tommy Knowles, and Allen White. Core drilling and the laboratory testing of drill cuttings and cores were done by staff of the Board's Materials Testing Laboratory and Core Drill Branch under the direction of James Sansom and Henry Sampson.

Acknowledgements

The authors appreciate the cooperation extended by the property owners in the Winter Garden Area who supplied information concerning their wells and, in many instances, also allowed access to their property and the use of their wells to monitor water-level changes and production capabilities. Acknowledgement is also extended to the water well drillers of the area, city officials, water superintendents, officials of independent water districts, electric and natural gas distribution cooperatives and companies, and consultants for their assistance and cooperation throughout this investigation. The cooperation of fede-al and other State agencies, especially the Texas Highway Department, is also gratefully acknowledged.

Special acknowledgement is extended to Mr. Billy Deagan of Sutherland Springs, Mr. J. D. Harrison of Palo Alto, and Mr. Calvin Hardt and Mr. George Thompson of Devine. These men generously permitted the use of their property in order that perrnanent water-level observation wells might be drilled and other types of investigations conducted.

Finally, appreciation is expressed to the Carrizo Sand Water Group, whose helpful cooperation and interest contributed toward the successful completion of this investigation and a better understanding of the ground-water resources of the Winter Garden Area.

WATER-BEARING STRATA OF THE WILCOX AND CLAIBORNE GROUPS

The Wilcox and Claiborne Groups contain the major aquifers within the study area. The strata of these units are marine and continental in origin and consist mainly of clay, cross-bedded river sand, beach sand, silt, and lignite. The stratigraphic units of the Wilcox and Claiborne, their approximate thickness, lithologic description, and water-bearing characteristics are given in Table 1. Their position in the subsurface is illustrated in the geohydrologic sections, Figures 27, 28, and 29. Estimates of the amount of ground water obtained from the aquifers for irrigation, public supply, and industrial purposes are given in Table 4.

For the purpose of this report, the Wilcox Group will be considered as an undifferentiated geologic unit. The upper section of the Wilcox contains some massive sand beds which are continental in origin. The middle portion is composed principally of nonmarine sand, clay, and lenticular beds of lignite. The basal portion contains mainly sand and clay of shallow marine origin. The Wilcox reaches a maximum thickness of about 2,800 feet and contains fresh to very saline water in the Winter Garden Area. Figure 2 illustrates the extent of sands containing fresh to slightly saline water-having less than 3,000 mg/l (milligrams per liter) dissolved solids--in the Wilcox aquifer (Wilcox Group). The approximate depth to and altitude of the top of the Wilcox aquifer are shown on Figure 10.

Overlying the Wilcox is the Carrizo Sand, the lowermost formation of the Claiborne Group. The Carrizo is composed mainly of very permeable, massive, cross-bedded, medium-grained sand and ranges in thickness from 150 to 1,200 feet in the report area. It is the principal and most developed (heavily pumped) water-bearing unit in the Winter Garden Area.

The general extent of fresh to slightly saline water in the Carrizo aquifer (Carrizo Sand) is given in Figure 2. The approximate depth to and altitude of the top of the Carrizo aquifer are illustrated in Figure 8. The total thickness and net sand thickness of the Carrizo aquifer are shown on Figure 9. The depth to and altitude of the base of the Carrizo aquifer are illustrated in Figure 10.

Because some of the sands in the Wilcox Group may be hydraulically connected with the Carrizo Sand,

Table 1.—Water-Bearing Characteristics of the Wilcox and Claiborne Groups in the Winter Garden Area

Yield, in gallons per minute : small, less than 50; moderate, 50 to 500; large, over 500.
Salinity (total dissolved solids), in milligrams per liter: fresh, less than 1,000; slightly saline, 1,000 to 3,000; moderately saline, 3,000 to 10,000; very saline, 10,000 to 35,000; brine, over 35,000.

SYSTEM	SERIES	GROUP	GEOLOGIC UNIT		APPROXIMATE THICKNESS (FT)		CHARACTER OF ROCKS		WATER-BEARING PROPERTIES	
Tertiary	Eocene	Claiborne	Yegua Formation		700-1,000+		Clay, silt with interbedded thin lignites and sandstones. Some minor beds of limestone and oyster shells are found.		Yields small quantities of slightly to moderately saline water to wells in the outcrop area.	
			Laredo Formation	Cook Mountain Formation	600-700	400-500	Glauconitic sand and clay. Some gypsiferous clay and impure limestones.	Fossiliferous clay and shale. Some interbedded sandstone and limestone.	Yields small to moderate quantities of fresh to moderately saline water to wells.	Yields small quantities of slightly to moderately saline water to wells.
				Sparta Sand		40-200		Medium to fine sand. Some interbedded clay.		Yields small to moderate quantities of fresh to moderately saline water to wells.
			El Pico Clay	Weches Formation	700-1,500	50-200	Clay with interbedded sandstones, claystones, and lignite coal lenses.	Fossiliferous, glauconitic shale and sand.	Yields small quantities of slightly to moderately saline water to wells.	Not known to yield water to wells.
				Queen City Sand		500-1,400		Marine, medium to fine sand with interbedded clay and shale.		Yields small to moderate quantities of fresh to slightly saline water to wells.
			Bigford Formation	Reklaw Formation	200-900	200-400	Sands with interbedded silts and shales. Plant remains are abundant.	Clay with interbedded glauconitic sand.	Yields small to moderate quantities of fresh to very saline water to wells.	Yields small quantities of slightly to moderately saline water to wells in or near the outcrop.
			Carrizo Sand		150-1,200		Coarse to fine sand, massive, cross-bedded with a few partings of carbonaceous clay.		Principal aquifer in the report area. Yields moderate to large quantities of fresh to slightly saline water to wells.	
		Wilcox			0-2,800		Interbedded sand, clay, and silt with discontinuous beds of lignite. The shale and clay sometimes contain gypsum.		Yields small to moderate quantities of fresh to slightly saline water to wells in the northern and western parts of the report area.	

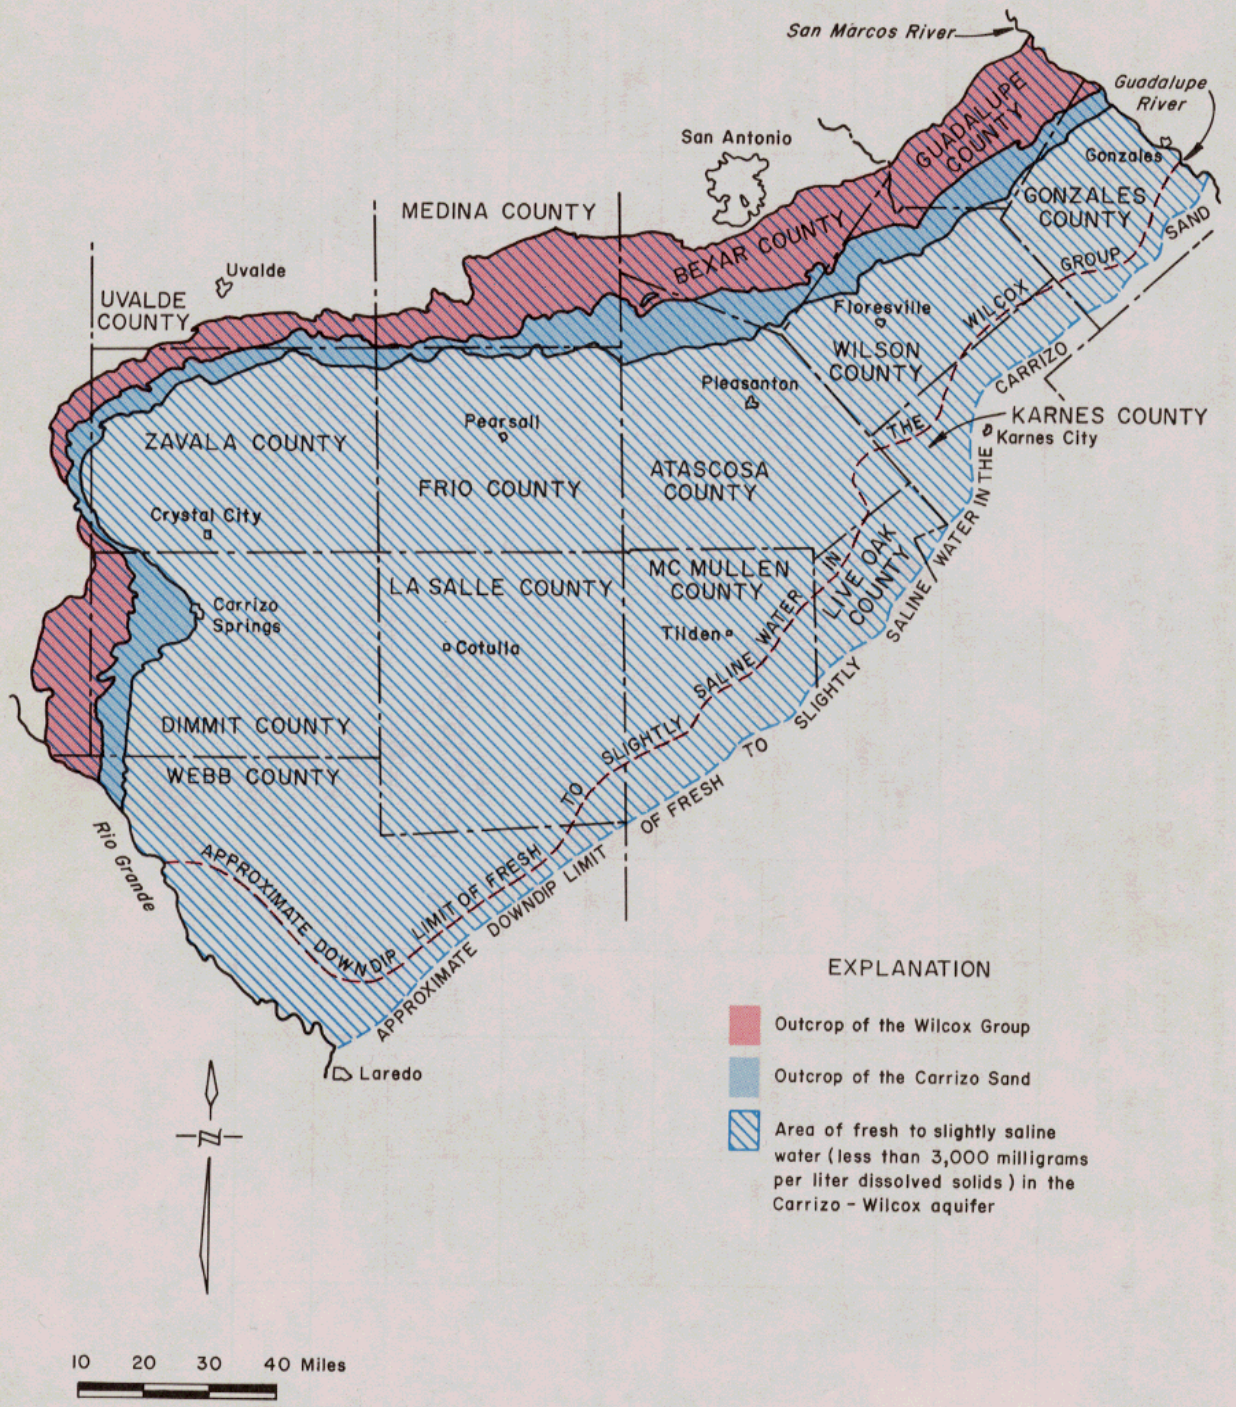

Figure 2
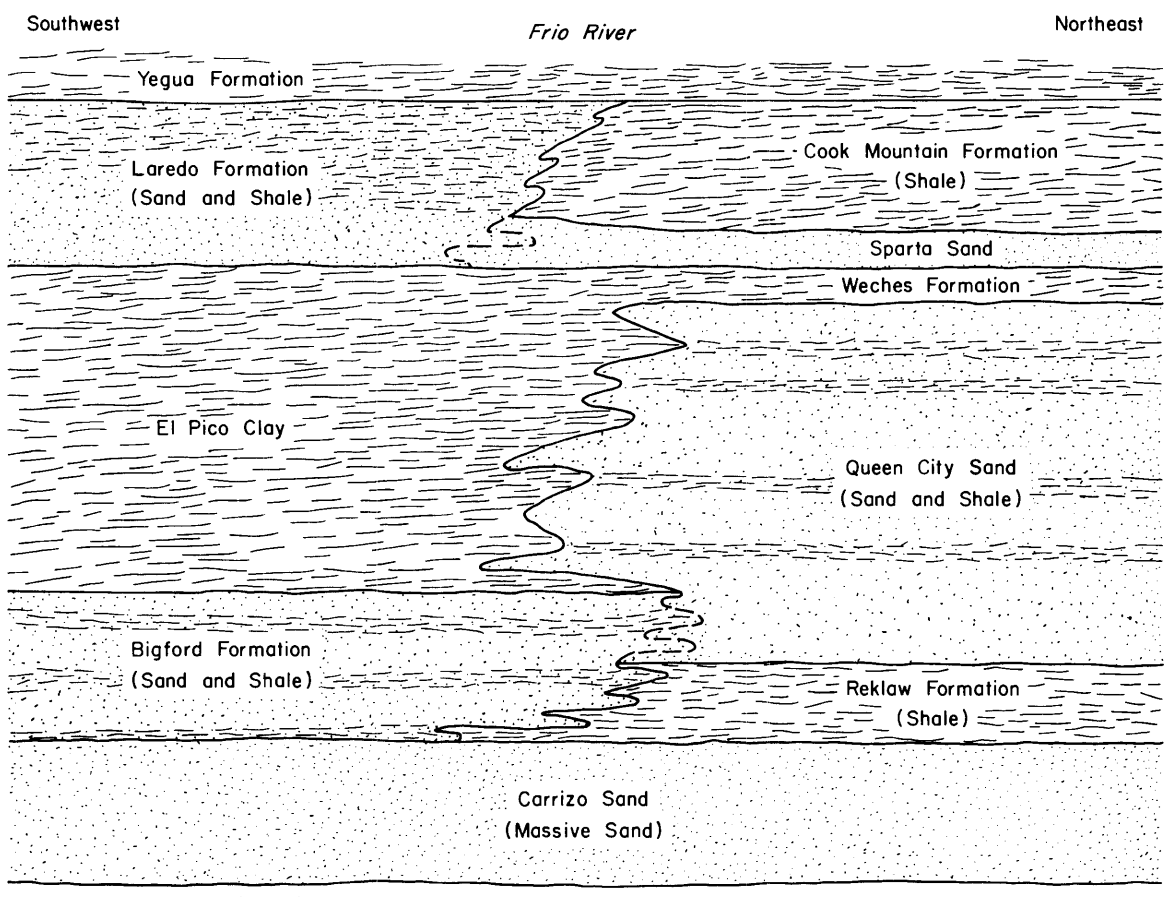
Extent of Fresh to Slightly Saline
Water in the Carrizo-Wilcox Aquifer

the term "Carrizo-Wilcox aquifer" is often used. The waters probably comingle to a degree, although most of the sand beds in the Wilcox Group are less permeable and most contain poorer quality water than the Carrizo Sand. Within the Wilcox, also, water quality in most areas generally diminishes with greater depth. The depth to and altitude of the base of fresh to slightly saline water in the Carrizo-Wilcox aquifer (Carrizo Sand and Wilcox Group) are shown on Figure 11. A better understanding of the extent of fresh to slightly saline water in the aquifer can be had by referring to the geohydrologic sections (Figures 27, 28, and 29). The total saturated thickness, and net saturated sand thickness, of the Carrizo-Wilcox aquifer above the base of fresh to slightly saline water are illustrated in Figure 12.

Above the Carrizo in areas west and southwest of the Frio River are the Bigford, El Pico Clay, Laredo, and Yegua Formations, which differ in lithologic character and fossil content from their equivalent counterparts northeast of the Frio River—the Reklaw, Queen City Sand, Weches, Sparta Sand, and Cook Mountain. Nomenclature of these and other formations of the Claiborne Group is detailed by Eargle (1968). The predominantly sandy units—the Queen City Sand, Bigford Formation, Sparta Sand, and Laredo Formation—interfinger in the vicinity of the Frio River to form two aquifers. These are the Queen City-Bigford and the Sparta-Laredo aquifers, which yield fresh to slightly saline water in the study area. The interfingering relationships of the formations in the vicinity of the Frio River are illustrated in Figure 3.

The Queen City-Bigford aquifer includes the water-bearing sands of the Queen City Sand and Bigford Formation. The Bigford Formation consists of sand, silt, and thin beds of shale, with the shale making up about 25 percent of the formation in the outcrop (Eargle, 1968). The Queen City Sand is a thick unit of sand, clay, and sandy clay. The Queen City-Bigford aquifer ranges in thickness from approximately 200 feet in Zavala



Modified from Eargle (1968)

Figure 3.—Idealized Geologic Section Illustrating the Interfingering of Sands and Shales of the Claiborne Group in the Vicinity of the Frio River

County to 1,400 feet in Frio County. Figure 4 shows the general extent of fresh to slightly saline water in the Queen City-Bigford aquifer in the study area.

The Sparta-Laredo aquifer contains the water-bearing sands of the Sparta Sand and Laredo Formation. The Sparta Sand ranges from 40 to 200 feet in thickness and consists of sand with minor amounts of clay. The Laredo Formation, consisting of sand and sandstone at the base and grading into sandy clay and clay at the top, attains a maximum thickness of 600 to 700 feet. The general extent of fresh to slightly saline water in the Sparta-Laredo aquifer in the study area is shown in Figure 5.

The uppermost formation of the Claiborne Group is the Yegua, consisting of fine sand, silt, and clay. The Yegua Formation generally yields small amounts of slightly to moderately saline water (1,000 to 10,000 mg/l dissolved solicls) east of the Frio River. West of the Frio River, the Yegua yields highly mineralized water that is generally unfit for livestock use.

THE CARRIZO AQUIFER

The name "Carrizo" was first applied by Owen (1889) to the thick, massive sand beds that unconformably overlie the sand, silt, and clay of the Wilcox Group in the vicinity of Carrizo Springs, Texas. Plummer (Sellards, Adkins, and Plummer, 1932) suggests that the type locality for the Carrizo Sand be designated at Brand Rock on the east bank of Pena Creek, which is about 5 miles west of Carrizo Springs. The development of the Carrizo aquifer dates back to 1884 when S. D. Frazier completed the first flowing well at Carrizo Springs in Dimmit County at a depth of 165 feet (Roesler, 1890). Today, the Carrizo aquifer is the most prolific source of fresh ground water in the Winter Garden Area.

Recharge, Discharge, and Movement

Annual recharge to the Carrizo aquifer in Dimmit, Zavala, and Maverick Counties according to Turner and others (1948) averages about 25,000 acre-feet. Alexander and White (1966) estimated the annual average recharge to the Carrizo aquifer in Atascosa and Frio Counties to be 13,000 and 10,000 acre-feet, respectively. Barnes (1956) reported approximately 26,000 acre-feet per year being recharged in Wilson County. These areas account for about 75 percent of the Carrizo outcrop in the Winter Garden Area. From these data it was estimated that the remaining outcrop areas would receive about 26.000 acre-feet annually, based upon the higher permeability of the aquifer and the higher amount of precipitation in the eastern portion of the study area. Thus, the average rate of recharge to the Carrizo aquifer in the Winter Garden Area is about 100,000 acre-feet per year or 89 mgd (million gallons per day).

In some local areas of the Carrizo aquifer's extent, some of the sands containing fresh to slightly saline water in the Wilcox Group, Bigford Formation, and Reklaw Formation may be hydrologically connected with the Carrizo Sand. Leakage into the Carrizo aquifer is known to occur in the regions of intensive irrigation in Dimmit, Frio, and Zavala Counties where water of higher mineral content in other formations leaks through confining beds or percolates down well bores of poorly constructed and abandoned wells. Computer simulations of the aquifer, which will be discussed later, have indicated that much greater water-level declines should have occurred during the period 1963-1969 than actually occurred except as may be accounted for by interformational leakage. The computer simulations indicate that about 9,500 acre-feet per year (8.5 mgd) leaked into the Carrizo during the period 1963-1969.

The estimated amount of water pumped for irrigation, public supply, and industrial use from the Carrizo aquifer in the study region and in the Winter Garden District (Dimmit, Zavala, and eastern Maverick Counties) is given in Figure 7. The graph shows that pumpage in the Winter Garden Area averaged about 272,000 acre-feet per year (243 mgd) for the period 1963-I 969.

Ground water in the Carrizo aquifer moves downward from the recharge zone to the zone of saturation and then generally in the direction of the slope of the piezometric surface. The piezometric surface is an imaginary surface that everywhere coincides with the static water level in the aquifer. The piezometric surfaces of the Carrizo aquifer in 1929-30 and in 1970 are illustrated in Figures 13 and 14, respectively.

Hydraulic Characteristics

An aquifer's hydraulic characteristics are generally described in terms of its coefficients of transmissibility and storage. These were determined for the Carrizo aquifer by conducting pumping tests in selected wells, and from the well performance tests that had been made by water well drilling and servicing companies. The tests consist of pumping a well for a period of time and taking periodic water-level measurements in the pumping well and in one or more nearby observation wells if available.

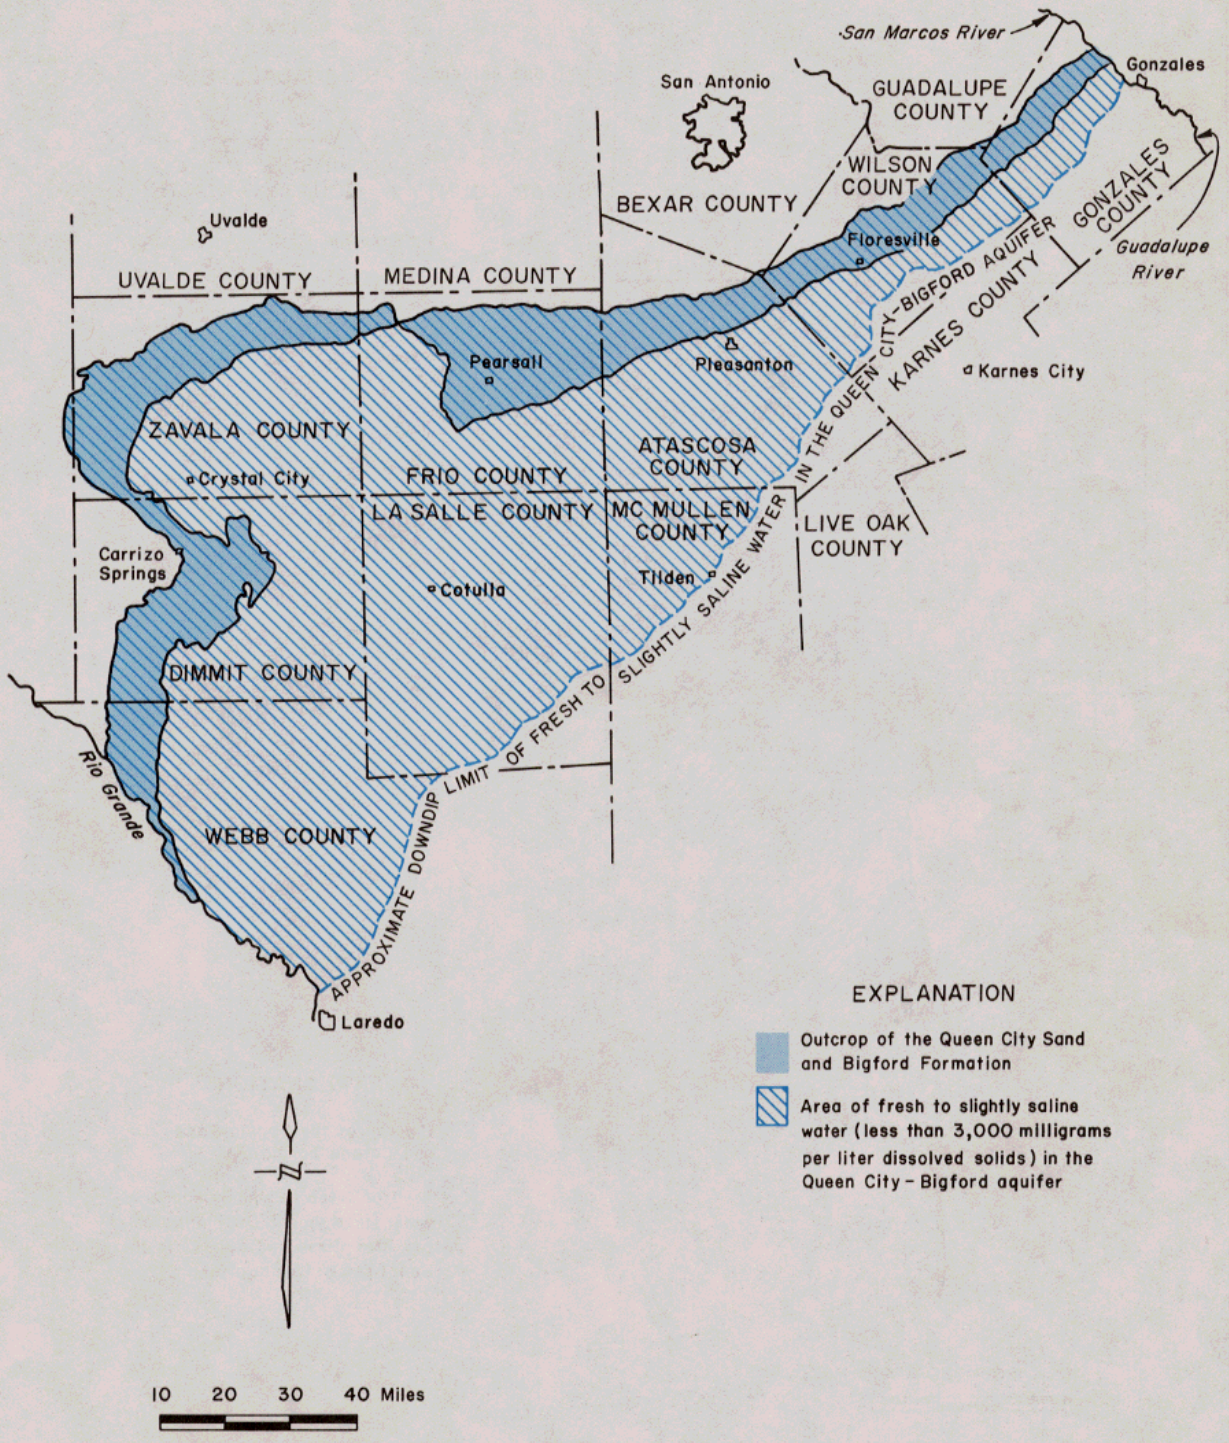


Figure 4

Extent of Fresh to Slightly Saline Water in the Queen City-Bigford Aquifer

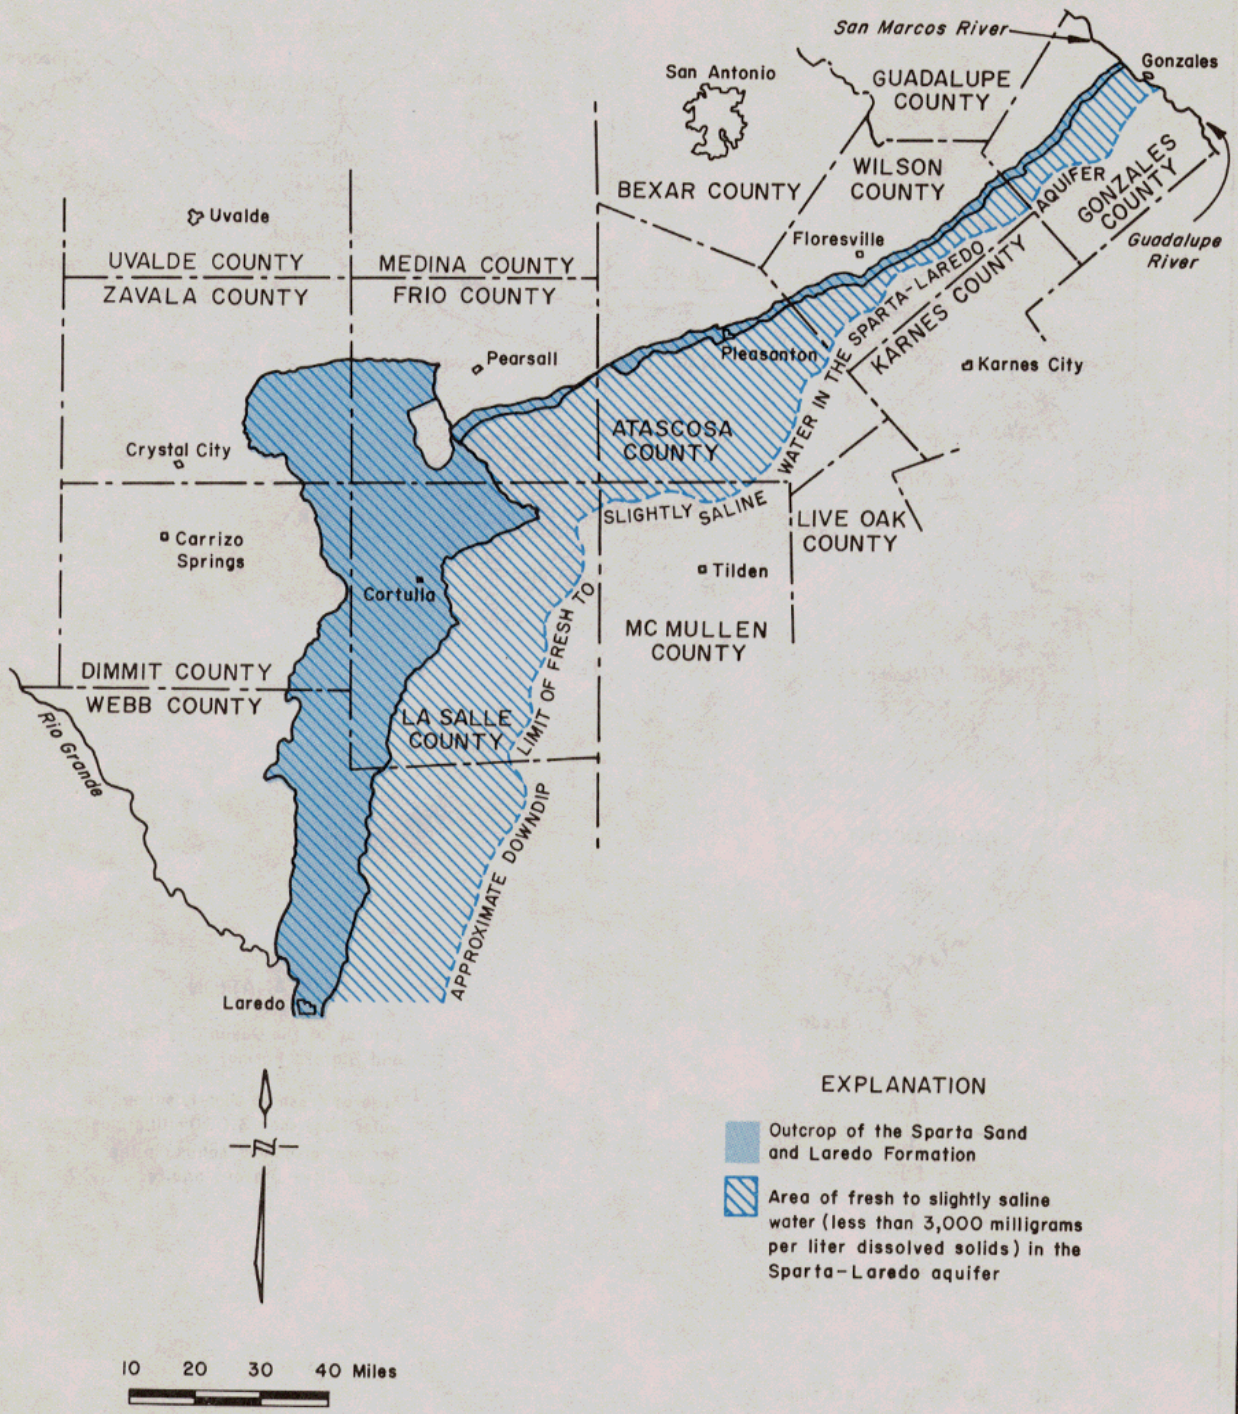

Figure 5

Extent of Fresh to Slightly Saline Water in the Sparta-Laredo Aquifer

Data obtained from pumping tests were analyzed using the Theis (1935) nonequilibrium formula. For tests conducted under water-table conditions, the water-level drawdown data were corrected in the manner described by Jacob (1944) for the decrease in aquifer transmissibility that accompanies the decrease in its saturated thickness during the test. Performance test data were analyzed by the modified Thiem formula as presented by Thomasson (1960) and with further modification by the authors to consider well completion efficiencies. Specific capacities of wells were also determined, by dividing the well's yield by the total water-level drawdown measured in the well.

Each well test provided transmissibility data for only that portion of the aquifer screened by the well. These transmissibility values were divided by the effective sand thickness utilized by the well, to obtain a coefficient of aquifer permeability. The permeability coefficients were then multiplied by an estimate of the aquifer's total net thickness of sand containing fresh to slightly saline water to obtain approximate coefficients of transmissibility for the aquifer's total fresh to slightly saline water section.

The coefficients of permeability determined for the aquifer are shown in Figure 15, and the coefficients of transmissibility are given in Figure 16. The specific capacities of individual water wells are given in Figure 17.

The largest permeability and transmissibility coefficients found in selected counties are presented below:

COUNTY	MAXIMUM COEFFICIENT OF PERMEABILITY (GPD/FT^2 AT FORMATION TEMPERATURE)	MAXIMUM COEFFICIENT OF TRANSMISSIBILITY (GPD/FT AT FORMATION TEMPERATURE)
Atascosa	475	317,000
Dimmit	410	65,000
Frio	500	230,000
Gonzales	300	200,000
La Salle	170	110,000
McMullen	90	100,000
Webb	70	7,000
Wilson	500	30 1,000
Zavala	425	75,000

The average coefficient of storage in the outcrop, under water-table conditions, is approximately 0.25. Downdip, where the aquifer is under artesian conditions, the average coefficient of storage is approximately 5×10^{-4} or 0.0005. The coefficient of storage is a dimensionless term which indicates the volume of water that an aquifer releases from or takes into storage per unit surface area of the aquifer per unit change in the component of head normal to that surface. For water-table conditions the coefficient of storage is the same as the specific yield of the material dewatered during pumping, and for artesian conditions it reflects the amount of aquifer compression and water expansion when the head or pressure is reduced during pumping.

An aquifer's permeability depends on the shape, sorting, arrangement, and cementation of its component sediment grains. To obtain permeability data for the Carrizo aquifer in the outcrop, a test-hole drilling program was initiated. Test holes were drilled with the Texas Water Development Board's drilling rig in the outcrop of the Carrizo Sand in seven counties, and the cores obtained from these test holes were analyzed by the Board's Materials Testing Laboratory to obtain information on sand particle diameters and to determine coefficients of grain-size uniformity and permeability. Permeability coefficients, in gallons per day per square foot (gpd/ft^2), were determined by using a falling head permeameter and correcting the results to 60°F (16°C).

The results of laboratory determinations for selected test holes in the Carrizo Sand outcrop are summarized by county below. The coefficients of permeability shown are generally higher than those obtained from analyses of pumping tests of wells in the Carrizo Sand outcrop.

COUNTY	NUMBER OF TEST HOLES	AVERAGE SAND GRAIN DIAMETER 50 PERCENT RETAINED (INCHES)	AVERAGE SAND GRAIN DIAMETER 90 PERCENT RETAINED (INCHES)	AVERAGE UNIFORMITY COEFFICIENT	AVERAGE COEFFICIENT OF PERMEABILITY (GPD/FT² AT 60°F)	
					CORES	CUTTINGS
Atascosa	2	0.0115	0.0066	2.00	487	555
Dimmit	1	.0092	.0048	2.09	40	479
Frio	1	.0106	.0064	1.82	–	
Maverick	1	.0122	.0063	2.24	–	685
Medina	2	.0086	.0051	1.85	748	626
Wilson	4	.009 1	.0047	2.11	475	556
Zavala	4	.0088	.0055	1.72	944	539

Chemical Quality

All ground water contains minerals carried in solution, the type and concentration of which depend upon the surface and subsurface environment, rate of ground-water movement, and source of the ground water. Precipitation is relatively free of minerals until it comes in contact with the various constituents which make up the soils and component rocks of the aquifer. As a result of the water's solvent power, minerals are dissolved and carried into solution as the water moves through the aquifer. The concentration depends upon the solubility of the minerals present, the length of time water is in contact with the rocks, and the amount of dissolved carbon dioxide the water contains. Concentrations of dissolved minerals in ground water generally increase with depth where circulation has been restricted due to various geologic conditions.

The source, significance, and range in concentration of selected chemical constituents in ground water in the Carrizo aquifer are given in Table 2. Dissolved-solids concentrations and sodium adsorption ratios (SAR) in water samples collected from the Carrizo aquifer are illustrated in Figures 18 and 19.

The characteristics of an irrigation water that seem to be most important in determining its quality are as follows: (a) total concentration of soluble salts; (b) relative proportion of sodium to other principal cations (magnesium, calcium, and potassium); (c) concentration of boron or other elements that may be toxic; and (d) under some conditions, the bicarbonate concentration as related to the concentration of calcium plus magnesium. These have been termed, respectively, the salinity hazard, the sodium (alkali) hazard, the boron hazard, and the bicarbonate ion hazard.

For the purposes of diagnosis and classification of irrigation waters, the total concentration of soluble salts (salinity hazard) in the water can be adequately expressed in terms of specific conductance. Specific conductance is the measure of the ability of the ionized inorganic salts in solution to conduct an electrical current and is usually expressed in terms of micromhos per cubic centimeter at 25°C. In general, water having a conductance below 750 micromhos per cubic centimeter is satisfactory for irrigation; however, salt-sensitive crops, such as strawberries and green beans, may be adversely affected by irrigation water having a conductance in the range of 250 to 750 micromhos per cubic centimeter. The specific conductance of water samples collected from the Carrizo aquifer ranged from 94 to 4,990 micromhos per cubic centimeter at 25°C.

In the past, irrigation waters were divided into the three following classes based on the percent sodium: (a) water with a percent sodium less than 60, excellent

Table 2.—Source, Significance, and Concentration Range of Selected Chemical Constituents in Ground Water in the Carrizo Aquifer

(Concentration ranges shown are in milligrams per liter except specific conductance, pH, percent sodiu sodium-adsorption ratio, and residual sodium carbonate.)

CONSTITUENT OR PROPERTY	SOURCE OR CAUSE	SIGNIFICANCE	CONCENTRATION RANGE
Silica (SiO_2)	Dissolved from practically all rocks and soils, commonly less than 30 mg/l. High concentrations, as much as 100 mg/l, generally occur in highly alkaline waters.	Forms hard scale in pipes and boilers. Carried over in steam of high pressure boilers to form deposits on blades of turbines. Inhibits deterioration of zeolite-type water softeners.	4 - 95
Iron (Fe)	Dissolved from practically all rocks and soils. May also be derived from iron pipes, pumps, and other equipment.	On exposure to air, iron in ground water oxidizes to reddish-brown precipitate. More than about 0.3 mg/l stains laundry and utensils reddish-brown. Objectionable for food processing, textile processing, beverages, ice manufacture, brewing, and other processes. U.S. Public Health Service (1962) drinking-water standards state that iron should not exceed 0.3 mg/l. Larger quantities cause unpleasant taste and favor growth of iron bacteria.	<1 - 68.62
Calcium (Ca) and Magnesium (Mg)	Dissolved from practically all soils and rocks, but especially from limestone, dolomite, and gypsum. Calcium and magnesium are found in large quantities in some brines. Magnesium is present in large quantities in sea water.	Cause most of the hardness and scale-forming properties of water; soap consuming (see hardness). Waters low in calcium and magnesium desired in electroplating, tanning, dyeing, and in textile manufacturing.	(Ca) 2 - 323 (Mg) <1 - 103
Sodium (Na) and Potassium (K)	Dissolved from practically all rocks and soils. Found also in oilfield brines, sea water, industrial brines, and sewage.	Large amounts, in combination with chloride, give a salty taste. Moderate quantities have little effect on the usefullness of water for most purposes. Sodium salts may cause foaming in steam boilers and a high sodium content may limit the use of water for irrigation.	(Na) 8 - 1,310 (K) <1 - 23
Bicarbonate (HCO_3) and Carbonate (CO_3)	Action of carbon dioxide in water on carbonate rocks such as limestone and dolomite.	Bicarbonate and carbonate produce alkalinity. Bicarbonates of calcium and magnesium decompose in steam boilers and hot water facilities to form scale and release corrosive carbon dioxide gas. In combination with calcium and magnesium, cause carbonate hardness.	(HCO_3) <1 - 2,760
Sulfate (SO_4)	Dissolved from rocks and soils containing gypsum, iron sulfides, and other sulfur compounds. Commonly present in some industrial wastes.	Sulfate in water containing calcium forms hard scale in steam boilers. In large amounts, sulfate in combination with other ions gives bitter taste to water. U.S. Public Health Service (1962) drinking-water standards recommend that the sulfate content should not exceed 250 mg/l.	<1 - 1,160

Table 2.—Source, Significance, and Concentration Range of Selected Chemical Constituents in Ground Water in the Carrizo Aquifer—Continued

CONSTITUENT OR PROPERTY	SOURCE OR CAUSE	SIGNIFICANCE	CONCENTRATION RANGE
Chloride (Cl)	Dissolved from rocks and soils. Present in sewage and found in large amounts in oil-field brines, sea water, and industrial brines.	In large amounts in combination with sodium, gives salty taste to drinking water. In large quantities, increases the corrosiveness of water. U.S. Public Health Service (1962) drinking-water standards recommend that the chloride content should not exceed 250 mg/l.	.9 - 970
Fluoride (F)	Dissolved in small to minute quantities from most rocks and soils. Added to many waters by fluoridation of municipal supplies.	Fluoride in drinking water reduces the incidence of tooth decay when the water is consumed during the period of enamel calcification. However, it may cause mottling of the teeth depending on the concentration of fluoride, the age of the child, amount of drinking water consumed, and susceptibility of the individual (Maier, 1950, p. 1120-1132).	<1 - 10.7
Nitrate (NO_3)	Decaying organic matter, sewage, fertilizers, and nitrates in soil.	Concentration much greater than the local average may suggest pollution. U.S. Public Health Service (1962) drinking-water standards suggest a limit of 45 mg/l. Waters of high nitrate content have been reported to be the cause of methemoglobinemia (an often fatal disease in infants) and therefore should not be used in infant feeding (Maxcy, 1950, p. 271). Nitrate has been shown to be helpful in reducing inter-crystalline cracking of boiler steel. It encourages growth of algae and other organisms which produce undesirable tastes and odors.	<1 - 120
Boron (B)	A minor constituent of rocks and of natural waters.	An excessive boron content will make water unsuitable for irrigation. Wilcox (1955, p. 11) indicated that a boron concentration of as much as 1.0 mg/l is permissible for irrigating sensitive crops; as much as 2.0 mg/l for semitolerant crops; and as much as 3.0 mg/l for tolerant crops. Crops sensitive to boron include most deciduous fruits and nut trees and navy beans; semitolerant crops include most small grains, potatoes and some other vegetables, and cotton; and tolerant crops include alfalfa, most root vegetables, and the date palm.	<1 - 1.5
Dissolved solids	Chiefly mineral constituents dissolved from rocks and soils.	U.S. Public Health Service (1962) drinking-water standards recommend that waters containing more than 500 mg/l dissolved solids not be used if other less mineralized supplies are available. For many purposes the dissolved-solids content is a major limitation on the use of water. A general classification of water based on dissolved-solids	6 - 3,139

Table 2.—Source, Significance, and Concentration Range of Selected Chemical Constituents in Ground Water in the Carrizo Aquifer—Continued

CONSTITUENT OR PROPERTY	SOURCE OR CAUSE	SIGNIFICANCE	CONCENTRATION RANGE
		content, in mg/l, is as follows (Winslow and Kister, 1956, p. 5): Waters containing less than 1,000 mg/l of dissolved solids are considered fresh; 1,000 to 3,000 mg/l, slightly saline; 3,000 to 10,000 mg/l, moderately saline; 10,000 to 35,000 mg/l, very saline; and more than 35,000 mg/l, brine.	
Hardness as $CaCO_3$	In most waters nearly all the hardness is due to calcium and magnesium. All the metallic cations other than the alkali metals also cause hardness.	Consumes soap before a lather will form. Deposits soap curd on bathtubs. Hard water forms scale in boilers, water heaters, and pipes. Hardness equivalent to the bicarbonate and carbonate is called carbonate hardness. Any hardness in excess of this is called non-carbonate hardness. Waters of hardness up to 60 mg/l are considered soft; 61 to 120 mg/l, moderately hard; 121 to 180 mg/l, hard; and more than 180 mg/l, very hard.	1 - 2,027
Specific conductance (micromhos per cubic centimeter at 25°C)	Mineral content of the water.	Indicates degree of mineralization. Specific conductance is a measure of the capacity of the water to conduct an electric current. Varies with concentration and degree of ionization of the constituents.	94 - 4,990
Hydrogen ion concentration (pH)	Acids, acid-generating salts, and free carbon dioxide lower the pH. Carbonates, bicarbonates, hydroxides, phosphates, silicates, and borates raise the pH.	A pH of 7.0 indicates neutrality of a solution. Values higher than 7.0 denote increasing alkalinity; values lower than 7.0 indicate increasing acidity. pH is a measure of the activity of the hydrogen ions. Corrosiveness of water generally increases with decreasing pH. However, excessively alkaline waters may also attack metals.	3.3 - 8.8
Percent sodium (% Na)	Sodium in water.	A ratio (using milliequivalents per liter) of the sodium ions to the total sodium, calcium, and magnesium ions. A sodium percentage exceeding 50 percent is a warning of a sodium hazard. Continued irrigation with this type of water will impair the tilth and permeability of the soil.	2.0 - 99.7
Sodium-adsorption ratio (SAR)	Sodium in water.	A ratio for soil extracts and irrigation waters used to express the relative activity of sodium ions in exchange reactions with soil (U.S. Salinity Laboratory Staff, 1954, p. 72, 156). Defined by the following equation: $$SAR = \frac{Na^{+}}{\sqrt{\frac{Ca^{++} + Mg^{++}}{2}}},$$ where Na^{+}, Ca^{++}, and Mg^{++} represent the concentrations, in milliequivalents per liter (me/l), of the respective ions.	.06 - 161.28

Table 2.—Source, Significance, and Concentration Range of Selected Chemical Constituents in Ground Water in the Carrizo Aquifer—Continued

CONSTITUENT OR PROPERTY	SOURCE OR CAUSE	SIGNIFICANCE	CONCENTRATION RANGE
Residual sodium carbonate (RSC)	Sodium and carbonate or bicarbonate in water.	As calcium and magnesium precipitate as carbonates in the soil, the relative proportion of sodium in the water is increased (Eaton, 1950, p. 123-133). Defined by the following equation: $RSC = (CO_3^{--} + HCO_3^-) - (Ca^{++} + Mg^{++})$, where CO_3^{--}, HCO_3^-, Ca^{++}, and Mg^{++} represent the concentrations, in milliequivalents per liter (me/l), of the respective ions.	<1 - 45.02

to good; (b) water with a percent sodium between 60 and 75, good to injurious, and (c) water with a percent sodium greater than 75, injurious to unsatisfactory. The percent sodium in water samples collected from the Carrizo aquifer ranged from 2.0 to 99.7.

A better measure of the sodium hazard of water for irrigation is the sodium-adsorption ratio (SAR) which is used to express the relative activity of sodium ions in exchange reactions with soil. The SAR is easily computed from the data determined in the usual water analysis by using the following equation:

$$SAR = \frac{Na^+}{\sqrt{\frac{Ca^{++} + Mg^{++}}{2}}},$$

where Na^+, Ca^{++}, and Mg^{++} represent the concentrations of sodium, calcium, and magnesium ions in milliequivalents per liter (me/l). The SAR of water samples collected from the Carrizo aquifer ranged from 0.06 to 161.28.

When the SAR and the specific conductance of a water are known, the classification of the water for irrigation can be determined by graphically plotting these values on the diagram shown in Figure 6. Low-sodium water (S1) can be used for irrigation on almost all soils with little danger of the development of harmful levels of exchangeable sodium. Medium-sodium water (S2) will present an appreciable sodium hazard in certain fine-textured soils having high cation-exchange capacity, especially under low-leaching conditions, unless gypsum is present in the soil. This water may be used on coarse-textured or organic soils having good permeability. High-sodium water (S3) may produce harmful levels of exchangeable sodium in most soils and will require special soil management such as good drainage, leaching, and addition of organic matter. Very

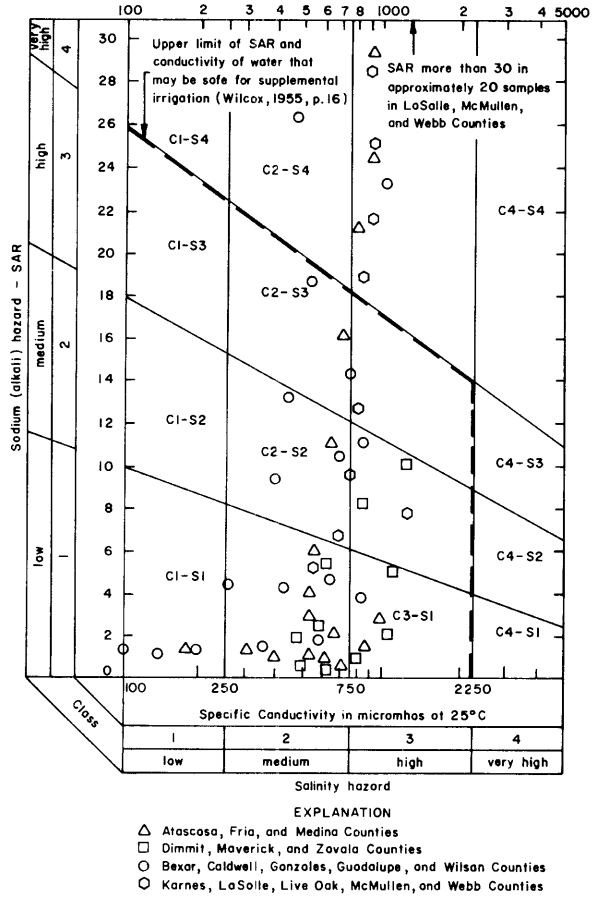

Figure 6.—Classification of Irrigation Waters, and Quality of Water From Representative Wells in the Carrizo Aquifer (After U.S. Salinity Laboratory Staff, 1954, p. 80)

high sodium water (S4) is generally unsatisfactory for irrigation unless special action is taken, such as addition of gypsum to the soil.

Low-salinity water (Cl) can be used for irrigation of most crops on most soils with little likelihood that soil salinity will develop. Medium-salinity water (C2) can be used if a moderate amount of leaching occurs. High salinity water (C3) cannot be used on soils with restricted drainage.

The classification of ground water from representative wells completed in the Carrizo aquifer, sampled throughout the Winter Garden Area, shows low to high salinity hazard (specific conductivity 100 to 1,300 micromhos per cubic centimeter at 25°C) while the sodium (alkali) hazard is generally low to medium (SAR 0.06 to 13) as illustrated in Figure 6.

In appraising the quality of an irrigation water, first consideration must be given to salinity and sodium hazards (Figure 6). Then consideration should be given to independent characteristics such as boron and bicarbonate, either of which may change the quality rating. The use of water of any quality must take into account such factors as land and crop management practices and soil drainage.

In the Winter Garden Area most public and domestic ground-water supplies are obtained from the Carrizo aquifer. Concentration limits recommended by the U.S. Public Health Service (1962, p. 7-8) for chemical constituents in public and domestic water supplies are shown in the following table. It should be noted that these concentration limits will prevail except where suitable water supplies are not available or cannot be made available at a reasonable cost.

SUBSTANCE		CONCENTRATION (MG/L)
Chloride	(Cl)	250
Fluoride	(F)	.8*
Iron	(Fe)	.3
Manganese	(Mn)	.05
Nitrate	(NO^3)	45
Sulfate	(SO_4)	250
Dissolved-solids		500

*Upper limit based on annual average of maximum daily air temperature range of 79.3 – 90.5°F. The recommended control limits of fluoride concentration in mg/l are: lower, 0.6; optimum, 0.7; and upper, 0.8.

Water samples from wells completed in the Carrizo aquifer were examined for chloride, sulfate, and dissolved solids. The chloride content ranged from 0.9 to 970 mg/l in 819 samples; only 5 percent of the samples contained water having greater than 250 mg/l chloride. Sulfate content ranged from less than 1 to 1,160 mg/l in 807 samples; only 4 percent of the samples contained water having greater than 250 mg/l sulfate. The dissolved-solids content in Carrizo aquifer samples ranged from 6 to 3,139 mg/l in 772 samples; only 18 percent of the samples contained water having greater than 500 mg/l dissolved solids.

Water containing less than 1,000 mg/l of dissolved solids is regarded in this report as fresh and more than 1,000 mg/l as saline. Less than 500 mg/l is recommended by the U.S. Public Health Service (1962) in potable water where water of this quality is available. However, it must be recognized that in many areas of Texas the only available water supply may have a dissolved-solids concentration greatly in excess of 1,000 mg/l. Only 7 percent of the Carrizo samples contained water having more than 1,000 mg/l dissolved solids.

Water having a dissolved-solids concentration of 1,000 to 3,000 mg/l is classified as slightly saline and is used by many small communities, farms, and ranches. Water of this class has been recognized as somewhat unsatisfactory but generally not harmful. Less than 1 percent of the Carrizo wells within the Winder Garden Area contained water having greater than 3,000 mg/l dissolved solids.

The chemical quality of ground water from the Carrizo aquifer is generally favorable for industrial use throughout most of the Winter Garden Area. The tolerance in chemical quality of water for industrial use differs widely for different industries and different processes. Table 3 illustrates some of the suggested tolerances for a number of industries (American Water Works Association, 1950, p. 66-67).

Aquifer Development and the Decline of Water Levels

Development of ground water from the Carrizo aquifer in the Winter Garden Area prior to 1900 was mainly for domestic, livestock, and public supply purposes. One of the earlier irrigation wells was completed at Carrizo Springs, Dimmit County, in 1884, at a depth of 165 feet. This was a flowing well that was used for both domestic and irrigation purposes (Roesler, 1890). During the period 1900-1930, large-scale irrigation development took place in Dimmit and Zavala Counties due to introduction of the efficient deep-well turbine pump. Later irrigation development spread northeast to many of the other counties in the Winter Garden Area.

Pumpage from the Carrizo aquifer during 1930-1969 is shown in Figure 7. The pumpage data in Figure 7 are based in part on power and yield tests conducted on selected irrigation wells, in part on questionnaires mailed annually by the Texas Water Development Board to municipalities and industries, and in part on various earlier studies in the region. The amount of ground water pumped from the Carrizo

1/ American Water Works Association, 1950.
2/ A—No corrosiveness; B—No slime formation; C—Conformance to Federal drinking water standards necessary; D-NaCl, 275 mg/l.
3/ Waters with algae and hydrogen sulfide odors are most unsuitable for air conditioning.
4/ Some hardness desirable.
5/ Water for distilling must meet the same general requirements as for brewing (gin and spirits mashing water of light-beer quality; whiskey mashing water of dark-beer quality).
6/ Clear, odorless, sterile water for syrup and carbonization. Water consistent in character. Most high quality filtered municipal water not satisfactory for beverages.
7/ Hard candy requires pH of 7.0 or greater, as low value favors inversion of sucrose, causing sticky product.
8/ Control of corrosiveness is necessary as is also control of organisms, such as sulfur and iron bacteria, which tend to form slimes.
9/ $Ca(HCO_3)_2$ particularly troublesome. $Mg(HCO_3)_2$ tends to greenish color. CO_2 assists to prevent cracking. Sulfates and chlorides of Ca, Mg, Na should each be less than 300 mg/l (white butts).
10/ Uniformity of composition and temperature desirable. Iron objectionable as cellulose adsorbs iron from dilute solutions. Manganese very objectionable, clogs pipelines and is oxidized to permanganates by chlorine, causing reddish color.
11/ Excessive iron, manganese, or turbidity creates spots and discoloration in tanning of hides and leather goods.
12/ Constant composition; residual alumina 0.5 mg/l.
13/ Calcium, magnesium, iron, manganese, suspended matter, and soluble organic matter may be objectionable.

Table 4.-Estimated Use of Ground Water for Irrigation, Public Supply, and Industrial Purposes From the Carrizo-Wilcox, Queen City-Bigford, and Sparta-Laredo Aquifers, 1969

AQUIFER	PUMPAGE, IN ACRE-FEET			
	PUBLIC SUPPLY	INDUSTRIAL	IRRIGATION	TOTAL'
Carrizo-Wilcox	–	–	–	273,000
a) Carrizo	8,900	3,100	255,000	–
b) Wilcox	2,000	480	3,700	–
Queen City-Bigford	1,100	31	4,000	5,130
Sparta- Laredo	120	–	850	97
			Total *	279,000

*Figures are approximate because some of the pumpage is estimated. Totals are rounded to three significant figures. In addition to the amounts shown in the table, approximately 3,000 acre-feet was lost from uncontrolled flowing wells and approximately 11,000 acre-feet was used for domestic and livestock purposes from these aquifers.

aquifer from 1930 to 1938 remained nearly constant. Since the late 1930's or early 1940's, the aquifer has undergone generally steady development to provide increasingly larger amounts of ground water, mostly for irrigation needs. Other causes for this increase include population growth, industrial expansion, and widespread drought conditions in early 1950's.

Table 4 provides estimates of the amounts of ground water obtained from the Carrizo and other aquifers in 1969 in the Winter Garden Area. The total irrigation, public supply, and industrial ground-water pumpage in 1969 in the Winter Garden Area was approximately 279,000 acre-feet or 249 mgd. Irrigation pumpage accounted for about 264,000 acre-feet (235 mgd), with about 255,000 acre-feet (228 mgd) coming from the Carrizo aquifer. These figures indicate that the Carrizo aquifer supplied 97 percent of the total irrigation pumpage, and that the irrigation pumpage amounts to 95 percent of the total irrigation, public supply, and industrial ground-water pumpage of the Winter Garden Area.

Large Carrizo water-level declines have taken place in the Winter Garden District (Dimmit, Zavala, and eastern Maverick Counties) where large amounts of ground water have been used in the production of garden vegetables. Figure 20 shows declines of 240 feet in this area for the period 1929-30 to 1970. Water-level declines in Atascosa, Wilson, and Gonzales Counties have not been as severe as in the Winter Garden District; however, south of Pearsall in Frio County, water levels have declined approximately 180 feet during this same period.

Availability of Ground Water for Future Development

Application of the Digital Computer Mathematical Model

One of the primary objectives of this study was to simulate the Carrizo aquifer in the Winter Garden Area with a digital computer mathematical model. The simulation process allows the prediction of water-level declines in the Carrizo aquifer based on projected pumpage, and the predicted water-level declines provide a means for evaluating the ability of the Carrizo aquifer to meet anticipated ground-water withdrawal requirements.

Three sets of aquifer simulations were made with the Carrizo aquifer model. First, the model was provided with data on the estimated past and projected future pumping rates and was programmed to compute and print out the amounts of resulting water-level decline for the periods 1970-l 980, 1970-l 990, and 1970-2020. County Agricultural Extension Agents furnished projections of irrigation pumpage requirements for these periods and studies conducted by the Board were used to project public supply and industrial

The following table summarizes the average annual pumpage that was programmed into the model for the periods 1963-1970, 1970-1980, 1980-1990, and 1990-2020:

PERIOD	FRIO COUNTY		WINTER GARDEN DISTRICT (DIMMIT, ZAVALA, AND EASTERN MAVERICK COUNTIES)		WINTER GARDEN AREA (REPORT AREA)	
	ACRE-FEET PER YEAR	MGD	ACRE-FEET PER YEAR	MGD	ACRE-FEET PER YEAR	MGD
1963-1970	72,700	64.86	121,400	108.31	272,000	242.65
1970-1980	74,200	66.20	120,600	107.59	306,000	272.99
1980-1990	76,300	68.06	119,600	106.69	314,000	280.12
1990-2020	79,000	70.48	119,000	106.16	332,000	296.19

Recharge and leakage to the Carrizo aquifer were assumed for these studies to approximate 100,000 acre-feet per year (89 mgd) and 9,500 acre-feet per year (8.5 mgd), respectively, in the Winter Garden Area.

Next, it was desired to know whether the Carrizo aquifer southeast of San Antonio in Wilson County could provide a firm municipal water supply of 20,000 to 40,000 acre-feet per year (18 to 36 mgd) for the San Antonio metropolitan area. The model was made to simulate two alternative lines of pumping wells or well fields, one under water-table conditions (Line A, shown on Figure 24) and the other under artesian conditions (Line B, shown on Figure 25). Wells along Line A were placed just southeast of the outcrop of the Carrizo Sand. Those along Line B were located approximately 5 miles downdip from the outcrop. Each of these lines of wells was simulated to produce 20,000 acre-feet per year (18 mgd), 30,000 acre-feet per year (27 mgd), and 40,000 acre-feet per year (36 mgd). This pumpage was in addition to the predicted irrigation, public supply, and industrial pumpage which had been forecast for the Winter Garden Area. Recharge to the Carrizo aquifer in the area of investigation was estimated to be approximately 26,000 acre-feet annually (23 mgd). This recharge area includes the Carrizo Sand outcrop in Wilson County and parts of Atascosa, Bexar, and Guadalupe Counties.

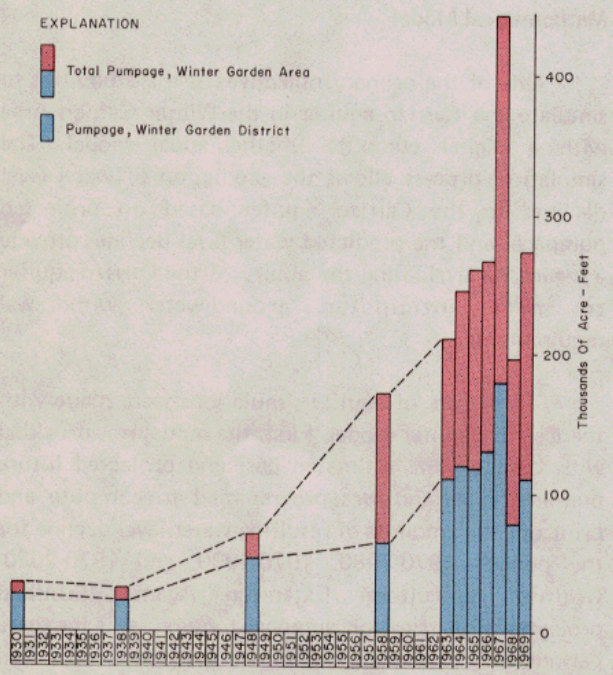

Figure 7.—Approximate Pumpage From the Carrizo Aquifer for Irrigation, Public Supply, and Industrial Use, 1930-1969

Last, simulations were made with the aquifer model to determine the annual withdrawal or pumping rate per unit area which would lower the Carrizo aquifer water levels to 400 feet below land surface throughout the Winter Garden Area. The pumping and lowering of water levels would occur from 1970 to 2020 and generally in the area between the outcrop and the downdip limit of fresh to slightly saline water (less than 3,000 mg/l dissolved solids). For the purpose of this study, ground-water development of the Carrizo aquifer in the downdip areas was considered economically feasible as long as water levels were 400 feet or less below land surface. Under these conditions, the following criteria were used as a basis for data input into the model prior to the simulation: (a) recharge and leakage to the Carrizo aquifer were assumed to approximate 100,000 acre-feet per year (89 mgd) and 9,500 acre-feet per year (8.5 mgd), respectively; (b) in the area where the Carrizo aquifer contains water having a dissolved-solids content greater than 1,000 mg/l, pumpage was not increased above the 1963-1969

average; and (c) pumpage was regulated so that water-level declines would be minimized in the outcrop and not fall below the top of the aquifer in the downdip area. The simulation provided data in the form of annual pumpage rates per unit area, which were used to determine the areas where the Carrizo aquifer is most and least favorable for future development.

Results of Aquifer Simulation

The simulation studies of the Carrizo aquifer indicate that, if pumpage remains unregulated and occurs at predicted rates, water levels will continue to decline rapidly in the heavily irrigated areas near Batesville and east of Carrizo Springs and Crystall City in Dimmit and Zavala Counties; elsewhere, water levels will slowly decline throughout the Winter Garden Area, including the downdip areas of interface between slightly saline and moderately saline ground water. The predicted water-level changes for the periods 1970-l 980, 1970-l990, and 1970-2020 are presented in the form of contour maps in Figures 21, 22, and 23.

The simulations of lines of pumping wells in areas of water-table and artesian conditions indicate that a firm water supply of 20,000 to 40,000 acre-feet (18 to 36 mgd) can be developed from the Carrizo aquifer in Wilson County for municipal use in the San Antonio region. The lines of pumping wells and their associated cones of water-level depression for the period 1970-2020 are illustrated in Figures 24 and 25. The maximum water-level drawdowns obtained from the simulations are summarized in the following table:

LINE OF PUMPING WELLS	PUMPAGE, 1970-2020 (ACRE-FEET)	MAXIMUM DRAWDOWN, 1970-2020 (FEET)
Line A	20,000 (18 mgd)	80
Line B	20,000 (18 mgd)	100
Line A	30,000 (27 mgd)	100
Line B	30,000 (27 mgd)	120
Line A	40,000 (36 mgd)	160
Line B	40,000 (36 mgd)	160

The annual recharge to the Carrizo aquifer in the area southeast of San Antonio is estimated to be approximately 26,000 acre-feet (23 mgd). The recharge area, for the most part includes the Carrizo Sand outcrop in Wilson County and parts of Atascosa, Bexar, and Guadalupe Counties. Recharge to the Carrizo aquifer would be increased as water levels are drawn down in the outcrop by the proposed well fields. The drawdown of water levels would reduce evapotranspiration losses and spring discharge into the San Antonio River and Cibolo Creek. The amount of increase in recharge which would result from the lowering of water levels in the vicinity of the outcrop was not estimated or used in the simulation studies.

Figure 26 illustrates pumpage patterns for optimizing development of ground water in the Carrizo aquifer in the Winter Garden Area. This rnap is a product of the 50-year aquifer simulation to determine the maximum constant pumping rates per unit area for the period 1970-2020, which would not bring water levels more than 400 feet below land surface or below the top of the aquifer. Possible water-quality changes due to the additional development of ground water were not considered in the analysis.

The aquifer simulation indicates that, under the constraints mentioned, approximately 330,000 acre-feet of water per year (294 mgd) could be pumped during the period 1970 to 2020 from the Carrizo aquifer in the Winter Garden Area. This is an increase of about 58,000 acre-feet per year (52 mgd) over the average annual withdrawals by large-capacity wells for the period 1963- 1969.

As shown in Figure 26, the areas favorable for future development of ground water from the Carrizo aquifer are generally located in (a) the Floresville, Stockdale, and Nixon areas of Wilson and Gonzales Counties; (b) northeast La Salle County; (c) an area west of Pearsall in Frio and Zavala Counties; (d) central and western Zavala County; and (e) central and southwestern Dimmit and northwestern Webb Counties. In these areas, approximately 118,000 acre-feet per year (105 mgd) could be developed in addition to the 1963-1969 average withdrawal rate without bringing water levels more than

400 feet below land surface or below the top of the water-bearing sands until the year 2020. The average annual withdrawal for the period 1963-1969 in these areas was approximately 22,500 acre-feet (20 mgd). The best locations for additional development generally correspond with the areas where the thickest accumulations of water-bearing sand occur within the aquifer (Figure 12j. Also, additional development must be distributed widely in order to avoid concentrated withdrawals of ground water in small areas.

Within the extensive area that is fully developed (Figure 26), ground-water withdrawal ideally should not be increased over the 1963-1969 rate, which was approximately 133,000 acre-feet per year (119 mgd).

The areas least favorable for future ground-water development from the Carrizo aquifer are the overdeveloped areas, shown in Figure 26 to be located: (a) in the outcrop of the Carrizo Sand in northern Frio, northern Atascosa, and southeastern Medina Counties; (b) at and southeast of Pearsall in Frio County; (c) near Batesville and in the outcrop of the Carrizo in northeastern Zavala County; (d) northeast, east, and southeast of Crystal City in Zavala and Dimmit Counties; and (e) near Carrizo Springs in Dimmit County. The 1963-1969 average annual withdrawal in these areas, approximately 117,000 acre-feet (104 mgd), should be reduced by approximately 59,800 acre-feet (53 mgd) if excessive water-level declines are to be avoided.

Artificial Recharge

Artificial recharge occurs when natural recharge is augmented so as to increase the amount of water entering the aquifer. The means of artificial recharge may include increasing the rate of infiltration through the soil profile, increasing the area in which surface runoff is in contact with the aquifer outcrop, and increasing the time during which the surface water is in contact with the aquifer outcrop. In addition to modifications to increase recharge in the aquifer's outcrop, water can be injected into the aquifer in downdip areas through injection wells.

Barnes (1956) estimated that a permanent water supply of 112,000 acre-feet per year (100 mgd) could be developed from the Carrizo aquifer in Wilson County for the San Antonio region by lowering water levels in the Carrizo outcrop in Atascosa, Bexar, and Wilson Counties, which would increase the amount of direct streambed infiltration from the San Antonio River and Cibolo Creek, and by spreading other waters over the outcrop. Barnes assumes that most of the water brought in for artificial recharge would be surplus water generated by the city of San Antonio. In order to lower the water table in the outcrop, Barnes proposes drilling 18 wells along a line parallel with the lower Carrizo outcrop edge. These wells would be spaced one mile apart and each produce 1,000 gpm (gallons per minute).

When evapotranspiration losses and spring flows have ceased in the aquifer outcrop due to water-level declines, other steps to increase the amount of recharge in the outcrop appear feasible. The Winter Garden District (Dimmit, Zavala, and eastern Maverick Counties) offers excellent possibilities, as large water-level declines have taken place in the outcrop in this region. Similarly, the well field proposed by Barnes (1956) or the well fields studied in this report in Wilson County would offer excellent possibilities for artificial recharge by creating large water-level declines in the outcrop.

Artificial recharge to the Carrizo aquifer in the outcrop could be achieved by: (a) constructing a series of diked basins, superimposed on the natural stream drainage to retard runoff and promote infiltration; (b) scarifying, leveling, and widening the beds of intermittent streams to increase infiltration; and (c) transporting to the outcrop the surplus water of cities, industry, or flood runoff.

Getzendaner (1953) describes an injection well experiment on the Byrd Ranch near Crystal City. Initially the injection rate was estimated at 1,800 gpm for 38 minutes, at which time the Carrizo aquifer ceased to take water at this rate and the injection rate was reduced to approximately 900 gpm. This lower injection rate was continued for 4 hours and 45 minutes until the experiment was terminated because of darkness. Getzendaner wrote:

> Many experiments with such wells, in California and elsewhere, have had little success. But excepting in Brooklyn and Queens, Long Island, where water is injected into gravel, there has been no attempt, so far as the literature discloses, to inject water through wells into as porous and permeable, nor as thick a formation as the Carrizo Sand in this district.

Clogging of the aquifer and low injection rates are problems which must be overcome if injection wells are to function successfully. Some of the causes of clogging are algea, silt, and entrained air. Poor recharge well design and completion of recharge wells in zones of low permeability in the aquifer may also contribute to low injection rates.

The amount and cost of water which can be recharged into the Carrizo aquifer depend on the

availability of recharge water, methods used, frequency of use, maintenance (clogging, weeds, sedimentation or flocculation, etc.) land costs, and capital works investment. The cost of artificial recharge projects may be reduced in part through the operation of sand pits or possibly by joint use of a recreation area. For example, sand excavated from the artificial recharge puts could be sold for construction purposes; and municipal recreational facilities such as parks, golf courses, baseball diamonds, football fields, public hunting and fishing areas, and skeet and trap ranges could be incorporated into an artificial recharge project.

Ground-Water Development Problems

Problems associated with the development of ground water from the Carrizo aquifer can be related to (a) improper well completion, (b) water-level declines, and (c) contamination of native ground water.

Improper well completion can usually be attributed to insufficient casing, open-hole rather than screened completion, slotted or perforated casing as a substitute for screen, improper gravelpacking, or lack of cement in the annulus between the casing and the borehole. The following are recommendations for the proper construction and completion of high-capacity wells in sand and gravel aquifers: (a) wells should be drilled to the base of the zone containing desirable quality water, thereby utilizing maximum saturated thickness; (b) all wells should be cased (including screen) from ground level to total depth; (c) gravel packing, when used, should be preceded by a sieve analysis of the aquifer to determine the proper size of the pack material to be used; and (d) the well should be completed with a properly designed well screen.

Large, concentrated withdrawals of ground water from storage in the Carrizo aquifer have caused large-scale water-level declines and possible contamination problems in the Winter Garden District (Dimmit, Zavala, and eastern Maverick Counties) where the aquifer has comparatively low transmissibility. This district is famous for its production of garden vegetables and has experienced a large amount of irrigation development since the late 1930's. As a result of these large water-level declines, well yields have decreased. In order to meet increased water demands, well pumps must be set deeper and larger motors installed. In some cases, new wells are needed to meet the demands for water supplies. These improvements cause operating costs to spiral upward as ground-water users attempt to meet demands and, in doing so, cause additional water-level declines.

Prior to large-scale development of ground water in Dimmit and Zavala Counties, the hydrostatic head of the Carrizo aquifer was considerably higher than the hydrostatic head of the highly mineralized waters of the overlying sands. As the hydrostatic head of the Carrizo dropped with development in Dimmit and Zavala Counties, the mineralized waters from these sands began moving into the Carrizo as leakage through the confining beds or down the well bores in which the casing was defective, improperly installed, or had not been cemented. This water mingles with the native Carrizo water, thus deteriorating its chemical quality. Although the problem is confined to individual wells at present, continued increase in development of the Carrizo in Dimmit and Zavala Counties could result in more wide spread aquifer contamination due to interformational leakage.

Developing and utilizing ground water from a well or well field require adequate planning. Future development of ground water in the Winter Garden Area should be based on a program of test drilling, test pumping, and chemical analysis of water from the producing aquifer. Such preliminary data can be used to determine the most efficient well completion, optimum pumping rate, efficient pump setting, optimum well spacing, and feasibility of drilling additional wells. Large, concentrated withdrawals of ground water in small areas should be avoided.

GROUND-WATER AVAILABILITY IN THE WILCOX, QUEEN CITY-BIGFORD, AND SPARTA-LAREDO AQUIFERS

Estimates of the amount of water available from the Wilcox, Queen City-Bigford, and Sparta-Laredo aquifers are based on the transmission and storage capacities of the aquifers. The transmission capacity of an aquifer can be approximated for any proposed development scheme by using the formula

$$Q=TWI,$$

where

Q = the average quantity of water in gallons per day moving through the aquifer;

T = the average coefficient of transmissibility in gallons per day per foot of aquifer width;

W = the width of the aquifer in miles, parallel to the strike of the formation; and

I = the average hydraulic gradient in feet per mile.

The development scheme considered is based on the following conditions: (a) the effect of pumping is such that static water levels are drawn down to a maximum depth of 400 feet below land surface, but not below the top of the aquifer; (b) the line along which the static water levels are 400 feet below the land surface is located about midway between the outcrop and the downdip limit of fresh to slightly saline water in the aquifer; and (c) lowering of water levels within the outcrop does not occur. The average coefficient of transmissibility in gallons per day per foot (gpd/ft) was determined from the average net sand thickness and the estimated permeability along the line described above; and the average artesian storage coefficient was estimated by multiplying the average net saturated sand thickness, in feet, by 10^{-6} per foot, which is proper for most confined aquifers (Lohman, 1972, p. 8).

In determining the quantity of water available, (a) a total amount of water obtained from artesian storage by lowering the static water level to a depth of 400 feet below land surface was calculated, and (b) the amount of water that the aquifer will transmit annually after static water levels have been lowered to a depth of 400 feet below land surface was calculated.

The following table summarizes the coefficients used to estimate the amount of water which can be developed from the Wilcox, Queen City-Bigford, and Sparta-Laredo aquifers. Only the portions of the Wilcox and Queen City-Bigford aquifers east of the Frio River are included in this determination since it is doubtful that these aquifers will be developed to any great extent west of the river.

AQUIFER	COEFFICIENT OF TRANSMISSIBILITY (GPD/FT)	WIDTH OF AQUIFER (MILES)	HYDRAULIC GRADIENT (FT/MILE)	ARTESIAN STORAGE COEFFICIENT
Wilcox	44,000	123	33	5×10^{-4}
Queen City-Bigforcl	14,000	111	88	5×10^{-4}
Sparta-Laredo	5,000	197	81	1×10^{-4}

Based on the above figures, east of the Frio River 200,000 acre-feet of water per year (178 mgd) can theoretically be transmitted by the Wilcox aquifer and 153,000 acre-feet annually (136.5 mgd) by the Queen City-Bigford aquifer to pumping wells in the Winter Garden Area. Approximately 89,000 acre-feet per year (79 mgd) can be transmitted by the Sparta-Laredo aquifer. These are the computed amounts which can be pumped annually without lowering the static water levels below the top of the aquifer or more than 400 feet below land surface, providing that the aquifer recharge in the outcrop is sufficient. In the opinion of the authors, the areas of aquifer outcrop may be too small to supply these estimated transmission capacities and they should be reduced by a factor of 2 or 3 for judging the amount of water continuously available.

The amount of water available from storage was calculated to be 244,000 acre-feet in the Wilcox, 100,000 acre-feet in the Queen City-Bigford, and 40,000 acre-feet for the Sparta-Laredo, should static water levels be lowered 400 feet below land surface along a line midway between the outcrop and the downdip limit of fresh to slightly saline water in the aquifers. These amounts can be pumped from storage only once, not annually, and should not be considered in long-range planning.

SUMMARY

The Winter Garden Area consists of approximately 11,800 square miles and lies within the Guadalupe, San Antonio, Nueces, and Rio Grande basins. It includes all or part of Atascosa, Bexar, Dimmit, Frio, Gonzales, Guadalupe, Karnes, La Salle, Live Oak, McMullen, Maverick, Medina, Uvalde, Webb, Wilson, and Zavala Counties. Within the Winter Garden Area is found the Winter Garden District which includes Dimmit and Zavala Counties and the eastern part of Maverick County.

The Carrizo aquifer (Carrizo Sand) is the most continuous and permeable aquifer in the area and therefore is the most developed water-bearing formation. In local areas of the aquifer's extent, some of the sands containing fresh to slightly saline water in the Reklaw Formation, Bigford Formation, and Wilcox Group may be hydrologically connected to the Carrizo Sand. The Carrizo aquifer ranges in thickness from about 150 to 1,200 feet. The transmissibility of the Carrizo ranges from less than 1,000 gallons per day per foot in Webb County to 317,000 gallons per day per foot in Atascosa County. The average coefficient of storage in the outcrop of the Carrizo aquifer is approximately 0.20. Downdip, where the aquifer is under artesian conditions,

the average coefficient of storage approximates 0.0005 or 5×10^{-4}.

Throughout the Winter Garden Area, the Carrizo aquifer yields fresh to slightly saline water which is acceptable for most irrigation, public supply, and industrial purposes. In the outcrop, the Carrizo aquifer contains hard water which is otherwise low in dissolved solids. Downdip the water is softer, has a higher temperature, and contains more dissolved solids. Carrizo aquifer water has a low to high salinity hazard for irrigation use, and the sodium (alkali) hazard is generally low to medium.

The average rate of recharge to the Carrizo aquifer in the Winter Garden Area is about 100,000 acre-feet per year or 89 mgd. In the heavily irrigated areas of Dimmit, Zavala, and Frio Counties, leakage into the Carrizo from other aquifers is occurring; an estimated 9,500 acre-feet per year (8.5 mgd) leaked into the Carrizo during the period 1963-1969. The approximate average annual pumpage from large wells (irrigation, public supply, and industrial) from the Carrizo aquifer in the Winter Garden Area during the period 1963-1969 was about 272,000 acre-feet (243 mgd); thus, about 162,500 acre-feet (145 mgd) of ground water was removed annually from storage in the aquifer. Although the water stored in the aquifer is in no danger of being depleted for many years, the increased pumping lifts caused by water-level declines will make it more costly to pump water for irrigation.

Contamination of native ground water in the Carrizo aquifer by water of higher mineral content from overlying sands is a serious problem in Dimmit and Zavala Counties. The water from these sands moves into the Carrizo as leakage through confining beds or down the well bores in which the casing is defective, improperly installed, or has not been cemented. At present the problem is confined to individual wells, but a continued increase in development of the Carrizo in Dimmit and Zavala Counties could result in more widespread contamination due to interformational leakage.

The digital computer simulation of the Carrizo aquifer for the period 1970 through 2020 indicates that: (a) water levels near Batesville and east of Carrizo Springs and Crystal City in the Winter Garden District will continue to decline rapidly; (b) elsewhere throughout the Winter Garden Area, water levels will slowly decline if pumpage remains unregulated and occurs at predicted rates; (c) a firm water supply of 20,000 to 40,000 acre-feet per year (18 to 36 mgd) of ground water from wells can be developed in Wilson County for municipal use; (d) approximately 330,000 acre-feet per year (294 mgd) of ground water can be developed from the Carrizo aquifer and not lower water levels below a 400-foot level below land surface or below the top of the water-bearing sands until the year 2020, representing an increase of 58,000 acre-feet per year (52 mgd) over the average withdrawals of 1963-1969; and (e) the areas most favorable for the development of additional ground-water supplies are in Wilson and Gonzales Counties.

Developing and utilizing ground water from a well or well field require adequate planning. Future development of ground water in the Winter Garden Area should be based on a program of test drilling, test pumping, and chemical analyses of water from the producing aquifer. Such preliminary data can be used to determine the most efficient well completion, optimum pumping rate, efficient pump setting, optimum well spacing, and feasibility of drilling additional wells. Large, concentrated withdrawals of ground water in small areas should be avoided.

GROUND-WATER RESOURCES OF THE CARRIZO AQUIFER

IN THE WINTER GARDEN AREA OF TEXAS

VOLUME 2

INTRODUCTION

This report is prepared in two volumes. Volume 1 contains interpretive information on the ground-water resources of the Carrizo aquifer presented as text and related illustrations and tables. Volume 2 contains supporting basic data including well location maps, records of 3,214 water wells, records of water levels in 474 wells, and chemical analyses of water samples from 1,553 wells. Also used in the study were drillers' logs of 711 wells which are available for reference in the files of the Texas Water Development Board.

The well-numbering system used in this report is one adopted by the Texas Water Development Board for use throughout the State and is shown in the accompanying figure. This system facilitates the location of wells and prevents duplication of well numbers in present and future studies. Each well is assigned a seven-digit number which is derived by using the following system.

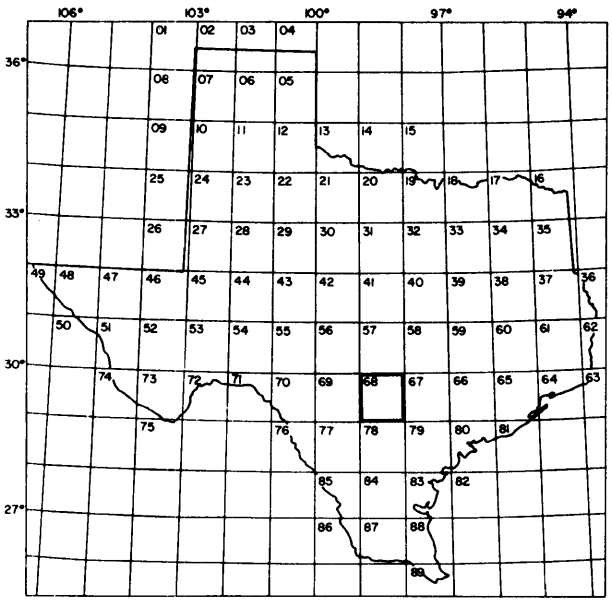
The State is divided into l-degree quadrangles of latitude and longitude. There are 89 such quadrangles, numbered 01 through 89. Each l-degree quadrangle is further subdivided into sixty-four 7½-minute quadrangles numbered 01 through 64. Finally, each 7½-minute quadrangle is subdivided into nine 2½-minute quadrangles, numbered 1 through 9. Within these 2½-minute quadrangles, each well is assigned a two-digit number beginning with 01.

The first two digits of each well number identify the l-degree quadrangle; the third and fourth digits indicate the 7½-minute quadrangle; the fifth digit identifies the 2½-minute quadrangle; and the last 2 digits identify the well within the 2½-minute quadrangle.

In addition to the seven-digit well number, a two-letter prefix is used to identify the county. The prefixes for the counties entirely or partially covered by this report are:

PREFIX	COUNTY	PREFIX	COUNTY
AL	Atascosa	SJ	Live Oak
AY	Bexar	su	McMullen
BU	Caldwell	TB	Maverick
HZ	Dimmit	TD	Medina
KB	Frio	YP	Uvalde
KR	Gonzales	VZ	Webb
KX	Guadalupe	ZL	Wilson
PZ	Karnes	ZX	Zavala
RX	La Salle		

For example, well AL-68-62-703 is in Atascosa County (AL); l-degree quadrangle 68; 7½-minute quadrangle 62; 2½-minute quadrangle 7; and was the third well inventoried in that 2½-minute quadrangle.



1 - degree Quadrangles

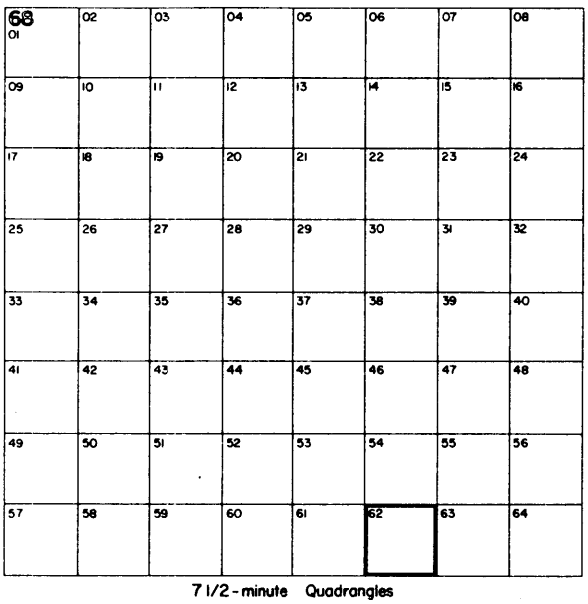
Location of Well AL-68-62-703

68 1 - degree quadrangle

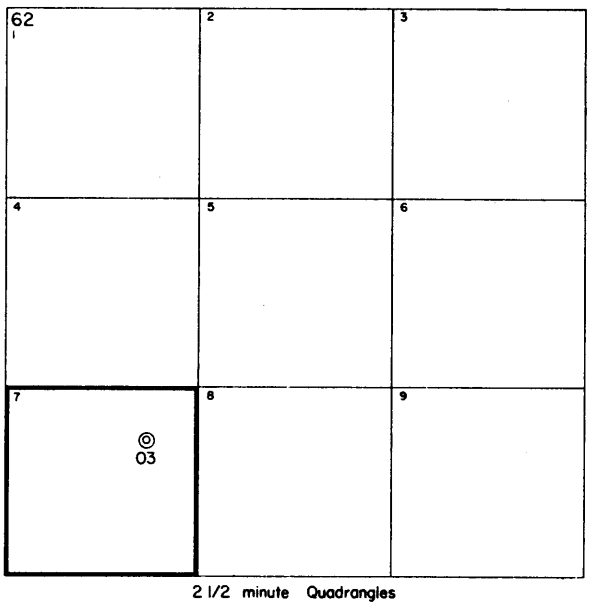
62 7 1/2 - minute quadrangle

7 2 1/2 - minute quadrangle

03 Well number within 2 1/2 - minute quadrangle



7 1/2 - minute Quadrangles



2 1/2 minute Quadrangles

Well-Numbering System

ATASCOSA COUNTY

Hydrogeologic Investigation and Simulation of Ground-Water Flow in the Upper Floridan Aquifer of North-Central Florida and Southwestern Georgia and Delineation of Contributing Areas for Selected City of Tallahassee, Florida, Water-Supply Wells

By Hal Davis

Abstract

A 4-year investigation of the Upper Floridan aquifer and ground-water flow system in Leon County, Florida, and surrounding counties of north-central Florida and southwestern Georgia began in 1990. The purpose of the investigation was to describe the ground-water flow system and to delineate the contributing areas to selected City of Tallahassee, Florida, water-supply wells. The investigation was prompted by the detection of low levels of tetrachloroethylene in ground-water samples collected from several of the city's water-supply wells.

Hydrologic data and previous studies indicate that; ground-water flow within the Upper Floridan aquifer can be considered steady-state; the Upper Floridan aquifer is a single water-bearing unit; recharge is from precipitation; and that discharge occurs as spring flow, leakage to rivers, leakage to the Gulf of Mexico, and pumpage. Measured transmissivities of the aquifer ranged from 1,300 ft^2/d (feet squared per day) to 1,300,000 ft^2/d.

Steady-state ground-water flow in the Upper Floridan aquifer was simulated using a three-dimensional ground-water flow model. Transmissivities ranging from less than 5,000 ft^2/d to greater than 11,000,000 ft^2/d were required to calibrate to observed conditions. Recharge rates used in the model ranged from 18.0 inches per year in areas where the aquifer was unconfined to less than 2 inches per year in broad areas where the aquifer was confined.

Contributing areas to five Tallahassee water-supply wells were simulated by particle-tracking techniques. Particles were seeded in model cells containing pumping wells then tracked backwards in time toward recharge areas. The contributing area for each well was simulated twice, once assuming a porosity of 25 percent and once assuming a porosity of 5 percent. A porosity of 25 percent is considered a reasonable average value for the Upper Floridan aquifer; the 5 percent porosity simulated the movement of ground-water through only solution-enhanced bedding plains and fractures. The contributing areas were generally elliptical in shape, reflecting the influence of the sloping potentiometric surface. The contributing areas delineated for a 5 percent porosity were always much larger than those determined using a 25 percent porosity. The lowest average ground-water velocity computed within a contributing area, using a 25 percent porosity, was 1.0 ft/d (foot per day) and the highest velocity was 1.6 ft/d. The lowest average ground-water velocity, determined using a 5 percent porosity, was 2.4 ft/d and the highest was 7.4 ft/d.

The contributing areas for each of the five wells was also determined analytically and

compared to the model-derived areas. The upgradient width of the simulated contributing areas were larger than the upgradient width of the analytically determined contributing areas for four of the five wells. The model could more accurately delineate contributing areas because of the ability to simulate wells as partially penetrating and by incorporating complex, three-dimensional aquifer characteristics, which the analytical method could not.

INTRODUCTION

Ground water from the Upper Floridan aquifer is the source of water-supply for Tallahassee, Fla., and for parts of the surrounding area. In most areas, the aquifer yields an ample supply of good quality water; however, in recent years low levels of tetrachloroethylene (PCE) have been detected in ground-water samples obtained from seven of the city's water-supply wells. PCE is attributed to past disposal practices of dry cleaners, service stations, and other businesses within the downtown area. The City of Tallahassee removes PCE from the water by passing it through granular-activated carbon units before distribution. This recent experience has increased the awareness of local authorities that ground-water resources need to be protected. To ensure that water-supply wells, presently free of contamination, remain clean, it is necessary to protect that portion of the aquifer from which the wells derive water. The delineation of areas contributing to supply wells requires an understanding of ground-water flow within the Upper Floridan aquifer. To gain this understanding, the U.S. Geological Survey (USGS), in cooperation with the City of Tallahassee and the Florida Department of Environmental Protection (FDEP), conducted an investigation of the Upper Floridan aquifer.

Purpose and Scope

The purpose of this report is to present the results of an investigation of that part of the Upper Floridan aquifer which underlies Tallahassee and Leon County, Fla., and the surrounding counties in north-central Florida and southwestern Georgia. The specific objectives of the investigation were to 1) determine the hydrogeologic framework of the Upper Floridan aquifer, 2) collect additional hydrogeologic data needed to characterize ground-water flow, 3) simulate ground-water flow using the USGS modular three-dimensional finite-difference ground-water flow model (MODFLOW) (McDonald and Harbaugh, 1988), 4) delineate contributing areas for selected City of Tallahassee water-supply wells, and 5) compare simulated contributing areas to analytically determined contributing areas. The contributing area of a pumping well, defined by Morrissey (1987), is the land area that has the same horizontal extent as that part of an aquifer..., from which ground-water flow is diverted to wells.

This report is organized to focus on the project objectives listed above and the following items are presented: 1) a description of the general hydrogeologic framework of the Upper Floridan aquifer in north-central Florida and southwestern Georgia, 2) a potentiometric-surface map of the Upper Floridan aquifer based on water levels measured during the fall of 1991, 3) river-discharge measurements made to estimate the volume of ground water discharging from the Upper Floridan aquifer in the fall of 1991, 4) an evaluation of the transmissivity of the Upper Floridan aquifer within downtown Tallahassee, determined with a multiple-well aquifer test, 5) a conceptual model of ground-water flow within the Upper Floridan aquifer describing flow directions, hydrologic boundaries, and ground-water sources and sinks, 6) the results of computer simulations of ground-water flow using MODFLOW (McDonald and Harbaugh, 1988), 7) a delineation of contributing areas to selected Tallahassee water-supply wells using the particle-tracking program MODPATH (Pollock, 1989), and 8) a comparison of the simulated and analytically determined contributing areas.

Study Area

The study area encompasses approximately 11,000 square miles in north-central Florida and southwestern Georgia (fig.1) and is within the Coastal Plain physiographic province. The topography is characterized by rolling hills and land-surface altitudes that range from about 350 ft above sea level in the north to sea level in the south. The study area extends to the major ground-water flow boundaries in the regional ground-water flow system, and thus encompasses the entire recharge area for ground water that moves beneath Leon County, Fla. The climate is humid subtropical with relatively high rainfall. From

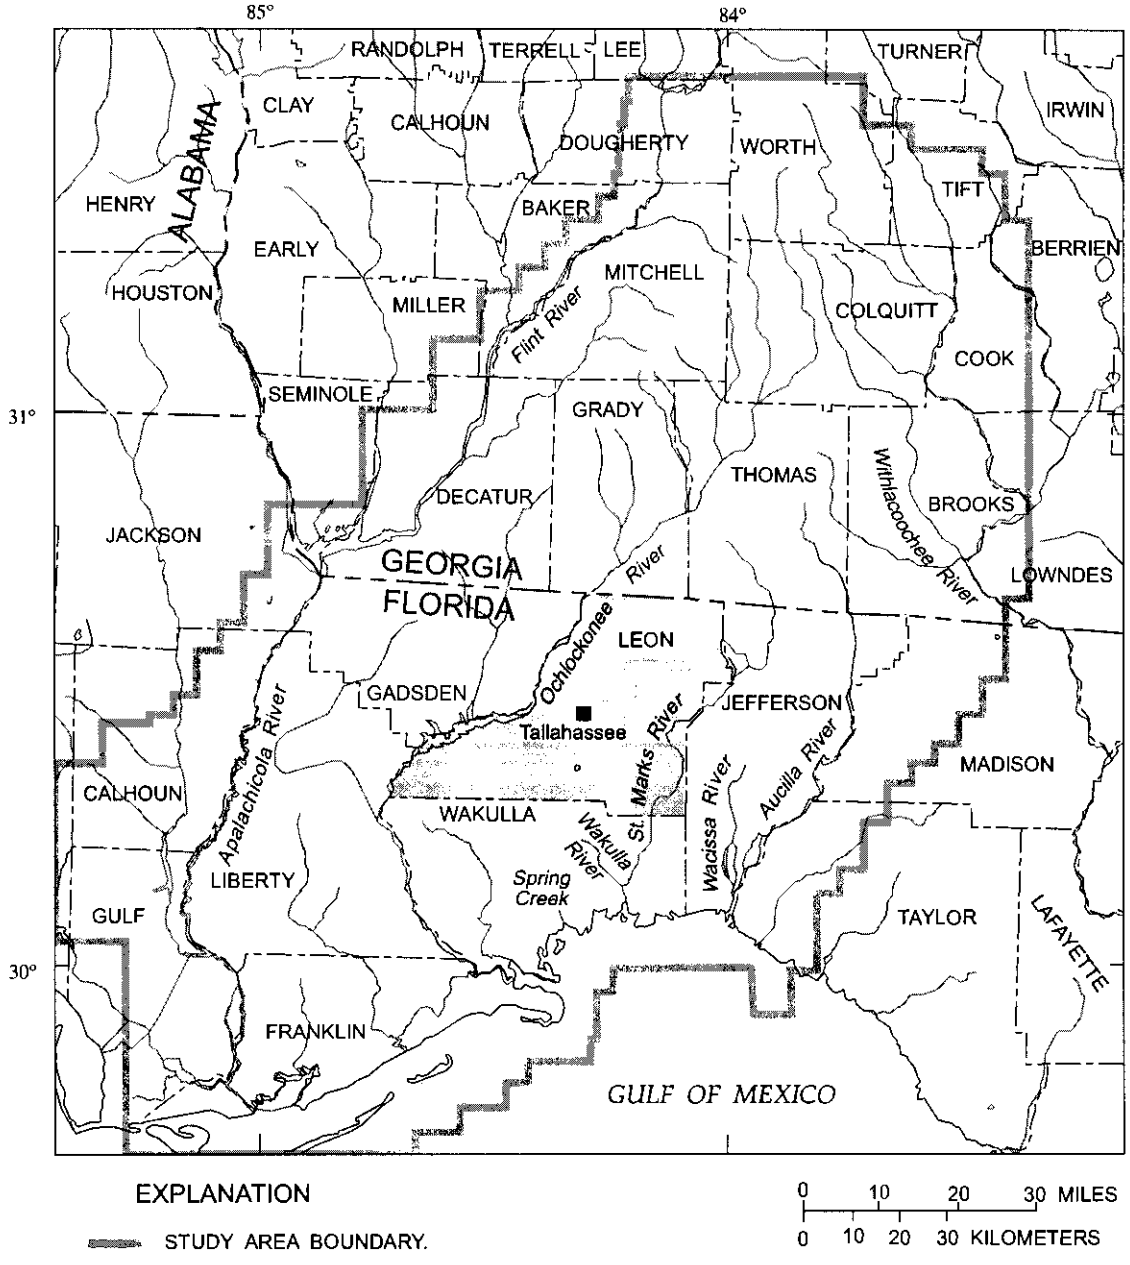

Figure 1. Study area in north-central Florida and southwestern Georgia.

1961 - 1990, the average annual temperature in Tallahassee was 67° F and the average precipitation was 66 in/yr (National Oceanic and Atmospheric Administration, oral commun., 1995).

The major physiographic features of the study area, delineated and described by Clark and Zisa (1976) for Georgia and by Brooks (1981) for Florida, were the Dougherty Plain District, Tifton Upland District, Apalachicola Delta District, and Ocala Uplift District (fig. 2). The topography of the Dougherty Plain District consists of gently rolling hills that are interrupted by numerous sinkholes. Karst topography prevails with many sinkholes still forming. The altitude within the Tifton Upland District ranges from about 480 ft in the north to 150 ft in the southeast, resulting in a gentle slope. This district contains a well

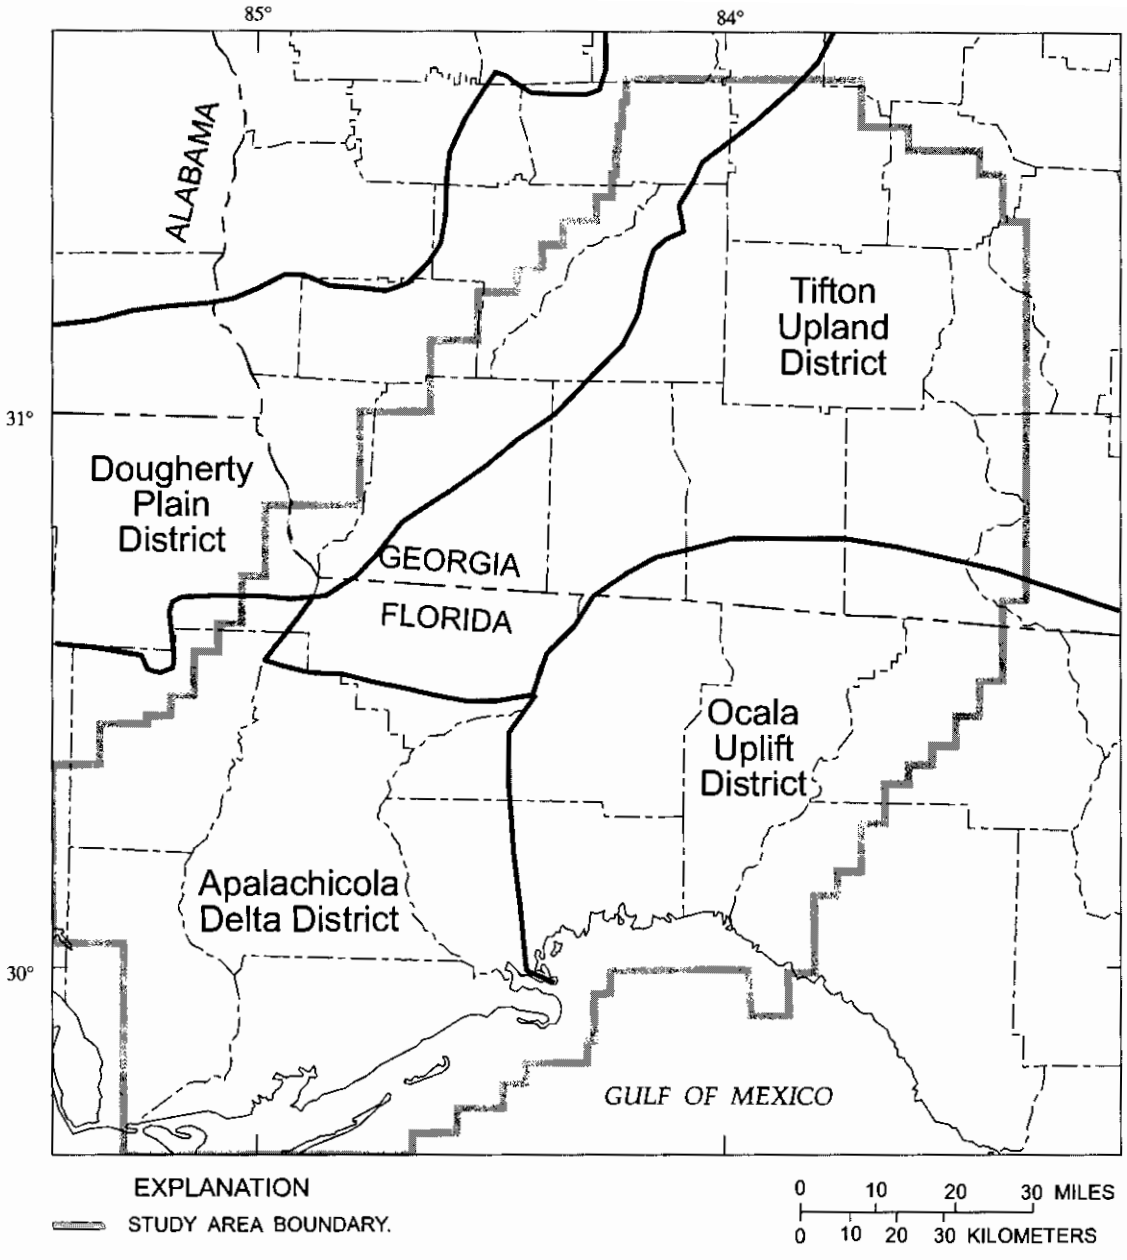

Figure 2. Major physiographic features in north-central Florida and southwestern Georgia (modified from Clark and Zisa, 1976, and Brooks, 1981).

developed dendritic drainage system. The Apalachicola Delta District contains river terraces and deltas, past and present, of the Apalachicola River and is a clastic terrain with no karst features. The topography of the Ocala Uplift District consists of gently rolling hills and in many places limestone occurs at or near land surface. The southward draining streams are continually modified by solution of the underlying limestones.

Previous Investigations

Hendry and Sproul (1966) investigated the geology and ground-water resources of Leon County. They described the geology and hydrology of the Upper Floridan aquifer, the overlying units, and the general water quality. Miller (1986) described the geology of the Floridan aquifer system that underlies all of Florida and parts of Georgia and South Carolina. Within the study area, Miller mapped the top, bottom, and

thickness of the Upper Floridan aquifer and described the geology of the formations that comprise the aquifer. His investigation was part of the Regional Aquifer System Analysis (RASA) program of the USGS. Bush and Johnston (1988) simulated ground-water flow in the entire Floridan aquifer system using a finite-difference model as part of the RASA program. During their investigation, model-derived transmissivities were determined for the Upper Floridan aquifer in the study area, as well as rates of recharge and discharge. A relatively coarse grid with spacing of 8 by 8 mi was used for these simulations.

GEOLOGIC SETTING

The study area is underlain by sedimentary rocks of Tertiary through Quaternary age that consist of limestone, dolostone, clay, and sand of varying degrees of lithification (Miller, 1986). The geologic units from oldest to youngest are: the Clayton Formation of Paleocene age, the Oldsmar Formation of early Eocene age, the Avon Park Formation of middle Eocene age, the Ocala Limestone of late Eocene age, the Suwannee Limestone of Oligocene age, the St. Marks and Chattahoochee Formations of early Miocene age, the Hawthorn Group of Miocene age, the Jackson Bluff, Miccosukee, and Citronelle Formations of Pliocene age, and the undifferentiated sediments of Pleistocene and Holocene age. A list of geologic units, their relation to the principal hydrogeologic units (aquifers and confining units), and corresponding model layers is shown in figure 3. The characteristics of the aquifers, confining units, and model layers are described in later sections. This report uses the terms St. Marks Formation, Chattahoochee Formation, and Hawthorn Group, because they are the currently accepted terminology of the Georgia and Florida Geological Surveys. The geologic descriptions in this section are based on work by Miller (1986), unless otherwise cited.

Sediments of Paleocene Age

The Paleocene-age Clayton Formation underlies the entire study area. The altitude at the top of this formation ranges from about 300 ft below sea level in the north to greater than 3,000 ft below sea level in the extreme south. The formation occurs as a massive calcareous marine clay in the southern part of the study area. Updip, it occurs as a fine- to medium-grained glauconitic sand and clayey sand with smaller amounts of medium- to dark-gray clay.

Sediments of Eocene Age

Eocene-age sediments can be subdivided into the Oldsmar and Avon Park Formations, and Ocala Limestone. The Oldsmar Formation underlies the entire study area, but consists of permeable limestones only in Wakulla, Leon, Jefferson, Taylor, and Madison Counties, Fla. Westward, the Oldsmar becomes increasingly argillaceous and less permeable as it interfingers with calcareous clastic rock. Northward, the Oldsmar grades from limestone to argillaceous limestone and calcareous clay into glauconitic calcareous sand. The altitude of the top of the permeable part of the Oldsmar Formation ranges from about 1,700 ft to greater than 2,500 ft below sea level and is approximately 500 feet thick.

The Avon Park Formation underlies the entire study area and ranges in thickness from about 300 ft in the north to about 1,200 ft in the south. The Avon Park consists of a permeable and relatively pure limestone only in parts of Wakulla, Leon, Jefferson, Taylor, and Madison Counties, Fla. Within these counties, the Avon Park Formation consists of a cream, tan, or light-brown, soft- to well-indurated limestone that is pelletal but locally micritic. To the west and north of these counties, the formation quickly grades into a low-permeability argillaceous, micritic, glauconitic limestone that, in turn, grades updip into calcareous, glauconitic, often shelly sand and clay beds. The altitude of the top of the permeable part of the Avon Park Formation ranges between 800 and 1,000 ft below sea level.

The Ocala Limestone is permeable through the entire study area and ranges in thickness from about 200 ft in the north to about 500 ft in the south. The altitude of the top of the Ocala is about 200 ft above sea level in the northwest where it outcrops in the Dougherty Plain. The Ocala slopes gently to the south, where it reaches depths of between 500 and 1,000 ft below sea level. The Ocala Limestone consists of two different rock types. The upper portion is a white, generally soft and friable, porous coquina consisting of foraminifera, bryozoan fragments, and whole to broken echinoid remains. The lower part of the Ocala Limestone is composed of cream to white, generally fine-grained, soft to semi-indurated, micritric limestone containing abundant miliolid remains and large foraminifers (Applin and Applin, 1944).

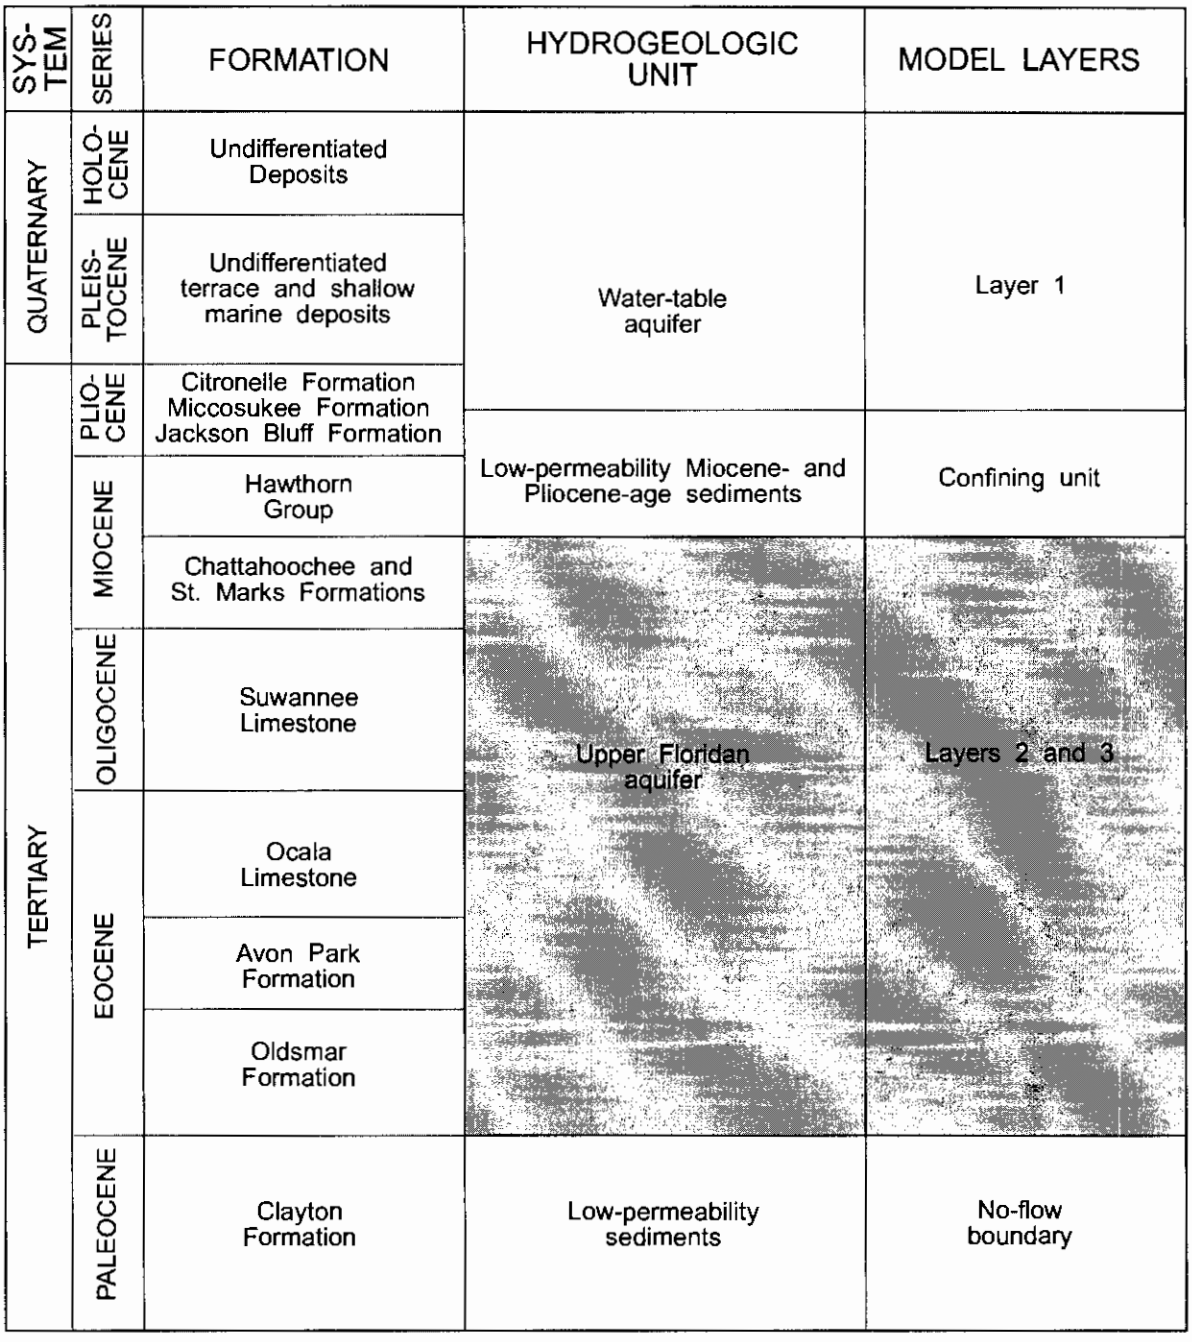

Figure 3. Relation of geologic units, hydrogeologic units, and model layers in north-central Florida and southwestern Georgia.

Sediments of Oligocene Age

The thickness of the Suwannee Limestone reaches a maximum of about 600 ft in the southwestern part of the study area and thins to less than 100 ft in the southeast, where it outcrops. The Suwannee also outcrops along the southern and western edge of the Dougherty Plain, but has been removed by erosion from most of the interior of the Dougherty Plain. The altitude of the top of the Suwannee ranges from just over 200 ft in the north to greater than 500 below sea level in the southwest. The Suwannee usually consists of two permeable rock types: 1) cream to tan, crystalline, highly vuggy limestone containing prominent

gastropod and pelecypod casts and molds and 2) white to cream, finely pelletal limestone containing small foraminifers and pellets of micrite bound to a finely crystalline limestone matrix.The two facies are interbedded and cannot be recognized at all locations.

Sediments of Miocene Age

The Miocene-age sediments can be subdivided into the St. Marks Formation, Chattahoochee Formation, and the Hawthorn Group. The St. Marks outcrops, or subcrops at shallow depths, in the western part of the Ocala Uplift Physiographic District. Northward, the St. Marks grades laterally into the Chattahoochee Formation. The Chattahoochee is not present in the Dougherty Plain due to lack of deposition or removal by erosion. The St. Marks is a predominantly fine- to medium-grained, partially recrystallized, silty to sandy limestone that has undergone degrees of secondary dolomitization (Hendry and Sproul, 1966). The Chattahoochee is primarily a dolostone containing quartz sand, clay, calcite, limestone, chert, mica, heavy minerals, phosphate, and fossils (Huddlestun, 1988). The permeability of the St. Marks and Chattahoochee Formations ranges from very permeable to relatively impermeable.

The Hawthorn Group is thin or absent in the Dougherty Plain and in parts of the Ocala Uplift due to lack of deposition or later removal by erosion. The group is thickest in the Apalachicola Delta Physiographic District and within the Tifton Uplands, where the thickness can exceed several hundred feet. The Hawthorn is predominantly sand and clay; subordinate components include dolomite, dolostone, calcite, limestone, phosphorite, phosphate, silica in the forms of claystone, chert, and siliceous microfossils, feldspar, heavy minerals, carbonaceous material and lignite, zeolites, and fossils (Huddlestun, 1988). Locally, in beds and lenses, dolostone, limestone, phosphorite, clay, or claystone can make up the dominant lithologies.

Sediments of Pliocene Age

The Pliocene-age sediments can be subdivided into several formations including the Jackson Bluff Formation, the Miccosukee Formation, and the Citronelle Formation. The Jackson Bluff and Citronelle Formations occur only in the southwestern part of the study area. The Jackson Bluff is composed of clayey sands and sandy clays that are very macrofossiliferous; the Miccosukee Formation is composed of interbedded and cross-bedded clays, silts, sands and gravels of varying coarseness and mixtures (Hendry and Sproul, 1966). The Citronelle Formation is composed of medium to coarse sand containing many stringers of gravel and a few thin clay beds. Similar in distribution to the Hawthorn Group, the Pliocene-age sediments are thin or absent in the Dougherty Plain and parts of the Ocala Uplift, and Tifton Uplands due to lack of deposition or later removal by erosion. Sediments of the Hawthorn Group and the clay, silts, and sandy clays of the Miccosukee and Jackson Bluff Formations form a continuous low-permeability unit that is referred to in this report as the low-permeability Miocene- and Pliocene-age sediments (fig. 3).

Sediments of Pleistocene and Holocene Age

Pleistocene-age sediments consist of medium- to coarse-grained, tan, white, and brown sand that locally contains trace amounts of carbonaceous material and shell fragments. The Holocene deposits include thin sand and gravel accumulations deposited mostly adjacent to streams, estuaries, and lagoons.

HYDROLOGIC SETTING

Aquifers in the study area include the water-table aquifer and Upper Floridan aquifer, which are separated by low-permeability Miocene- and Pliocene-age sediments (figs. 3 and 4). The water-table aquifer yields only small amounts of water when pumped and generally is not utilized. Some water, usually for domestic supply, is produced from the sandy units within the low-permeability Miocene- and Pliocene-age sediments. The Upper Floridan aquifer is utilized for municipal, industrial, agricultural, and domestic water supply. The transmissivity of the Upper Floridan aquifer ranges over several orders of magnitude within the study area. Where transmissivities are high, the Upper Floridan aquifer generally yields large quantities of good-quality water.

Water-Table Aquifer

The water-table aquifer lies within the shallow sediments exposed at land surface. The age of these sediments ranges from Holocene to Pliocene. The transmissivity ranges from very low where the

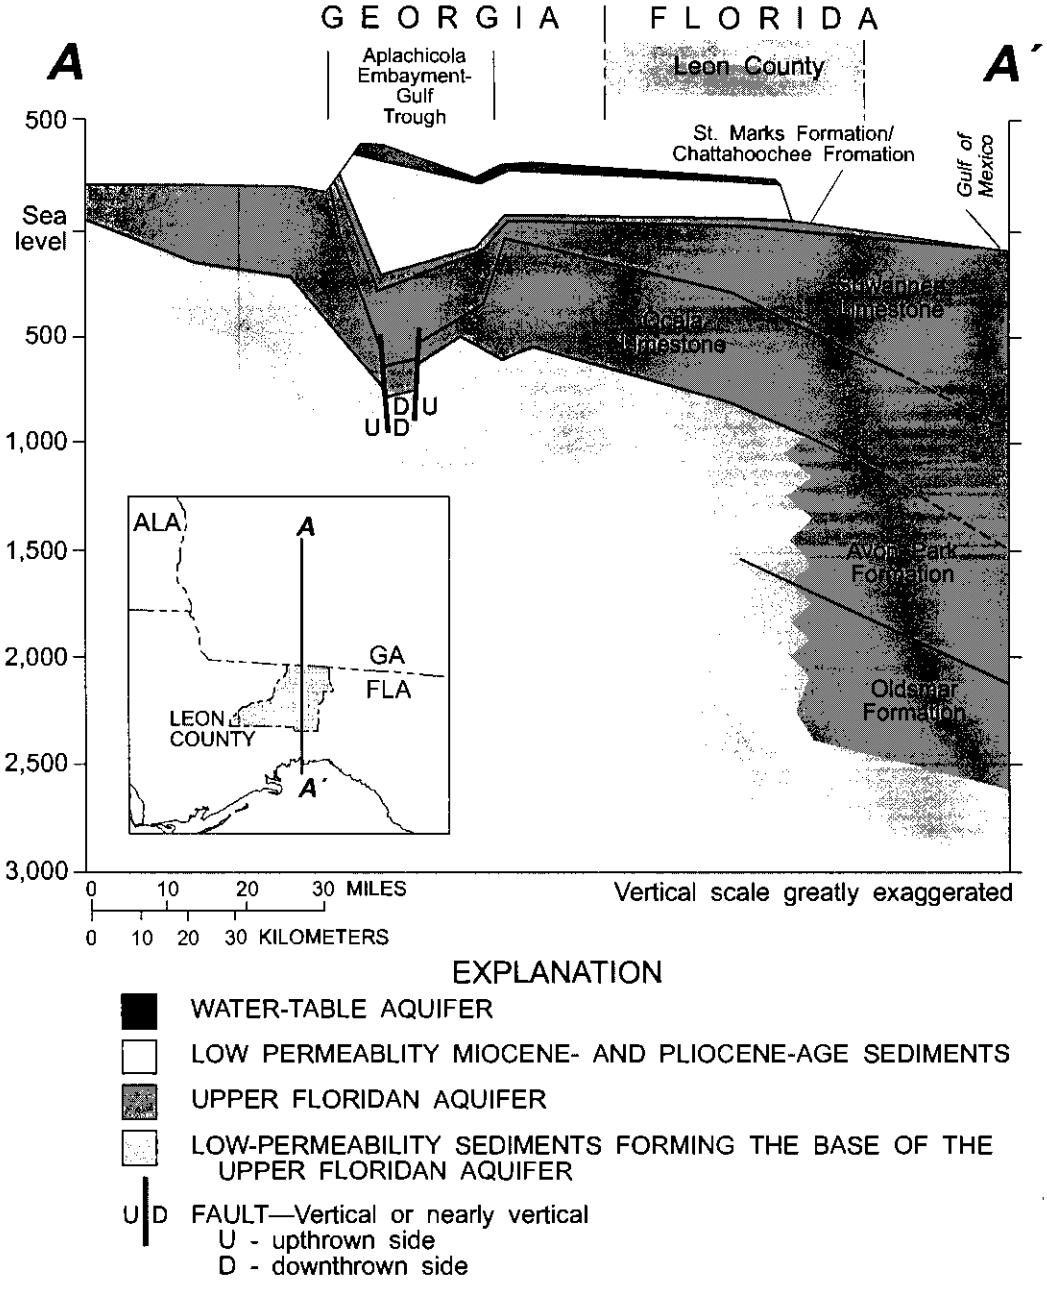

Figure 4. Generalized hydrogeologic section showing aquifers and geologic formations of the Upper Floridan aquifer in north-central Florida and southwestern Georgia.

sediments are fine grained, to moderately high where significant thicknesses of sand and gravel are present. The water-table aquifer is present through most of the study area and generally is less than 50 ft thick. It is generally absent from the Dougherty Plain and parts of the Ocala Uplift. In areas where the water-table aquifer is absent, the water table lies within the Upper Floridan aquifer.

Low-Permeability Miocene- and Pliocene-Age Sediments

The low-permeability Miocene- and Pliocene-age sediments overlie and in some areas confine the Upper Floridan aquifer. These sediments are several hundred feet thick in the Apalachicola Embayment-Gulf Trough feature (figs. 4 and 5). This feature has

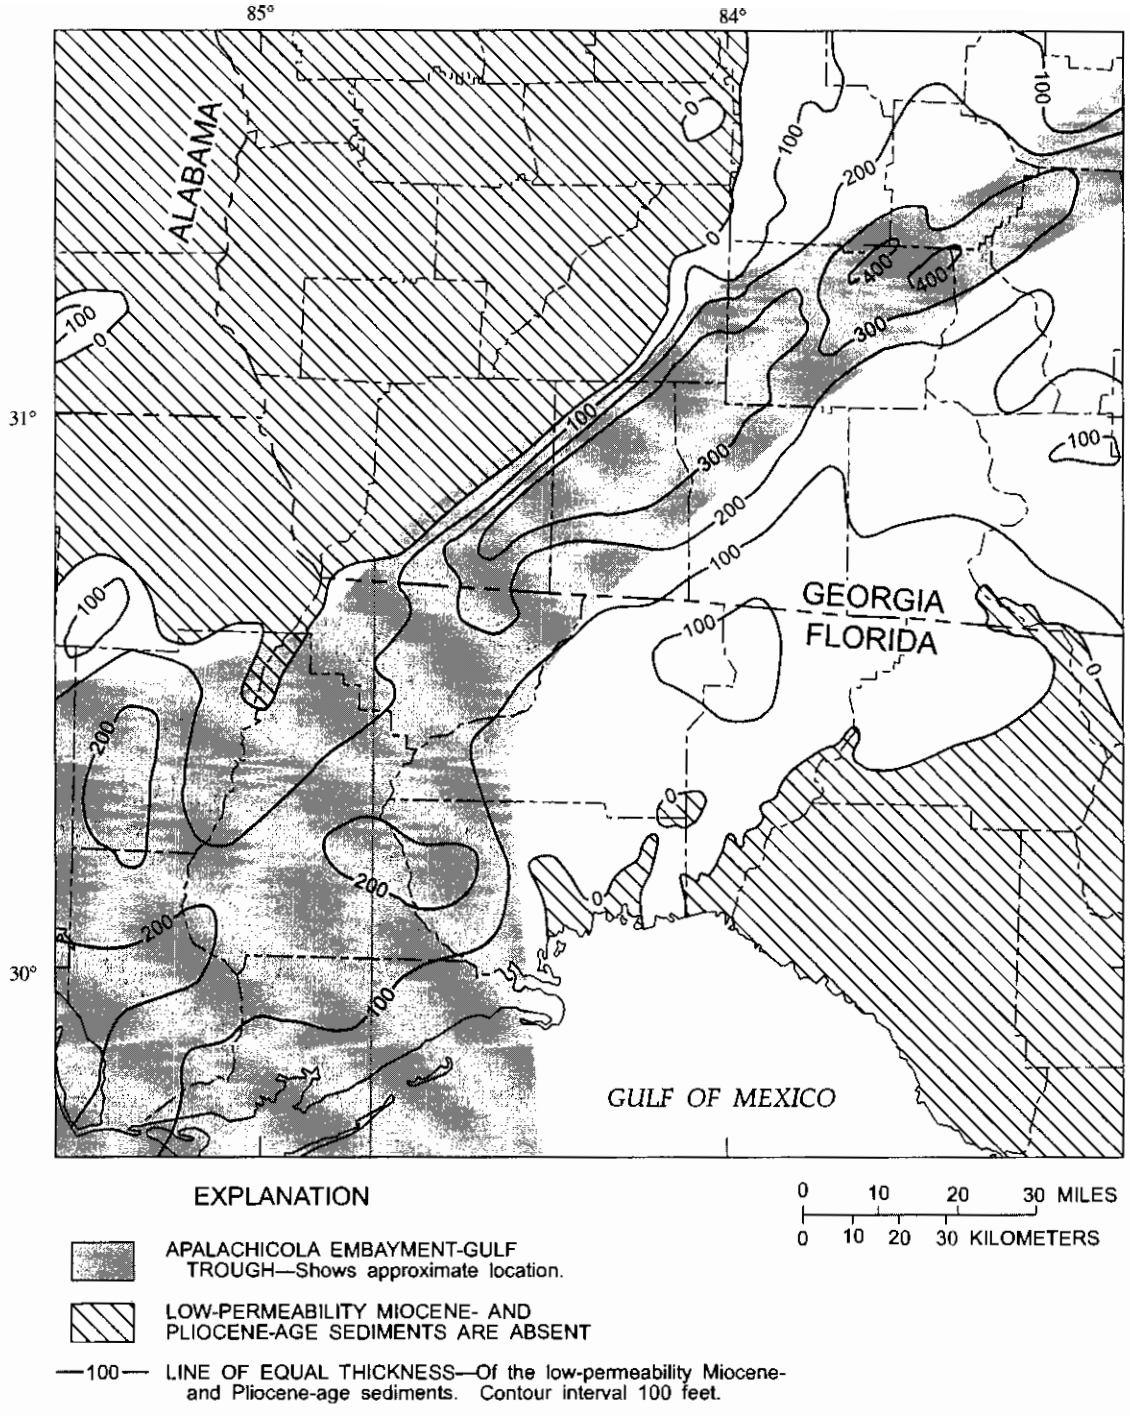

Figure 5. Thickness of low-permeability Miocene- and Pliocene-age sediments (modified from Miller, 1986).

been described as a marine channel that linked the Gulf of Mexico to the Atlantic Ocean during the early Tertiary (Huddlestun, 1988). Falling sea levels restricted circulation within this channel, allowing deposition of thick accumulations of fine grained material. The low-permeability Miocene- and Pliocene-age sediments are generally not present in the Dougherty Plain and are less than 100 ft thick in the Ocala Uplift District (fig.5) (Miller, 1986).

Upper Floridan Aquifer

The Upper Floridan aquifer is part of the Floridan aquifer system that occurs in Florida and parts of Georgia, South Carolina, and Alabama. Miller (1986) defined the Floridan aquifer system as a vertically continuous sequence of carbonate rocks of generally high permeability that are hydraulically connected in varying degrees and whose permeability is, in general, an order of magnitude to several orders of magnitude greater than those of the rocks that bound the system. Within the study area, the Upper Floridan aquifer includes all or parts of the Oldsmar Formation, Avon Park Formation, Ocala Limestone, Suwannee Limestone, St.Marks Formation, and Chattahoochee Formation (fig. 4).

Miller delineated the Upper Floridan aquifer based on the permeability characteristics of the rocks, thus neither the top nor bottom of the aquifer necessarily conforms to formation or time-stratigraphic boundaries. The altitude of the top of the Upper Floridan aquifer (fig. 6) ranges from about 200 ft above sea level in the Dougherty Plain to greater than 400 ft below sea level in parts of the Apalachicola Delta District and Tifton Uplands. The Upper Floridan aquifer is uplifted along the Barwick Arch (Sever, 1966), a subregional feature that lies southeast of the Apalachicola Embayment-Gulf Trough. The altitude of the base of the aquifer (fig. 7) ranges from 200 ft above sea level in the north, where it pinches out, to greater than 2,200 ft below sea level in the south. The aquifer thickens from about 100 ft in the north (fig. 8) to greater than 2,000 ft in the south.

Hydraulic Properties of the Upper Floridan Aquifer

Bush and Johnston (1988) conducted an investigation of the entire Floridan aquifer system and observed that carbonate rocks are nearly always characterized by an uneven distribution of permeability. Throughout much of the area where the Upper Floridan aquifer occurs, the water-bearing openings consist of one or more of the following: 1) openings in loosely cemented fossil hashes that are similar to the interstices of sands, 2) mosaics of many fractures and solution-widened joints, and 3) solution cavities ranging in size from less than 1 in to tens of feet or more. Large solution cavities generally occur near large springs and some sinkholes where dissolution of the limestone is greatest, but these areas represent only a small part of the aquifer on a regional scale. In areas away from the large solution openings, the fist two conditions dominate. The transmissivity of the Upper Floridan aquifer is directly related to the thickness and lithology of the overlying low-permeability sediments. Thinner and more permeable overlying sediments allow greater rates of infiltration and increased dissolution of the limestones. The removal of these sediments from some areas during Pleistocene time is largely responsible for the current distribution of karst, and, therefore, the current distribution of transmissivity.

Transmissivity values determined by aquifer tests for the Upper Floridan aquifer vary greatly within the study area, ranging from 1,300 ft^2/d to 1,300,000 ft^2/d (fig. 9). The highest transmissivity values generally occur within the Dougherty Plain, Ocala Uplift, and parts of the Tifton Uplands where the overlying low-permeability sediments are thinnest or absent. The lowest transmissivity values generally occur within the Apalachicola Embayment - Gulf Trough where the overlying low-permeability sediments are thickest.

Bush and Johnston (1988) simulated ground-water flow using a finite difference model. Their investigation indicated that transmissivity values were as high as 1,000,000 ft^2/d in the Dougherty Plain, ranged between 10,000 and 50,000 ft^2/d along the axis of the Apalachicola Embayment - Gulf Trough, and were greater than 1,000,000 ft^2/d in parts of the Ocala Uplift and Tifton Uplands. Assigned transmissivities in some areas near large springs were as high as 10,000,000 ft^2/d. Kellam and Gorday (1990) also recognized that the Upper Floridan aquifer, within the Apalachicola Embayment - Gulf Trough, consisted of poorly permeability limestones. They attributed the lower permeabilities to a combination of factors: 1) the lower primary permeability of the deeper-water limestones deposited in the feature, 2) the greater thickness of overburden which limits development of secondary porosity, and 3) possibly a lack of joints and fractures to enhance ground-water movement. They further postulated that ground-water movement was sluggish in parts of the feature based on high levels of dissolved ions in the water.

Ground-Water Pumpage

Wells and water-supply systems that withdraw water from the Upper Floridan aquifer are listed in table 1 and locations are shown in figure 10. Generally, the list contains wells or systems that pump, on

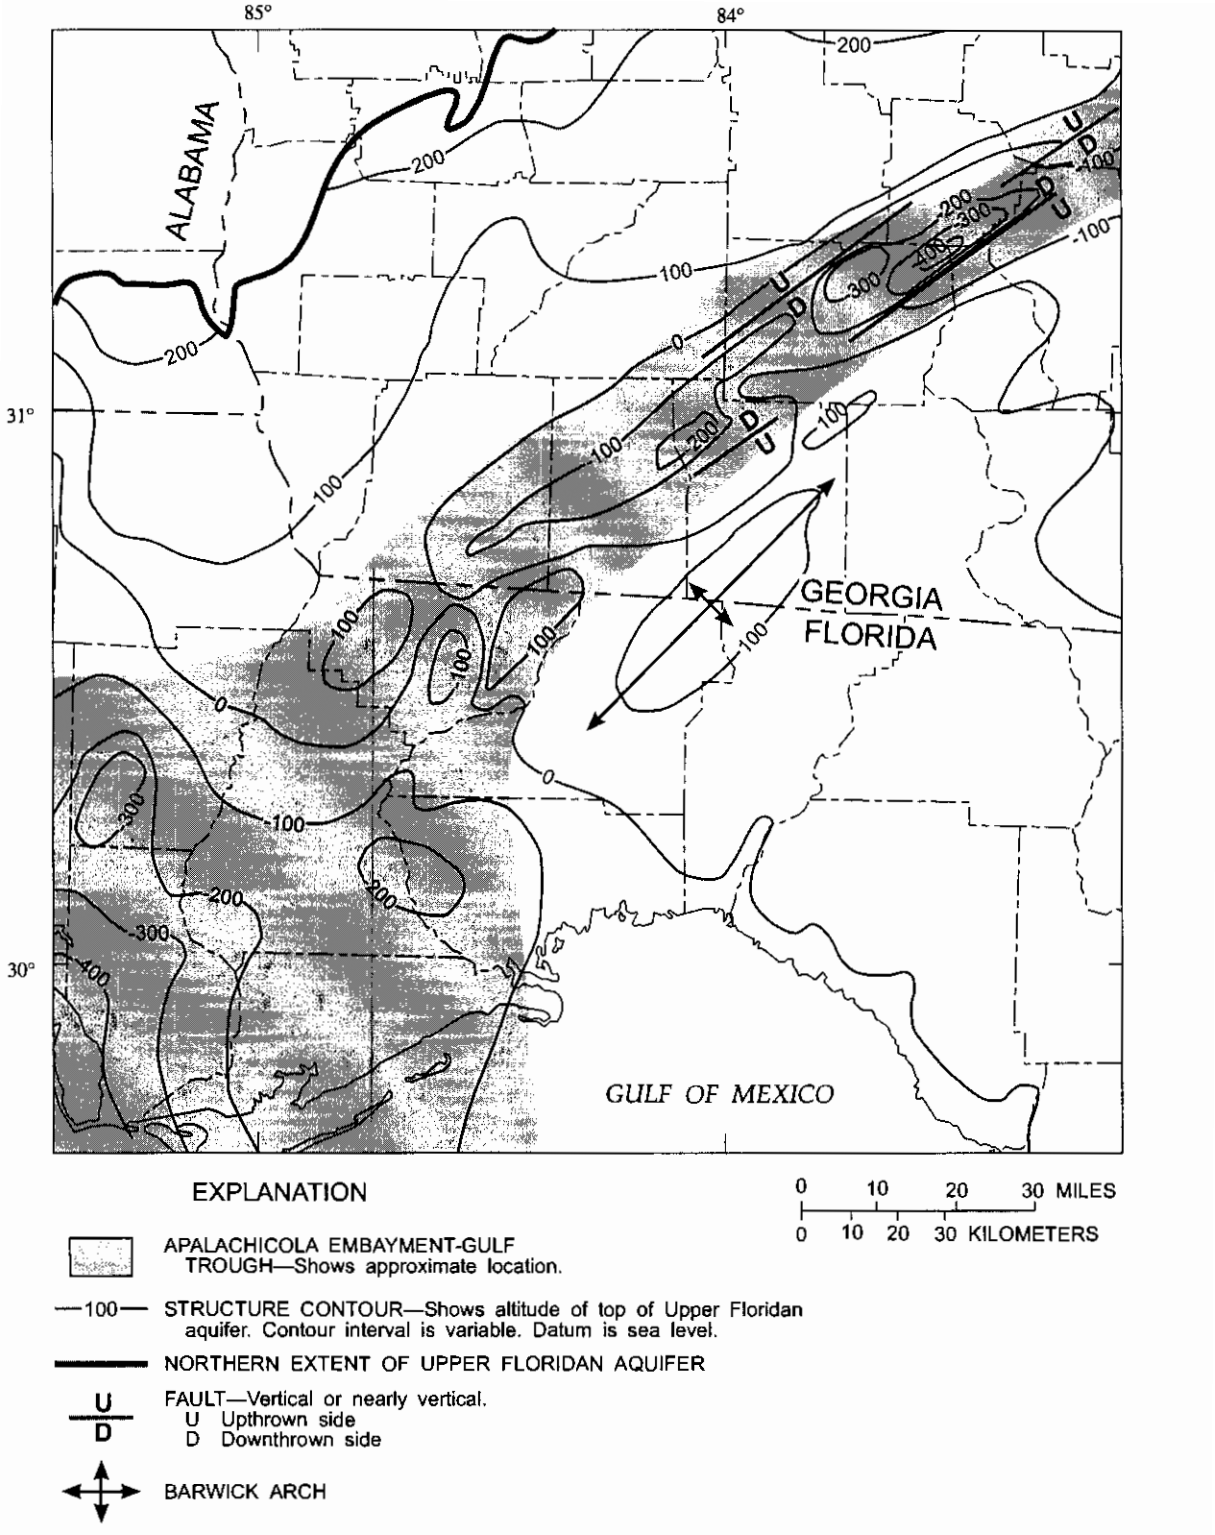

Figure 6. Structure at the top of the Upper Floridan aquifer (modified from Miller, 1986).

average, greater than 70 gal/min, although systems that pump lower rates were included if the information was readily available. This list does not include any domestic supply wells, because they pump much less than 70 gal/min. Although individual domestic supply wells pump relatively small amounts of ground water, the number of these wells can be large. Within Leon County, Fla., more than 6,000 domestic supply wells have been drilled since 1976 (Jay Johnson, City of Tallahassee, oral commun., 1995).

DATA COLLECTION

A data-collection program was undertaken to quantify hydrologic conditions needed for calibration of a ground-water flow model. Model calibration involves successfully simulating measured hydrologic conditions within acceptable limits of error, as will be discussed later. The potentiometric surface of the Upper Floridan aquifer was estimated by measuring ground-water levels in a network of wells. The rate of ground-water discharge to rivers from the Upper

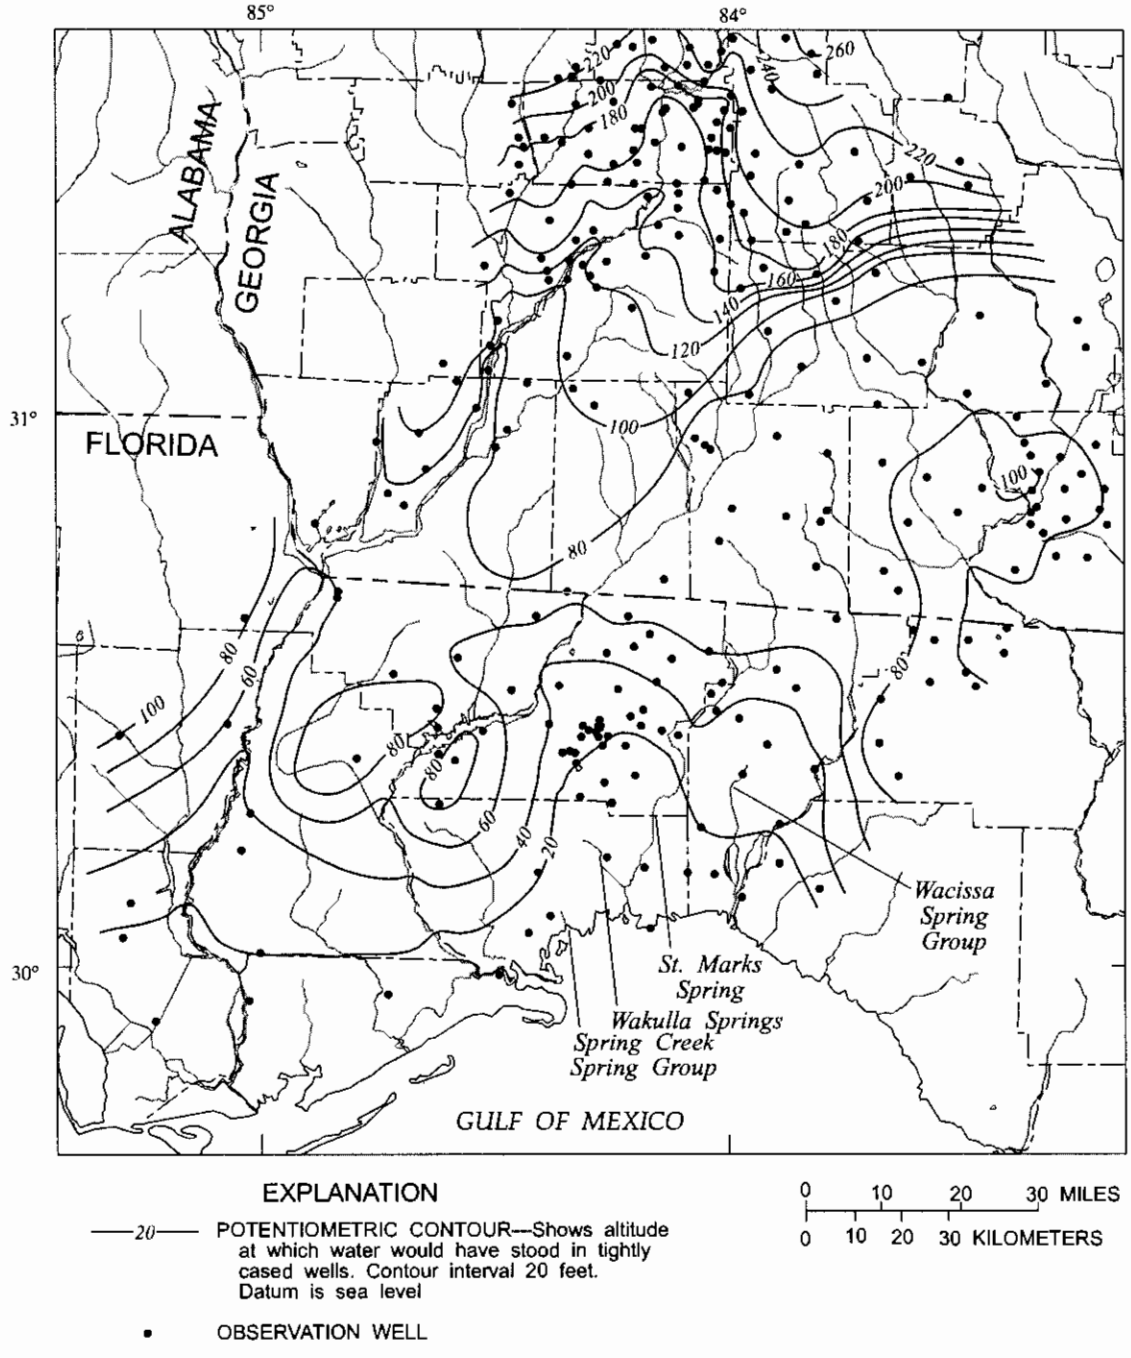

Figure 11. Altitude of the potentiometric surface of the Upper Floridan aquifer during October- November 1991.

Floridan aquifer was quantified by measuring river-discharge rates under base-flow conditions. One aquifer test was conducted to determine the transmissivity of the Upper Floridan aquifer that underlies downtown Tallahassee.

Water-Level Measurements

A potentiometric surface map of the Upper Floridan aquifer (fig. 11) was constructed from ground-water measurements made in 274 wells during the period October 21 to November 8, 1991. Wells

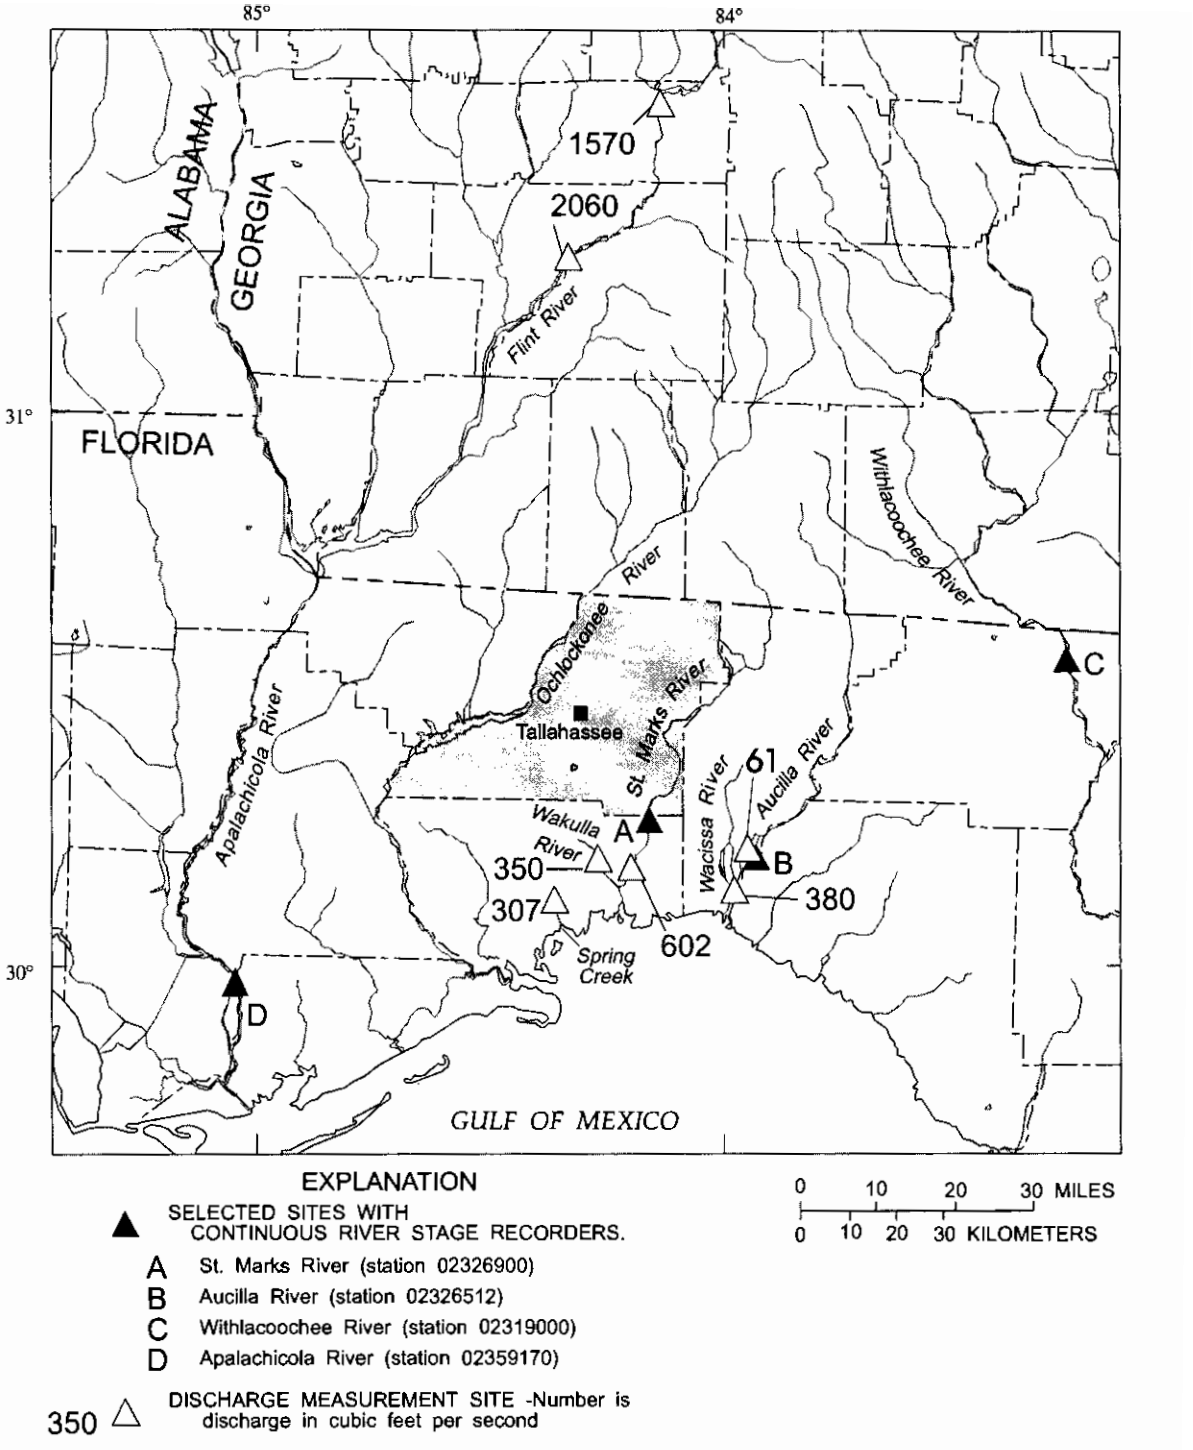

Figure 12. River-discharge measurement sites and related discharge rates on November 1, 1991.

were selected from data bases of agencies that included the USGS, Northwest Florida Water Management District, City of Tallahassee, and Florida Department of Environmental Protection.

River-Discharge Measurements

River-discharge measurements were made at seven locations, on November 1, 1991 (fig. 12) and were made concurrently with the ground-water level

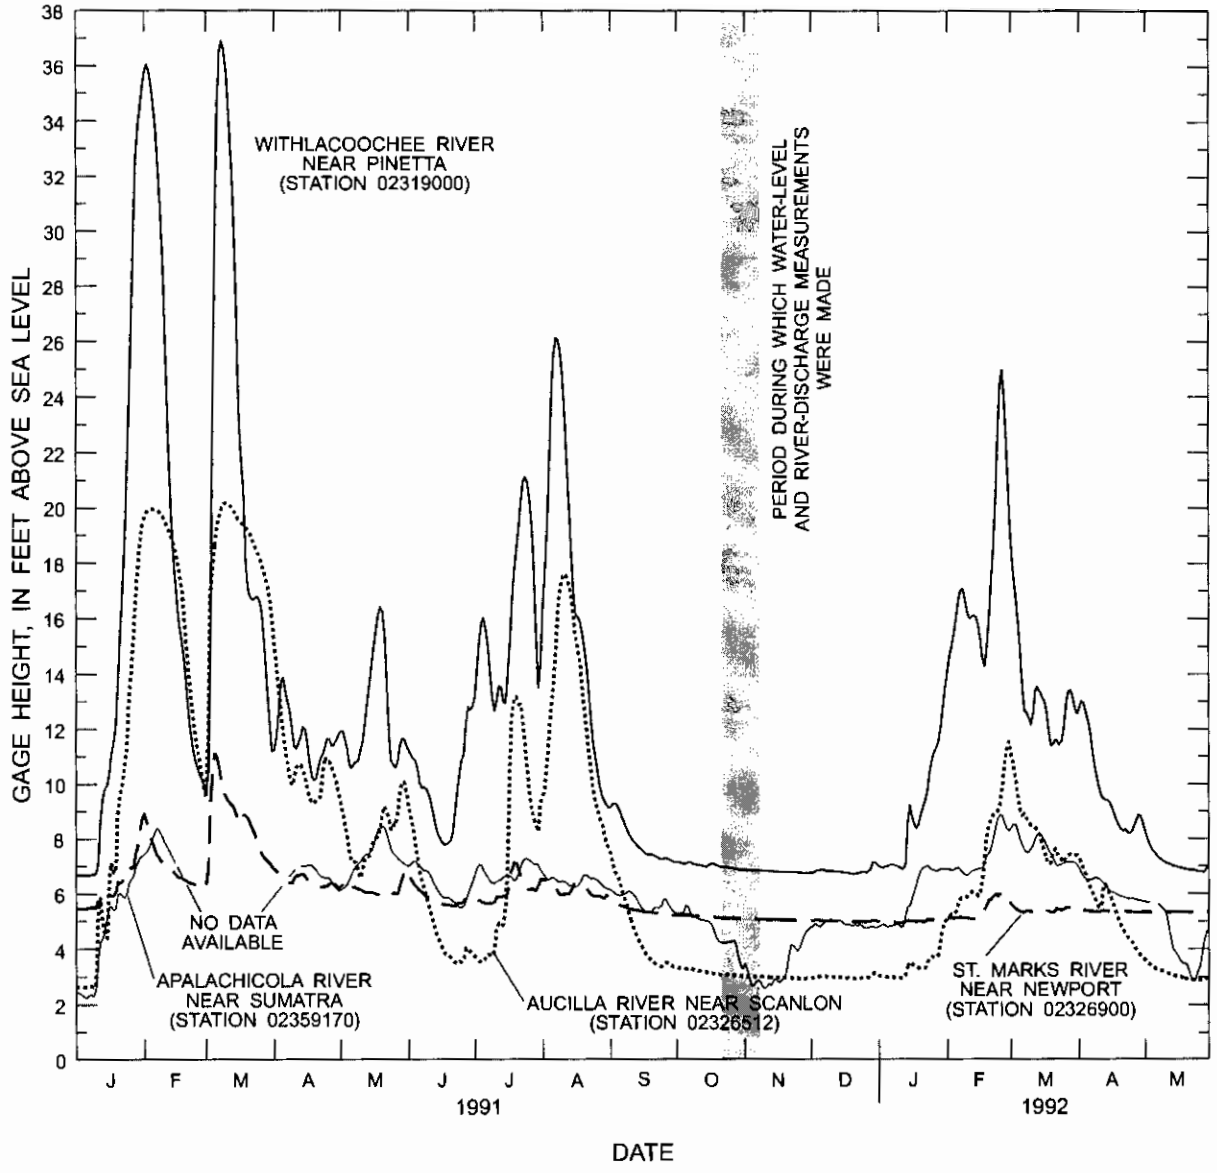

Figure 13. River stages at stations on the St. Marks, Aucilla, Withlacoochee, and Apalachicola Rivers from January 1991 through May 1992.

measurements. Three of the discharge measurements were obtained at established USGS gaging stations. Discharges of the Aucilla, St. Marks, and Wakulla Rivers, and Spring Creek were measured directly using a Price current meter and standard USGS flow-measuring techniques. The amount of error in measuring river discharges varies from station to station and measurement quality can range from very good (within 5 percent) to good (5 - 8 percent) to poor (greater than 10 percent). The error in the discharge measurements of the Aucilla, St. Marks, and Wakulla Rivers, and Spring Creek was estimated at about 10 percent; the other measurements ranged from very good to good. Discharge in the Apalachicola River and the Ochlockonee River and its tributaries was not measured because they are separated from the Upper Floridan aquifer by low-permeability sediments, and are not considered lines of discharge from the Upper Floridan aquifer.

Rivers in the study area were at base-flow conditions during field-data collection due to several months of low rainfall. Base-flow conditions were indicated by constant and low river stages in the Withlacoochee, St. Marks, Aucilla, and Apalachicola Rivers (fig. 13). Variability in stage in the

Apalachicola River is due to dams upstream storing and releasing water and not the variability caused by base flow.

Aquifer Testing

An aquifer test was conducted during November 1992. The purpose of the test was to: 1) determine the transmissivity of the Upper Floridan aquifer at a site within Tallahassee, 2) determine if the aquifer is a single vertically connected hydraulic unit, and 3) to determine if the aquifer acted as porous medium at the aquifer test scale. The test was conducted using the following methodology: City of Tallahassee well 2 was pumped at 1,400 gal/min for 8 days while water levels were measured in five monitoring wells (table 2, fig. 14). After 8 days, the pumping well was turned off and recovery was monitored for 5 hours in well 4, which was equipped with a pressure transducer.

Table 2. Description of pumping and monitoring wells used for aquifer test analysis

[--, not applicable. Locations of wells are shown on fig. 14.]

Monitoring well number	Altitude, in feet above sea level	Well depth, in feet below land surface	Casing depth, in feet below land surface	Distance from pumping well, in feet
Pumping Well:				
City #2	187	415	213	--
Monitoring Wells:				
1	213.32	300	220	1,127
2	212.60	602	485	1,108
3	195.89	340	189	1,220
4	205.47	320	210	805
5	185.99	300	190	1,325

Monitoring wells 1, 3, 4, and 5 had been installed prior to this investigation. Monitoring well 2 was drilled as part of this study. One purpose of the deep well (well 2) was to allow observation of the aquifer response in the lower part of the Upper Floridan aquifer during the aquifer test. Many existing wells penetrate the upper part of the aquifer, but very few penetrate the lower part. Consequently, little is known about the vertical hydraulic connection between the upper and lower parts of the Upper Floridan aquifer. Caliper, natural-gamma, acoustic-velocity, gamma-gamma, salt-tracer, fluid-resistivity, electric long- and short-normal resistivity, focused-resistivity, and spontaneous-potential geophysical logging was performed on the deep well. The geophysical logs showed numerous small openings of several inches in the upper 300 ft of the limestone. The openings are attributed to circulating ground water which dissolved the limestone as it moved along bedding planes and fractures. Such openings were not observed in the limestone in the lower 100 ft of the well; however, this section was believed to be very porous due to the loss of circulation during mud-rotary drilling. Based on the geophysical logs, the permeability of the Upper Floridan aquifer at the test site is considered the result of a mosaic of many fractures and solution-widened joints and openings in loosely cemented fossil hashes that are similar to the interstices of sands.

The aquifer-test data were analyzed by the Theis method (Lohman, 1979). A composite log-log plot of the water-level drawdown data and fitted Theis curve is shown in figure 14. Only data from the first 24 hours of the test were used in the calculation of transmissivity because the later data were affected by city pumpage occurring in areas away from the test and by rainfall. The drawdown data from wells 3, 4, and 5 plotted near a single line (the fitted Theis curve). Using these wells, a transmissivity of 1,300,000 ft^2/d was computed for the Upper Floridan aquifer. Although this is a large transmissivity value, it falls well within the range of values determined by Bush and Johnston (1988).

Wells 1 and 2 are located side-by-side, with well 1 completed in the upper third of the aquifer and well 2 completed in the lower half. The drawdown data from well 2 plotted slightly to the right of the fitted Theis curve, whereas drawdown data from well 1 plotted farther to the right. The delayed response of water levels at these wells could be due to an increase in aquifer storage in the direction of these wells. An increase in storage could be caused by greater dissolution of the limestone creating, a greater volume of void space than elsewhere in the aquifer.

During the aquifer test, water levels at well 2 (the deep well) responded to pumping slightly more quickly than well 1 (the shallow well), even though the pumping well is open at approximately the same interval as well 1 and above well 2. This indicates that a good vertical connection exists between the upper and lower parts of the aquifer and that the Upper Floridan aquifer does act as a single vertically connected unit. Long-term water-level measurements made in these two wells from May 1992 through October 1993

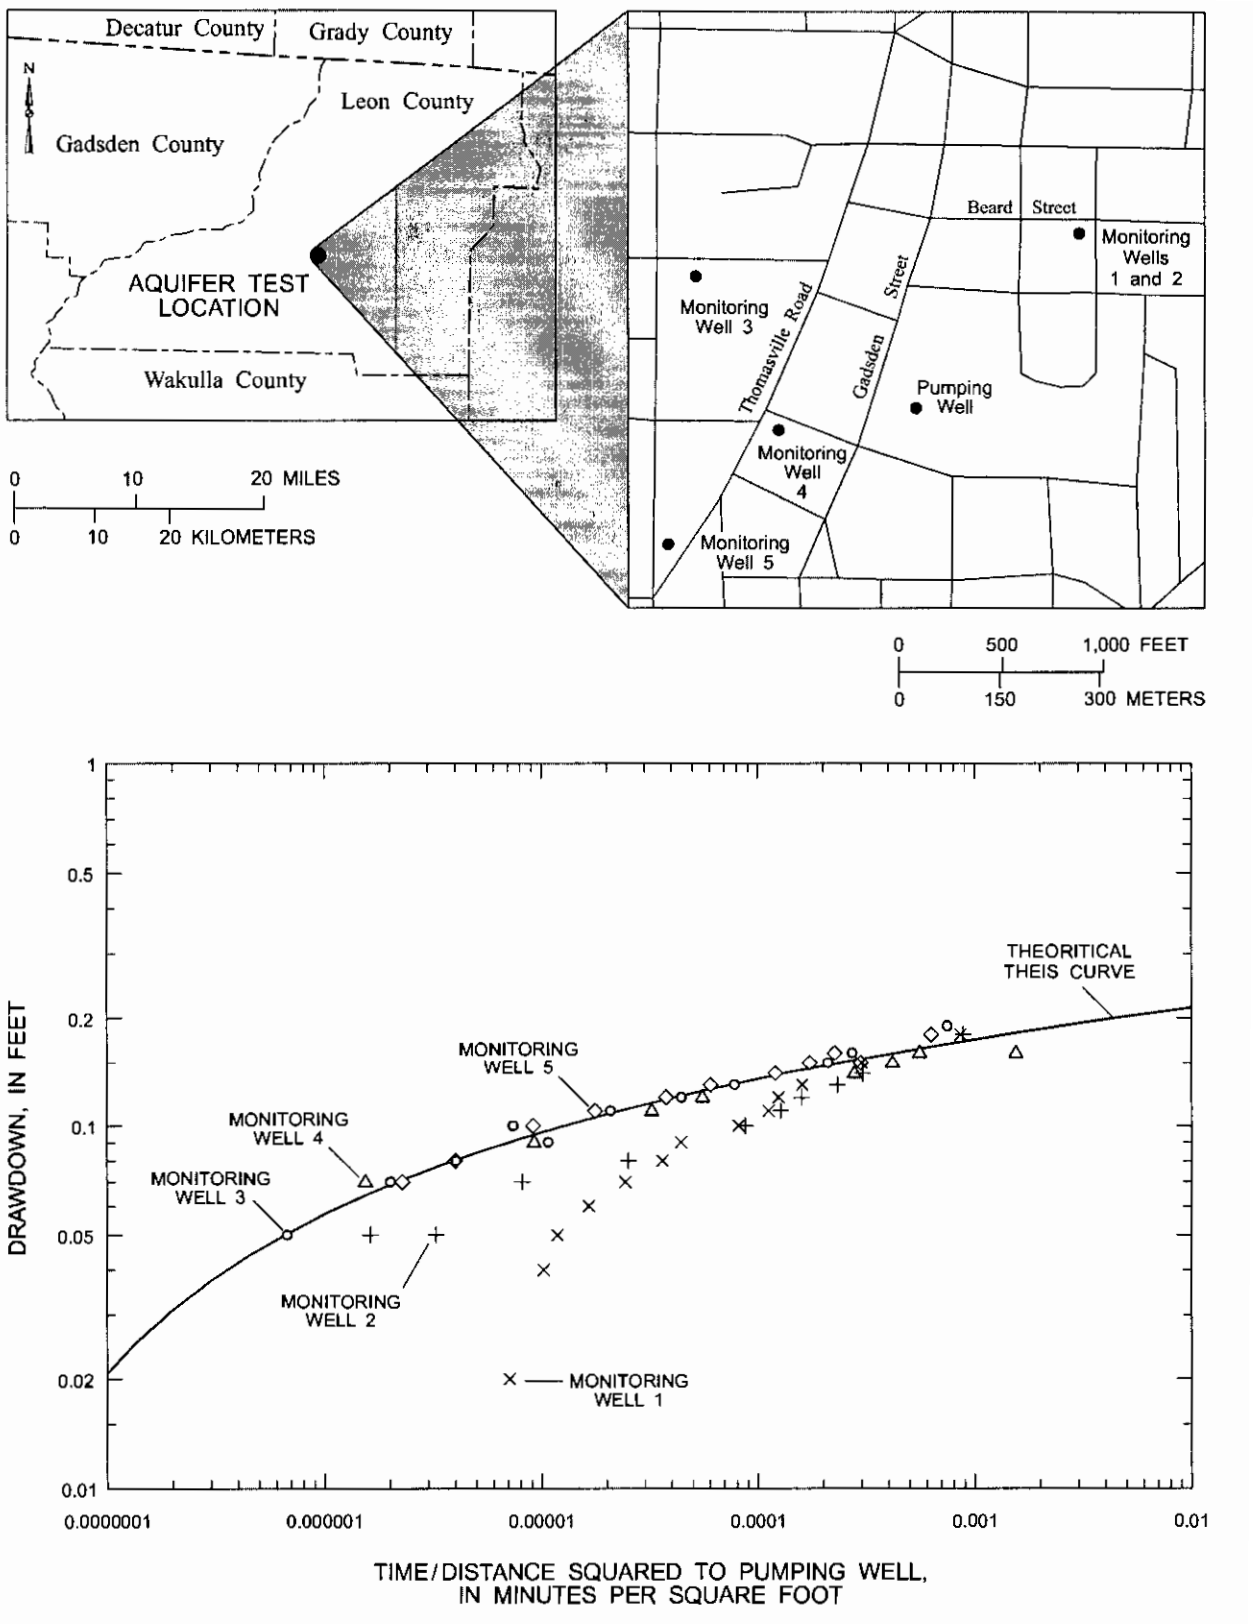

Figure 14. Aquifer response during testing conducted in November 1992, Tallahassee, Fla.

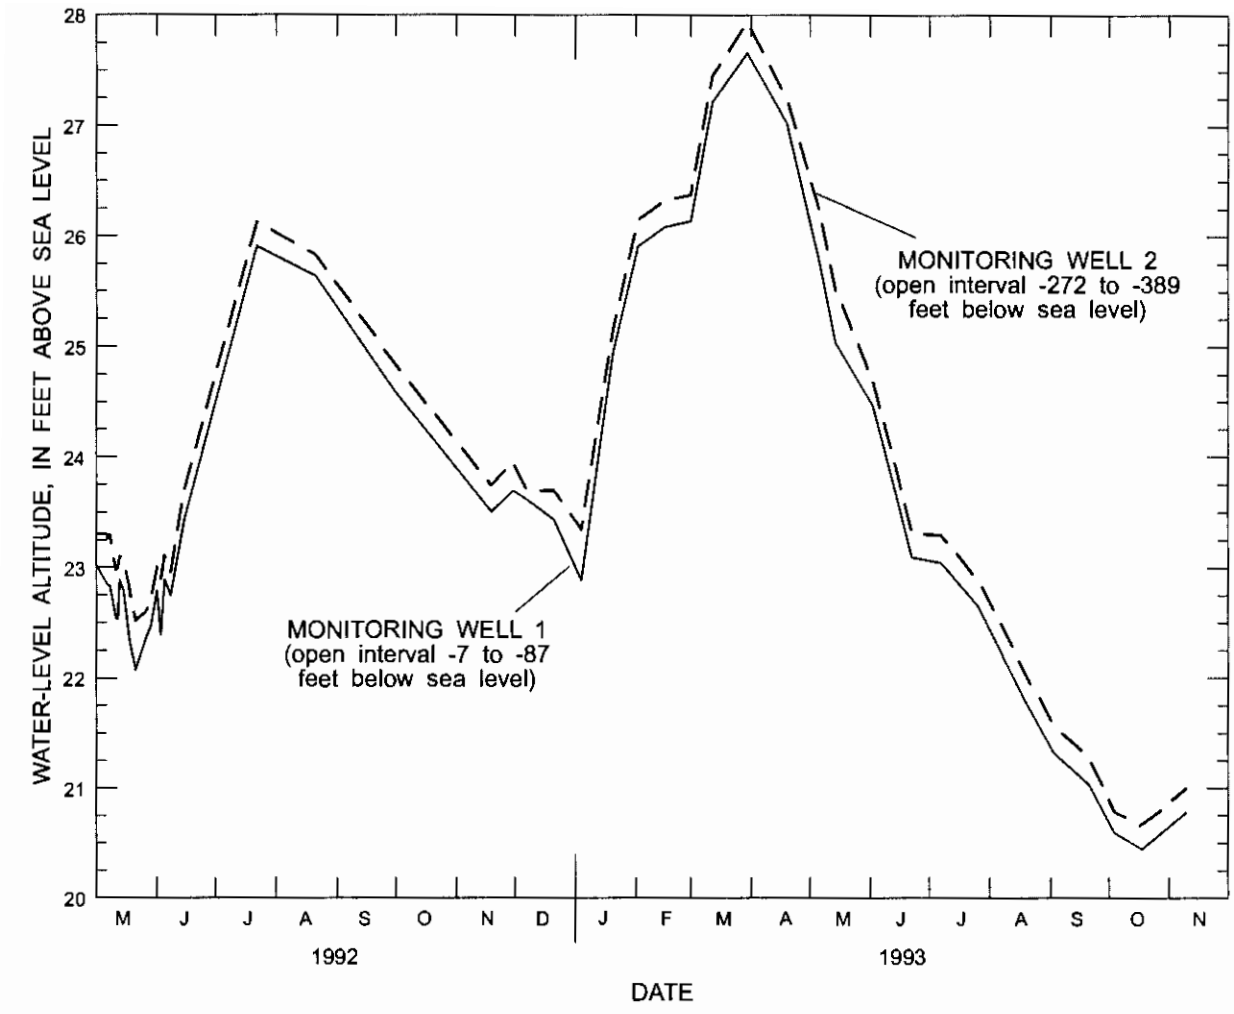

Figure 15. Water-level altitudes in monitoring wells 1 and 2 in Tallahassee, Fla., May 1992 through October 1993.

(fig. 15) show a close correlation of water-level altitudes, further indicating a good vertical connection.

Bush and Johnston (1988) reviewed many Floridan aquifer tests and found that data for many of these tests could be matched to the classic nonleaky, leaky, or delayed-yield response curves, even though the methods are based strictly on porous media assumptions. However, they further argued that porous media assumptions are probably valid in the Upper Floridan aquifer on the scale of the typical aquifer test where the cone of depression is hundreds if not thousands of feet across and where the aquifer response curves matched theoretical curves. For the Tallahassee test, the match between the theoretical Theis curve and the aquifer test data indicated that at the aquifer test scale, the Upper Floridan aquifer responded as a porous medium.

CONCEPTUAL MODEL OF THE GROUND-WATER FLOW SYSTEM

Developing a conceptual model of the aquifer system is an important step in constructing a computer model that accurately simulates ground-water flow. The Upper Floridan aquifer is conceptualized as having the following characteristics: 1) ground-water flow is in a state of dynamic equilibrium and thus can be investigated by assuming steady-state conditions during long term periods, 2) the aquifer acts a single water-bearing unit, 3) the aquifer is recharged by precipitation, and 4) discharge occurs as spring flow, leakage to rivers, leakage to the Gulf of Mexico, and pumpage. Developing a conceptual model also includes locating ground-water divides, determining

ground-water flow directions, and determining areas of recharge and discharge.

The location of the ground-water divides and general directions of ground-water flow were determined from the potentiometric surface map (fig. 16). The most prominent ground-water divide is positioned almost parallel to the axis of the Apalachicola Embayment-Gulf Trough feature. Ground water, on the western side of this divide, will discharge directly into the Flint River or discharge as upward diffuse leakage in the region of the Apalachicola River and Gulf of Mexico. Ground water east of this divide moves generally south toward either the large springs in and around Leon County or toward the Withlacoochee River near the Florida-Georgia border. The exact location of the dividing line between the ground-water basin drained by the large springs in and around Leon County and the basin drained by the Withlacoochee River is not readily apparent and was not drawn. Ground water in the Upper Floridan aquifer, moving beneath Leon County, could have entered the aquifer in counties to the west and north as shown in figures 16 and 17.

The position of the ground-water divides are not necessarily fixed and could move with changing recharge and discharge rates. The position of the divide along the Apalachicola Embayment-Gulf Trough probably fluctuates very little whereas the position of the divide that separates flow to the large springs in and around Leon County and flow to the springs in the Withlacoochee River could fluctuate significantly. For this reason, the study area boundaries were chosen to coincide with rivers, where possible, because their locations are fixed.

As indicated on the regional potentiometric maps for May 1985 (Bush and others, 1987) and May 1980 (Bush and Johnston, 1988), a saddle in the potentiometric surface occurs in Georgia along the eastern part of the study area. Only the westward half of this saddle is indicated on figure 16, the eastward half would occur outside the study area. A ground-water divide would occur at the low point of the saddle. However, the exact location of this divide is difficult to determine because the gradients are so low. Accordingly, ground-water flow out of the study area could occur, and because the transmissivity is high, this outflow could be significant.

The Upper Floridan aquifer within the study area is considered to be in a state of dynamic equilibrium. Dynamic equilibrium is indicated because there have been no known long term changes in the potentiometric surface of the Upper Floridan aquifer, although it has fluctuated seasonally and yearly in response to variations in rainfall (fig. 18). As shown in the figure, water levels rise in this Leon County well during extended periods of high rainfall and slowly decline during periods of low rainfall, but there appears to be no long-term trend of rising or declining water levels in the period from 1984 to 1992. Other studies agree with this finding. Hydrographs were examined from wells located in Leon and Wakulla Counties, Florida, and Seminole, Decatur, Miller, Mitchell, and Dougherty Counties, Georgia. These hydrographs also indicated only seasonal variation and no long-term water-level declines; consequently, the Leon County hydrograph is considered representative of Upper Floridan aquifer hydrographs in the study area and is the only one presented. Bush and Johnston (1988) found that the net decline between the estimated predevelopment potentiometric surface and the observed potentiometric surface in May 1980, was less than 10 ft (and could have been zero). The potentiometric surface shown on figure 16 was similar to the potentiometric surface measured in May 1985 (Bush and others, 1897) and in May 1980 (Bush and Johnston, 1988). The minor differences that occurred were attributed to different data point densities or minor seasonal fluctuations. Hendry and Sproul (1966) plotted the water-level altitudes of two Upper Floridan aquifer wells and one water-table aquifer well (located in Leon County) for the time period 1946 to 1965. The water levels showed seasonal and yearly fluctuations, but no long-term changes were apparent.

Ground-water flow in the Upper Floridan aquifer can be evaluated using steady-state methods, which are a special case of dynamic equilibrium. Assuming long-term steady-state conditions, the net recharge rate to the aquifer is the flux necessary to maintain the head in the aquifer at a constant level. This implies that the average recharge rate is equal to the average discharge rate over the long term, and that the volume of ground water stored in the aquifer does not change. No ground-water system will ever be at true steady-state. Freeze and Cherry (1979, p. 194) stated that if fluctuations in water-level altitudes are small in comparison with the total vertical thickness of the aquifer and the relative configuration of the potentiometric surface remains the same, then the system can be considered steady state. Hendry and Sproul (1966), after examining water-level records for 20 wells within Leon County, determined the maximum range in water-levels (the difference between the highest and lowest) was

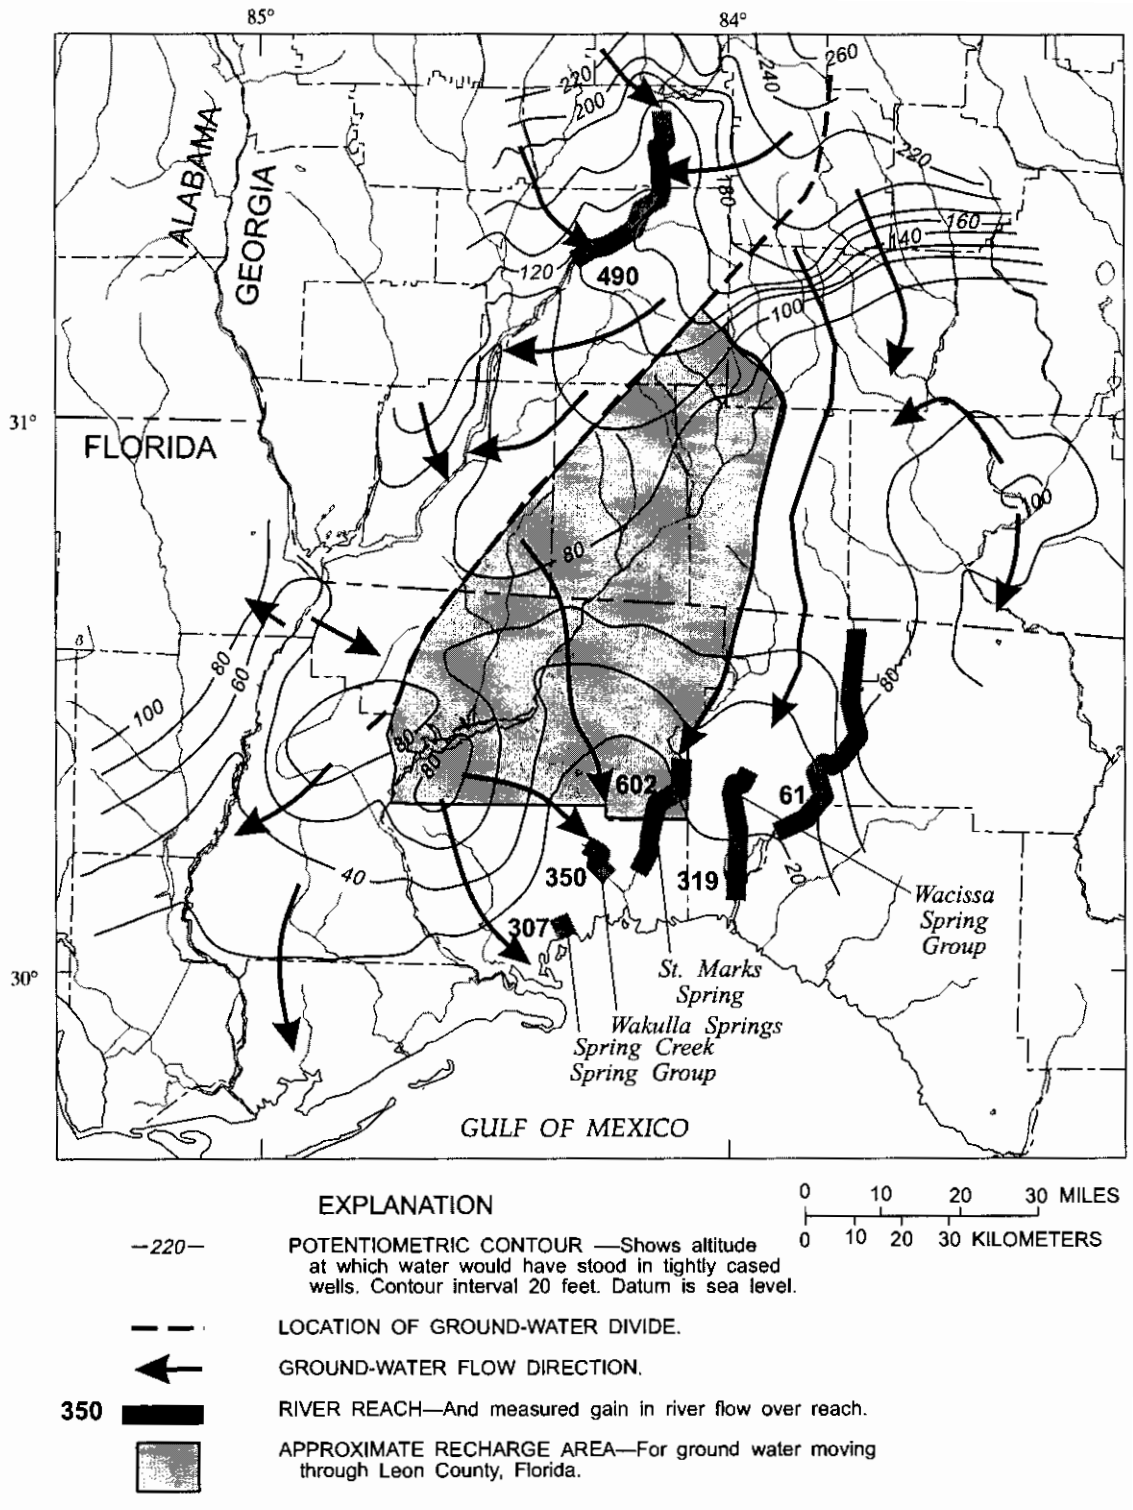

Figure 16. Ground-water flow directions, and net gain in river flow during October-November 1991.

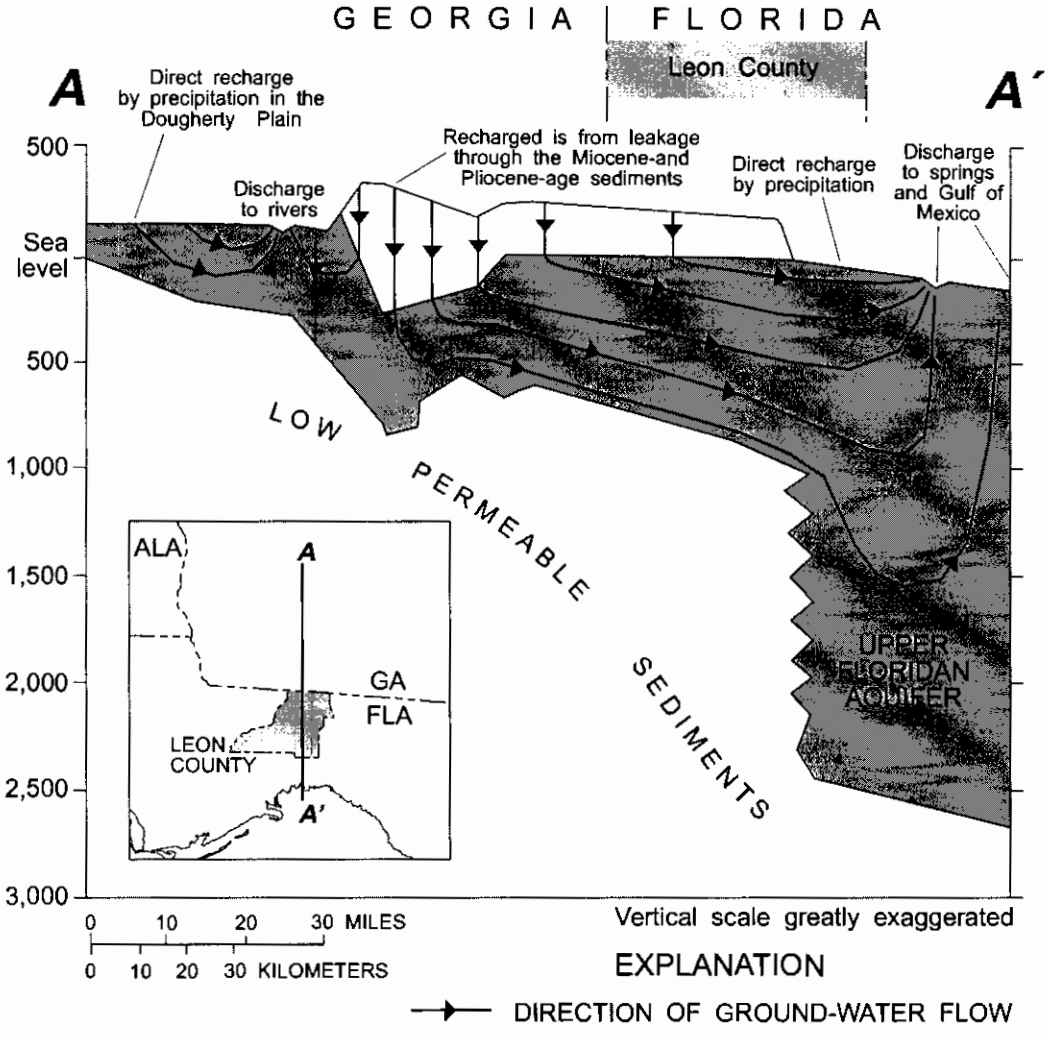

Figure 17. Conceptual model of the Upper Floridan aquifer system showing ground-water flow directions.

less than 14 ft between the years 1959 and 1965. A similar range was observed between 1984 and 1992 (fig. 18). Within Leon County, the Upper Floridan aquifer ranges in thickness between 500 ft in the north and 1,800 ft in the south. Using the argument of Freeze and Cherry (1979) and the fact that the maximum change in water levels in relation to aquifer thickness is about 3 percent, then long-term average conditions of ground-water flow within the Leon County area can be considered to be at steady state. Steady-state conditions were also indicated by the relatively constant stages of rivers that drained ground water from the Upper Floridan aquifer during the period September 1991, to January 1992 (fig.13).

The head in the Upper Floridan aquifer in Tallahassee, during field data collection, was very close to the average head for the period 1984 to 1992 (fig. 18). The average water-level altitude in well FSU 1 during October 21 to November 8, 1991, was 26.8 ft and the average water-level altitude from 1984 to 1992 was 26.2 ft, indicating that aquifer conditions were near a long-term average.

The Upper Floridan aquifer probably acts locally as well as regionally as single water-bearing unit within the study area. That is, there are no zones of sufficient areal extent and low permeability to divide the aquifer into distinct permeable units (Miller, 1986; and Bush and Johnston, 1988). Such assumptions are supported within the Tallahassee area by water-level data collected from two adjacent wells (discussed earlier) and shown in figure 15. The small upward gradient of between 0.2 and 0.5 ft could be caused by City of Tallahassee pumpage from the upper third of the aquifer.

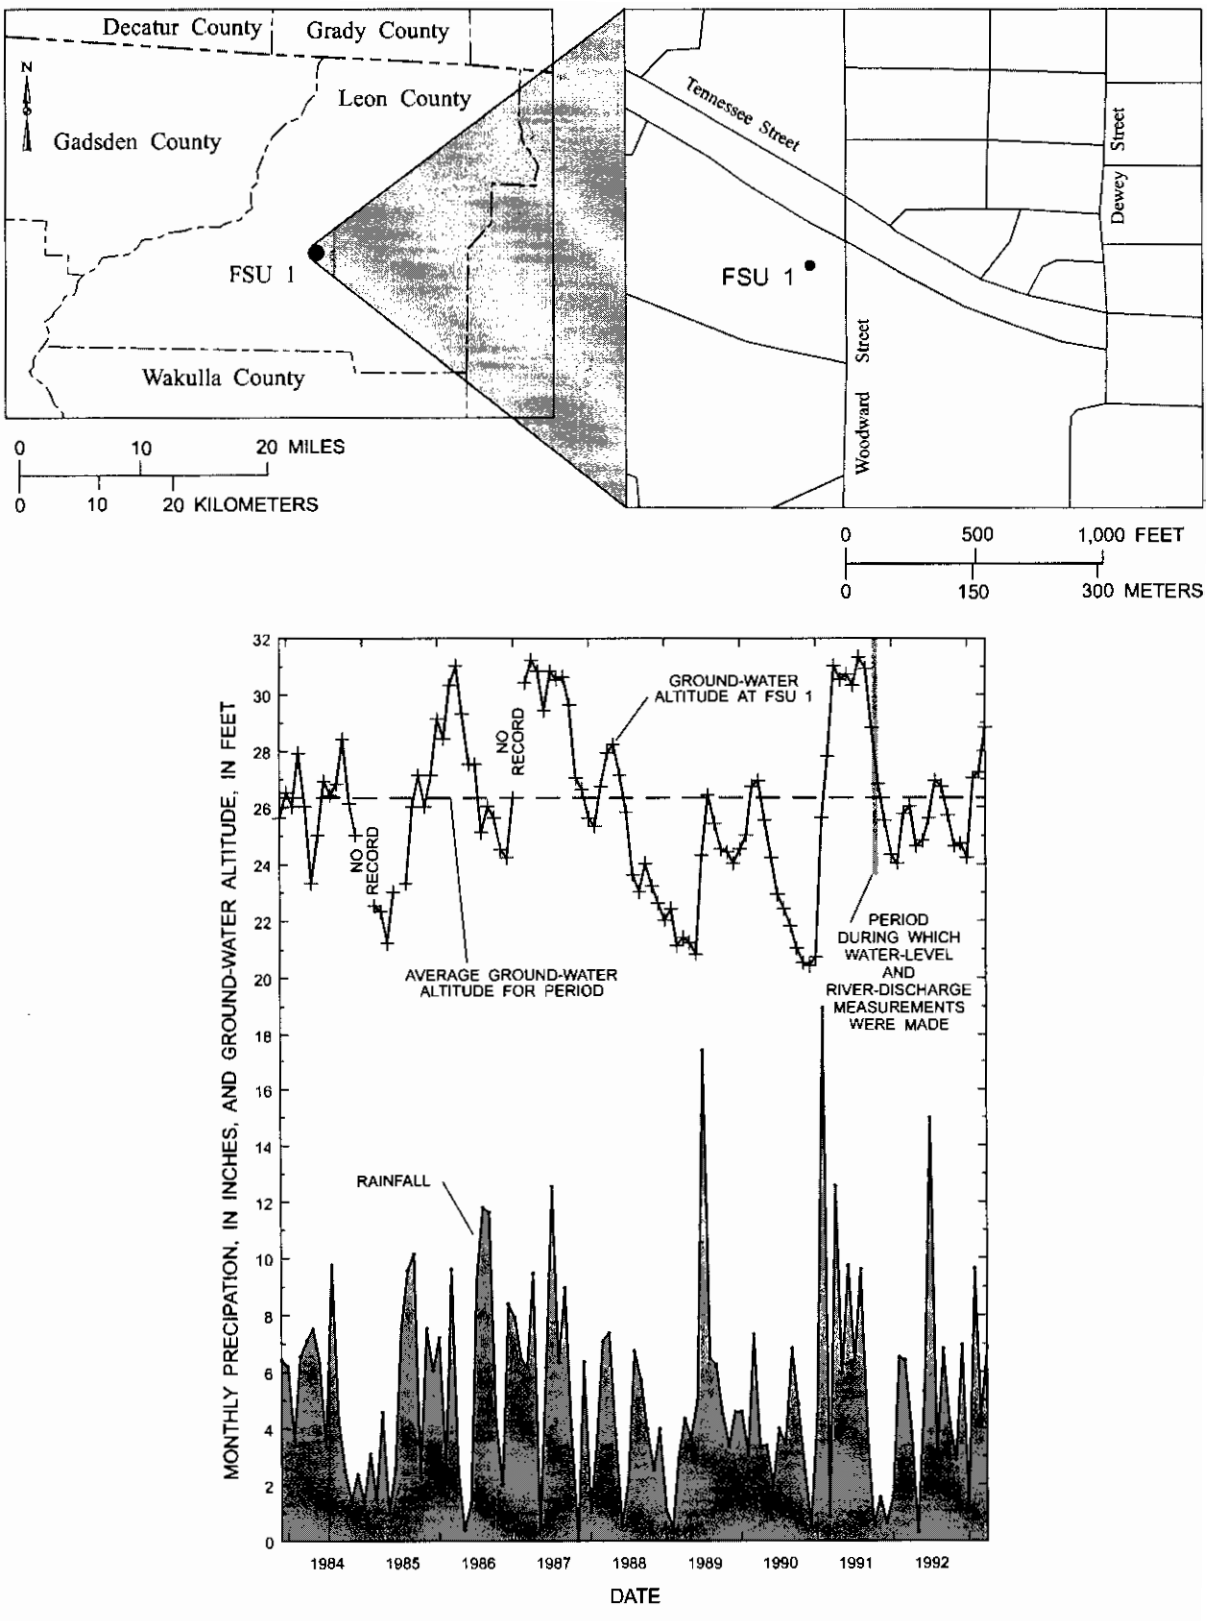

Figure 18. Rainfall and ground-water altitude fluctuations in the Upper Floridan aquifer in well FSU 1, Tallahassee, Fla., 1984 - 1992.

The ultimate source of recharge to the Upper Floridan aquifer is precipitation. Net recharge rates are relatively high in the karst areas (fig. 9) because the aquifer is exposed at land surface or covered only by a thin veneer of sediments. Precipitation falling in these areas can rapidly infiltrate through the overlying sediments or directly enter the aquifer through sinkholes and sumps. Outside the karst areas, the aquifer is overlain by low-permeability Miocene-and Pliocene-age sediments. Net recharge rates in these areas are less than in the karst areas because the low-permeability sediments cause a large proportion of precipitation to become runoff to streams. Model calibrated recharge rates determined by Bush and Johnston (1988) ranged from as high as 20 in/yr in the Ocala Uplift District to less than 1 in/yr in parts of the Apalachicola Embayment - Gulf Trough area.

The Upper Floridan aquifer is confined in some areas and unconfined in others (fig. 19). Unconfined conditions exist in the karst areas and in the area of the Barwick Arch. Near the center of the arch, the limestones comprising the Upper Floridan aquifer reach an elevation of about 150 ft and the potentiometric surface is about 60 ft (Sever, 1966). In this region, the limestones in the uppermost part of the Upper Floridan aquifer are unsaturated and unconfined conditions exist. A large part of Leon County lies within this area. Although the Upper Floridan aquifer is unconfined in the Barwick Arch area, the limestones comprising the aquifer are overlain by the low-permeability sediments which limits recharge to the aquifer. Outside the karst and Barwick Arch areas, the Upper Floridan aquifer is confined by the low-permeability Miocene-and Pliocene-age sediments.

In areas where the low-permeability sediments confine the Upper Floridan aquifer, the rate of recharge (leakage downward) is proportional to the difference in head between the water table and Upper Floridan aquifer. The rate of recharge is also proportional to the vertical hydraulic conductivity of the low-permeability sediments and inversely proportional to the thickness of these sediments. In the Barwick Arch area, the Upper Floridan aquifer is unconfined but overlain by the low-permeability sediments, here the rate of leakage is not dependent on the head in the Upper Floridan aquifer. In these areas, fluctuations in the head of the Upper Floridan aquifer do not change the rate of leakage through the overlying sediments.

Discharge of water from the Upper Floridan aquifer occurs as spring flow, seepage into rivers and the Gulf of Mexico, and withdrawals from wells. Rivers (or reaches of rivers) within the karst areas are directly hydraulically connected with the Upper Floridan aquifer, but rivers (or reaches of rivers) not in the karst areas are generally separated from the aquifer by the low-permeability Miocene- and Pliocene-age sediments. Rivers in the karst areas receive large volumes of water from the Upper Floridan aquifer, mostly as spring flow. A net gain in flow of 490 ft^3/s was measured for one reach of the Flint River in southern Lee and Dougherty County, Georgia (fig.16). In the karst areas of the Ocala Uplift, water is drained from the aquifer by several large springs and spring groups. The major springs in the southern part of the study area are Spring Creek Spring group, Wakulla Spring, St. Marks Spring, and the Wacissa Spring group. These four are among the eight largest springs in Florida (Rosenau and others, 1977). Discharges measured on November 1, 1991, in the rivers directly downstream of these springs were: Spring Creek (307 ft^3/s), Wakulla River (350 ft^3/s), St. Marks River (602 ft^3/s), and Wacissa River (319 ft^3/s). When the measurements were made, the rivers derived most, if not all, of their flow from spring discharges. Some discharge also occurs in smaller springs along the coast and directly to the Gulf of Mexico; however, the rate of discharge from these springs is unknown.

SIMULATION OF GROUND-WATER FLOW IN THE UPPER FLORIDAN AQUIFER

Ground-water flow in the Upper Floridan aquifer was simulated using the USGS modeling software MODFLOW (McDonald and Harbaugh, 1988). The modeling software requires that the aquifer system be divided into a horizontal grid of rows and columns and vertically into layers, creating a three- dimensional matrix of cells. Aquifer properties are assigned to cells (such as top of aquifer, base of the aquifer, hydraulic conductivity of the aquifer, and so forth) so that the cell matrix is tailored to represent known conditions present in the Upper Floridan aquifer. MODFLOW then uses finite-difference equations to simulate three-dimensional ground-water flow. The software iteratively solves the system of equations for hydraulic head at each active model cell and calculates the rate of ground-water flow between cells.

To ensure that the model simulation accurately reflects conditions present in the Upper Floridan aquifer, the model must be calibrated. Calibration is the

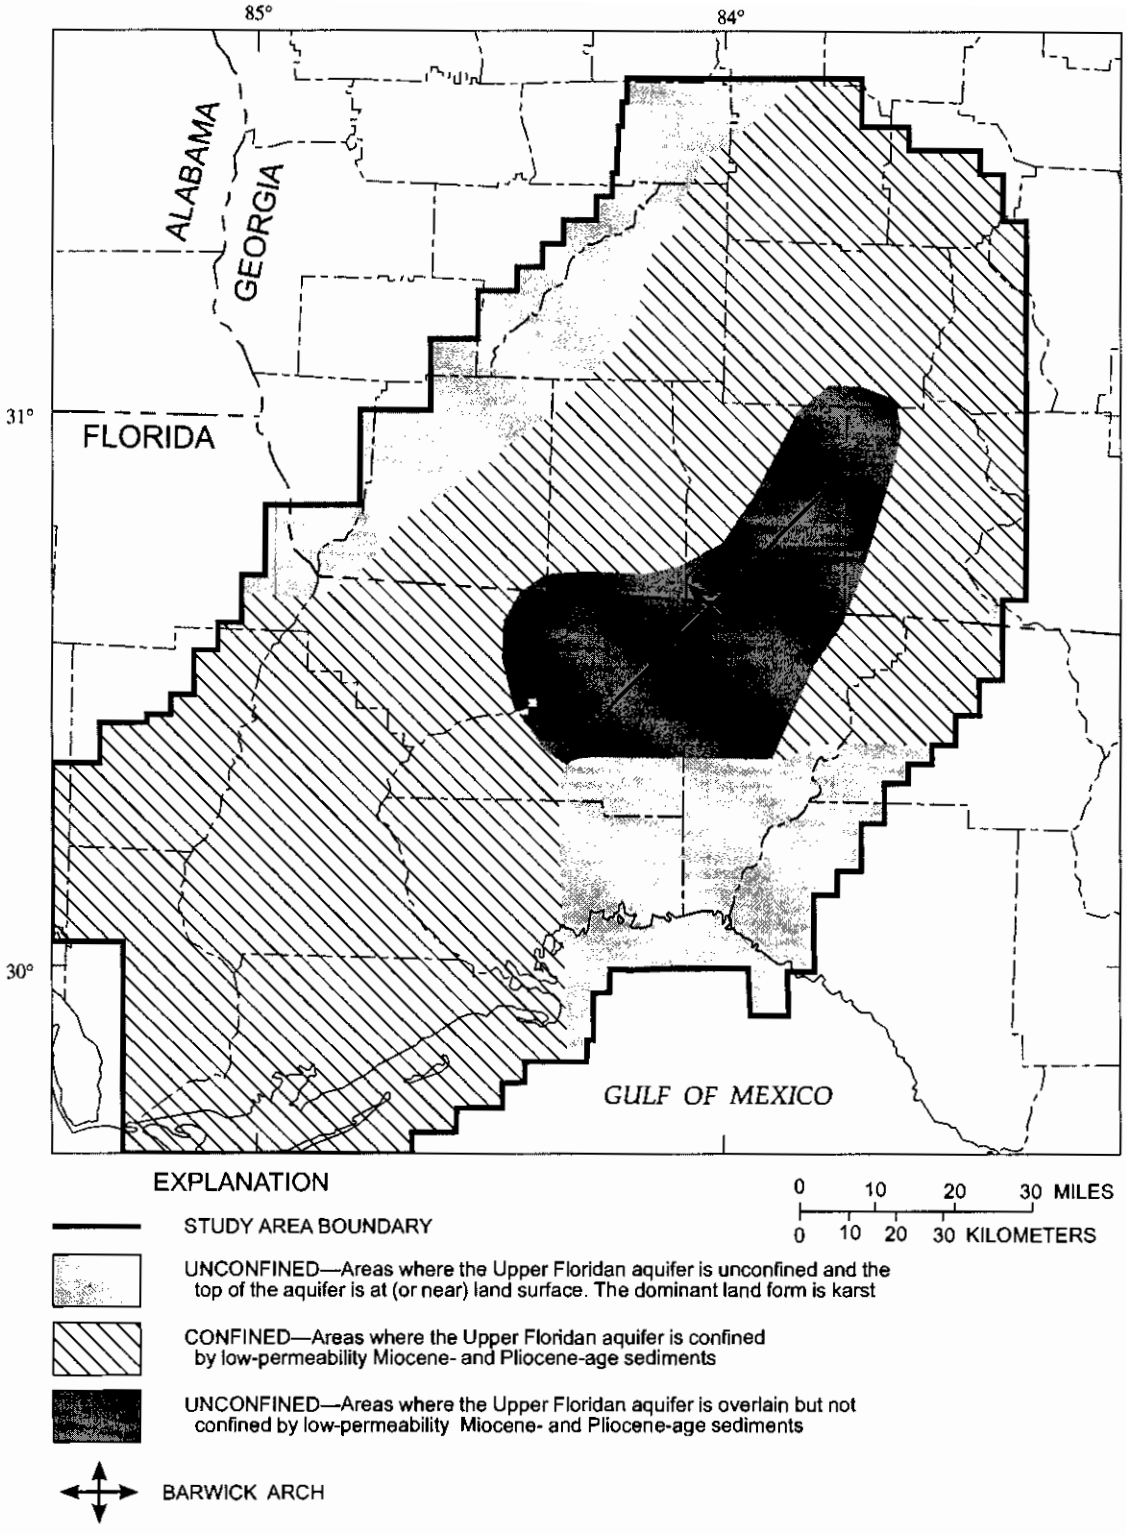

Figure 19. Areas where the Upper Floridan aquifer is confined and unconfined.

process of varying aquifer properties assigned to cells until the computer-simulated aquifer conditions match measured-aquifer conditions. The model was calibrated to hydrologic conditions measured during the data collection part of this investigation, which was late October to early November 1991. Ground-water flow was simulated as steady state, which assumes that the volume of ground-water recharge equals the volume of ground-water discharge. Once calibrated, the model was coupled with particle-tracking techniques to delineate the contributing areas to five City of Tallahassee municipal supply wells.

The model simulates the aquifer as an heterogeneous porous medium and assumes that ground-water flow is uniformly distributed within each active model cell. As discussed earlier, this assumption is valid over most of the study area. However, conduit flow occurs near large springs and near some sinkholes where cave systems are present. In these areas, the aquifer does not behave like a porous medium and the model may predict average ground-water flow velocities that are slower than those that actually occur within the conduits.

Grid Design

The first step in simulating ground-water flow was to divide the entire study area into a grid of cells. The grid consisted of 176 rows and 162 columns (fig. 20), resulting in 28,512 model cells per layer (fig.21). The aquifer system was simulated using 3 layers. Orientation of the grid was north-south. Cell size is variable with the smallest cells occurring near the center of the study area and larger cells occurring near the perimeter. Row and column spacing was chosen so that the water-supply wells, in which contributing areas were to be determined, would be positioned in the smallest model cells. The smallest cells are 30 by 30 ft and the largest cells are 3 by 3 mi. Not all cells in the matrix were used during the simulation of ground-water flow. Some cells were inactive, which allowed the study area to conform to irregular boundaries.

Model Layer 1

Layer 1 in the model represents the water-table aquifer. Layer 1 model cells are utilized only where the low-permeability Miocene- and Pliocene-age sediments confine the Upper Floridan aquifer (figs. 21 and 22). In these areas, layer 1 cells are treated as a specified-head boundary. For this type boundary condition, each cell in the layer can either provide water to or drain water from the cell in the next layer below, while maintaining a head at a specified altitude. If the head in a layer 1 cell is higher than the head in a layer 2 cell, water will flow from layer 1 to layer 2, and vice-versa. During ground-water flow simulation, the head of layer 1 cells was specified to represent the average head for the water-table aquifer located within that cell. The head within the water-table aquifer, in most places, reflects the land-surface topography and generally is a few feet below land surface (but can be tens of feet in some places). For most layer 1 cells, the head was specified to be a few feet below average land-surface altitude. However, in some highland areas the head was specified to be as much as 50 ft below land surface. The low-permeability Miocene- and Pliocene-age sediments were generally several hundred feet thick where the water-table aquifer was simulated, so small errors in the estimated head had a negligible effect on simulated leakage rates.

The movement of water to and from the water-table aquifer is restricted by low-permeability sediments. This resistance to flow between cells in layer 1 and layer 2 is a model input parameter designated Vcont 1. Vcont 1 is calculated for layer 1 cells using the following formula:

$$\text{Vcont } 1 = 1/(b_1/VK_1) \qquad (1)$$

where: b_1 is the thickness of the low-permeability Miocene- and Pliocene-age sediments (ft), and

VK_1 is the vertical hydraulic conductivity of the low-permeability Miocene- and Pliocene-age sediments (ft/d),

The thickness of the low-permeability Miocene- and Pliocene-age sediments is shown on figure 5 and the vertical hydraulic conductivities are discussed with the description of model calibration. An initial value of 0.00005 ft/day was assumed for the vertical hydraulic conductivity. However, this value was changed during model calibration.

Model Layers 2 and 3

The Upper Floridan aquifer is represented in the simulation by model layers 2 and 3 (fig. 21 and 22). Layer 2 represents the upper 230 ft of the aquifer, which, on average, is the zone penetrated by City of Tallahassee water-supply wells. Layer 3 represents the difference between the total thickness of the Upper

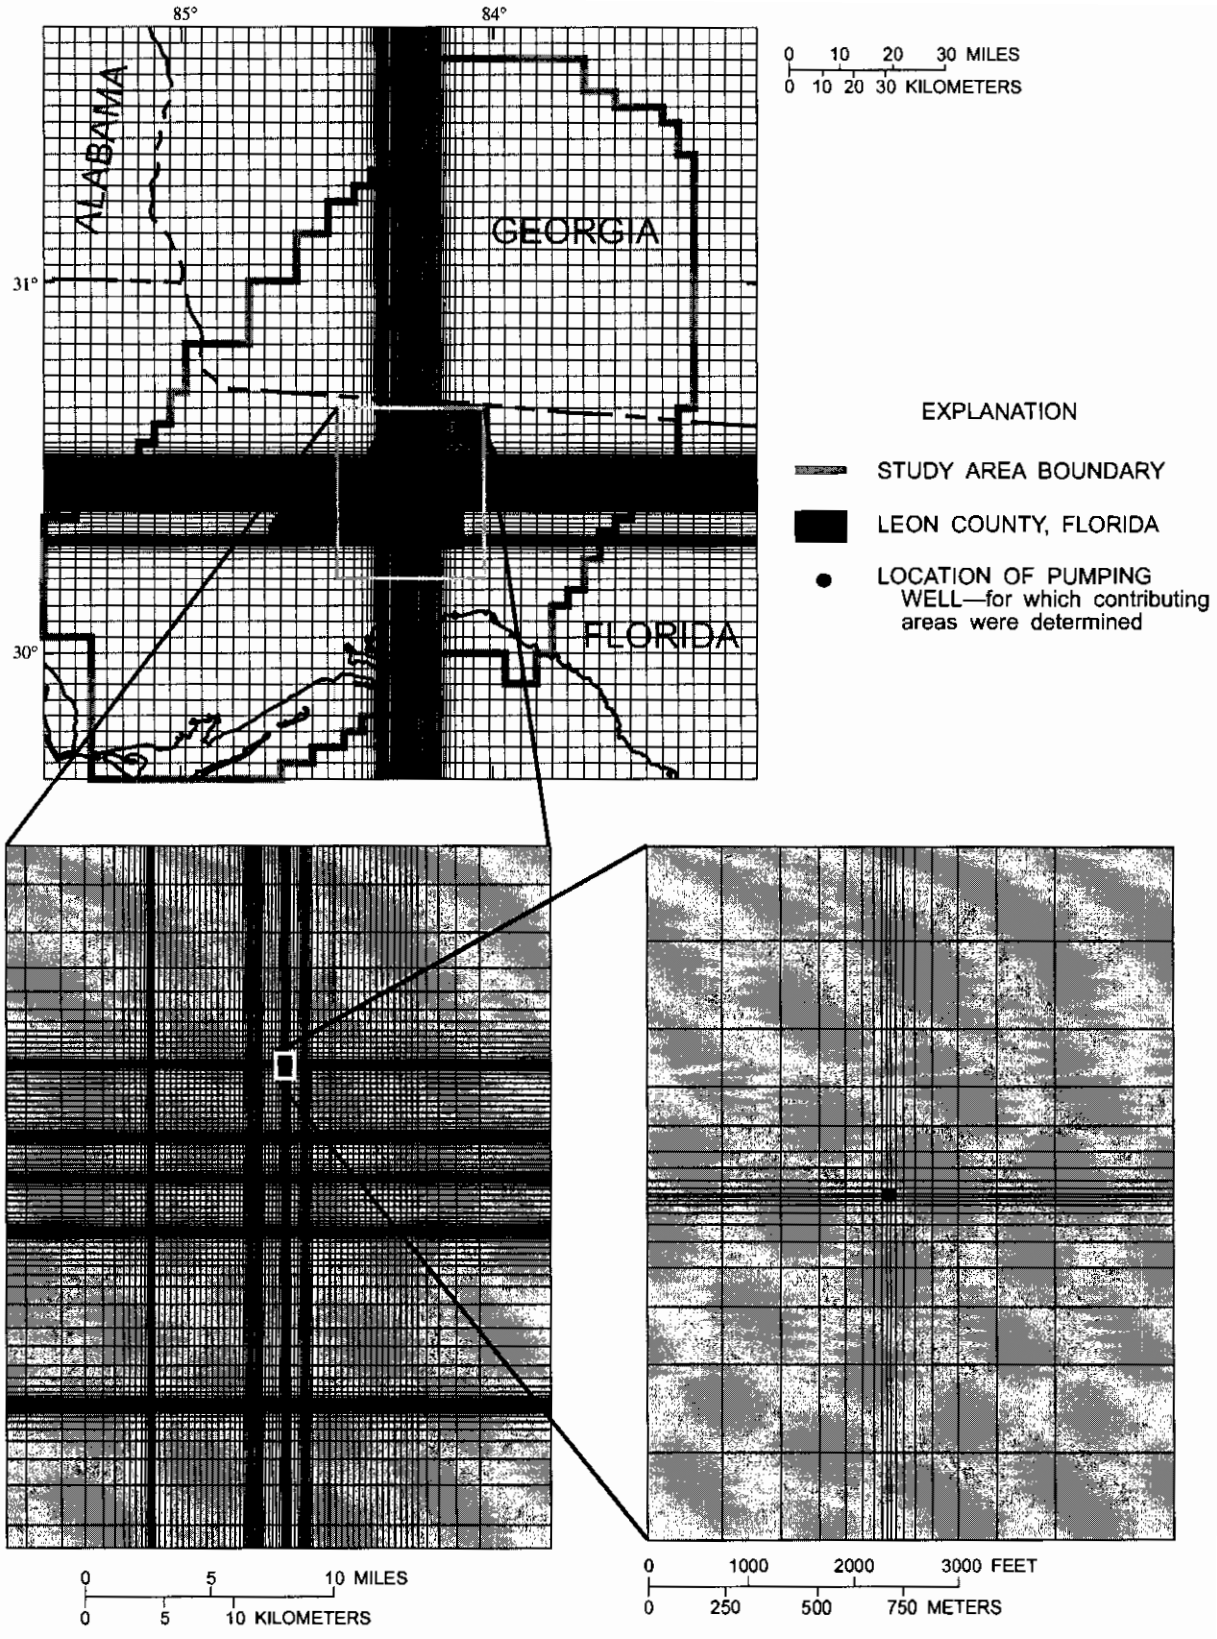

Figure 20. Location and orientation of finite-difference model grid.

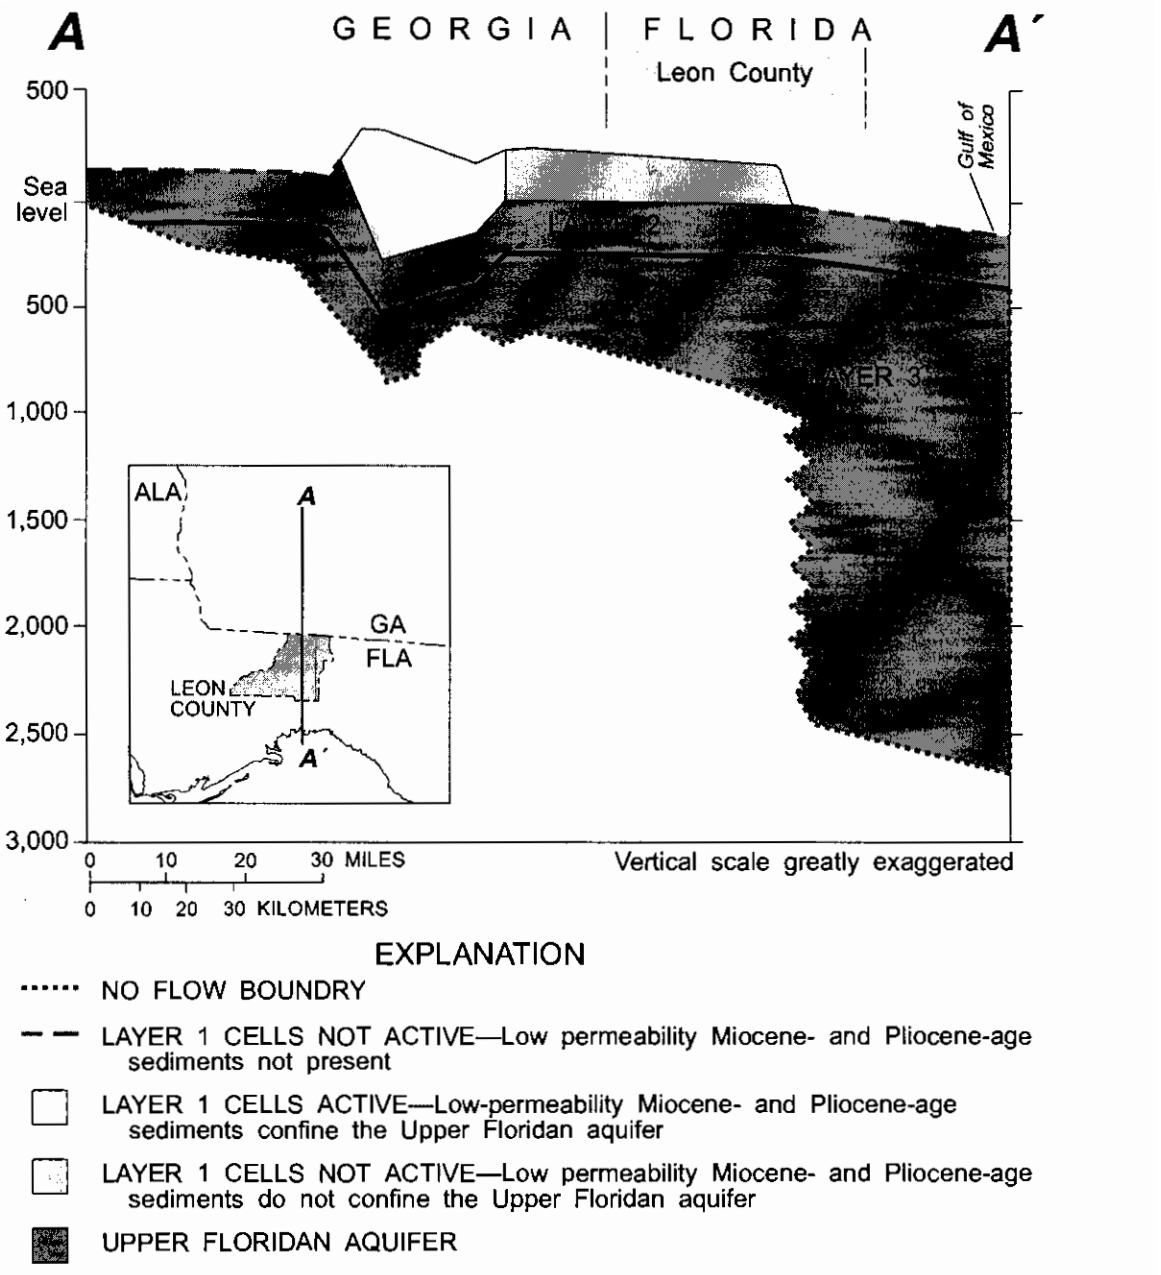

Figure 21. Generalized hydrogeologic section showing model layers.

Floridan and the thickness of layer 2. The Upper Floridan aquifer acts as a single water-bearing unit within the study area. The sole purpose for dividing the aquifer into two layers is to simulate withdrawals from water-supply wells at approximately their actual depths. This is important for accurate delineation of contributing areas (discussed in a later section). Layer 2 is the most areally extensive layer and defines the maximum lateral extent of the model. In the northwestern part of the study area, the Upper Floridan aquifer thins to less than 230 ft and the aquifer is represented completely by layer 2. The Upper Floridan aquifer is bounded below by low-permeability sediments so the base of the model is a no-flow boundary.

The resistance to vertical ground-water movement between layers 2 and 3 is a model input parameter designated Vcont 2, and was calculated by the equation:

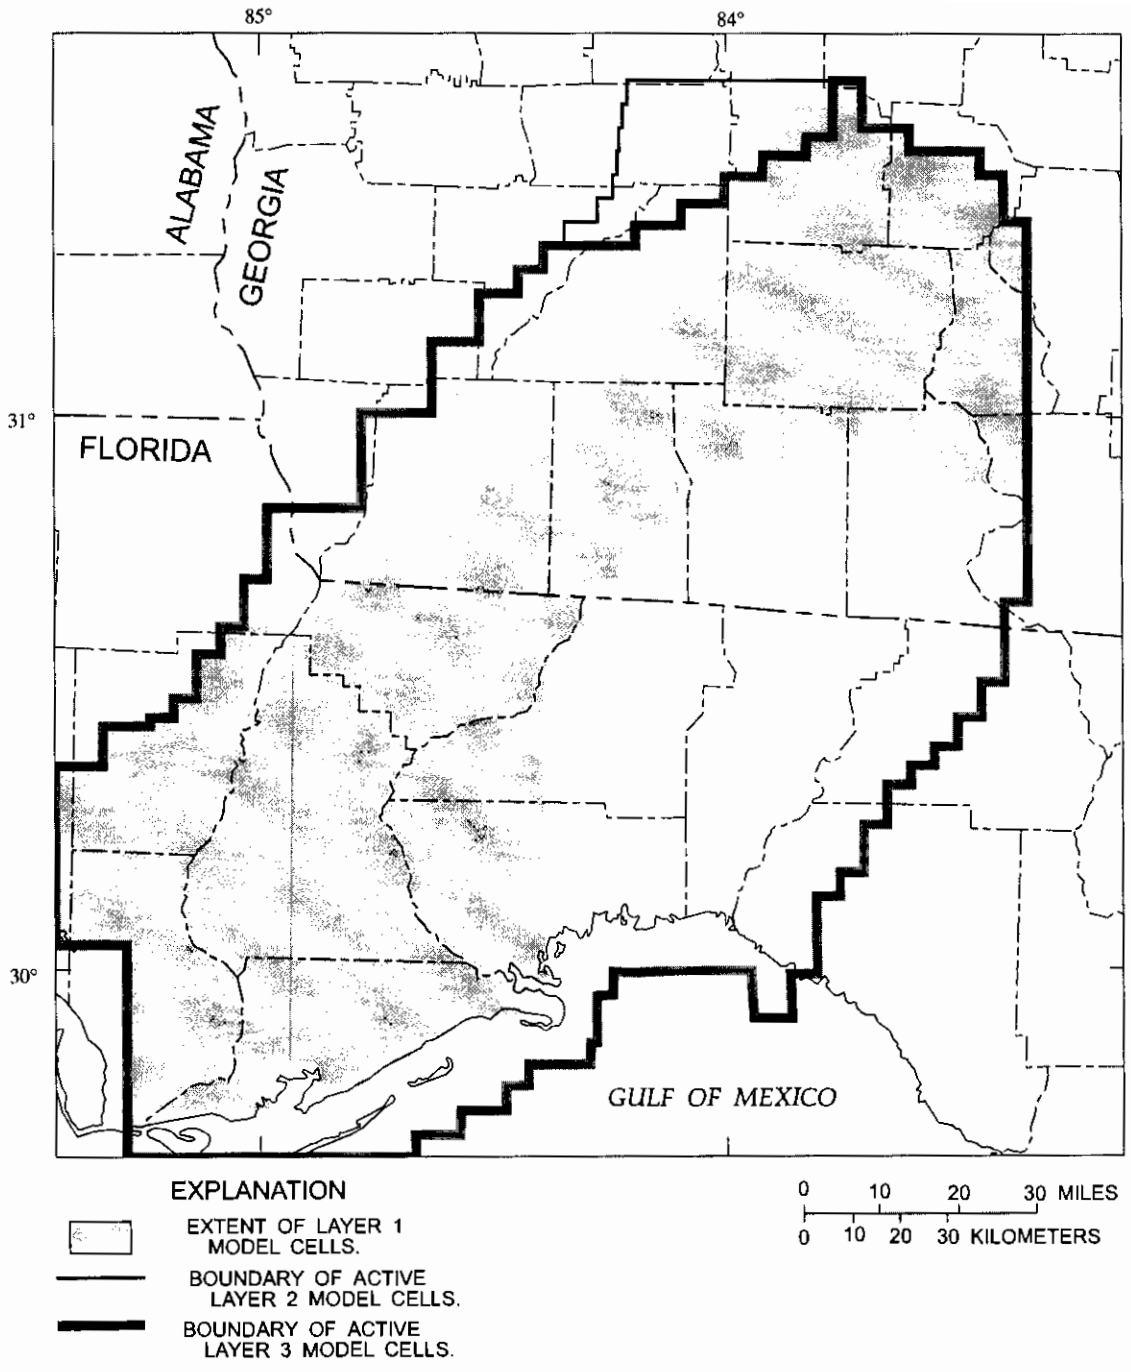

Figure 22. Location of model areas for layers 1, 2, and 3.

$$\text{Vcont 2} = 1/[(230\text{ ft}/2/VK_{UF}) + ([(b_{UF} - 230\text{ ft})/2]/VK_{UF})] \quad (2)$$

where:

VK_{UF} is the vertical hydraulic conductivity of the Upper Floridan aquifer (ft/d), and

b_{UF} is the thickness of the Upper Floridan aquifer (ft).

In calculating Vcont 2, the vertical hydraulic conductivity was set equal to the horizontal hydraulic conductivity of the Upper Floridan aquifer. Under this assumption, ground water can move both horizontally and vertically with equal resistance.

Model Input Parameters and Boundary Conditions

Model input parameters are specified and spatially distributed at active cells before simulation of ground-water flow begins. MODFLOW uses the input parameters to tailor the finite-difference equations to the particular aquifer being investigated. The model input parameters used for this investigation are altitude of the water-table which defines the top of layer 1, altitude at the base of layer 1, Vcont 1, altitude at the top of layer 2, altitude at the base of layer 2, hydraulic conductivity of layer 2, transmissivity of layer 3, and net recharge rates.

Initial estimates of transmissivity for the Upper Floridan aquifer were computed by contouring the transmissivity values (fig. 9) and assigning a transmissivity to each model cell from the contoured data. Values of horizontal hydraulic conductivity for layer 2 were calculated by dividing transmissivity by the total thickness of the aquifer. The transmissivity for each cell of layer 3 was computed by multiplying the thickness of layer 3 at each cell by the corresponding hydraulic conductivity.

An initial estimate of direct recharge to the Upper Floridan aquifer of 7 in/yr was calculated by dividing the net river gains by the approximate area of the aquifer drained by the rivers. This constant recharge rate was applied directly to layer 2 in areas where the Upper Floridan aquifer was unconfined (fig. 23) and was varied separately during model calibration.

Model boundaries were selected and located to approximate natural hydrologic boundaries of the Upper Floridan aquifer. Where feasible, the model boundaries were located at or slightly beyond the major rivers that drain water from the aquifer because these are permanent hydrologic boundaries. The result of the hydraulic connection between the aquifer and river is that stresses imposed on the aquifer (such as pumping) are unlikely to propagate beyond the rivers, both in the natural system and in the simulated system.

The western model boundary is located just west of the Apalachicola and Flint Rivers (fig.24). The eastern boundary is located approximately parallel to ground-water flow paths in the northeastern third of the study area, along the Withlacoochee River and its tributaries in the middle third of the study area, and just east of the Aucilla River at a natural ground-water divide in the lower third of the study area. The southern boundary is located just offshore to simulate diffuse upward leakage to the Gulf of Mexico.

The boundary conditions along the perimeter of the modeled area were either specified head or no flow. Specified-head cells were placed in areas where the potentiometric surface of the Upper Floridan aquifer indicated that ground water could potentiality enter or leave the modeled area due to lateral flow (fig. 24). Specified-head cells were placed west of the Flint River. Specified-head cells were placed in the Gulf of Mexico to simulate diffuse upward leakage of ground water at and near the coastline. The head in these cells was specified at sea level and the placement of the boundary was determined by projecting the onshore gradient offshore to zero. Specified-head cells were placed in two locations on the eastern model boundary. The southern specified heads were used to simulate the flow of ground water out of the model toward large springs located along the Withlacoochee River just outside the modeled area. The northern specified heads were similarly used where the potentiometric surface map indicated possible movement of ground-water out of the modeled area (fig. 16).

The modeled location of rivers that drain ground water from the Upper Floridan are shown in figure 24. A model cell containing a river reach is referred to as a river cell and was assigned a river stage, a river bottom elevation, and riverbed conductance. The volume of water flowing into or out of a river cell is dependent on the difference in altitude between the river stage and simulated head in the aquifer, and on the riverbed conductance. The higher the riverbed conductance, the larger the volume of water that will move between the river and the aquifer per unit head difference. The model input parameter, riverbed conductance, was calculated by the equation:

$$\text{riverbed conductance} = K*L*W / M$$

(McDonald and Harbaugh, 1988)

where:

- K is the vertical hydraulic conductivity of riverbed material (ft per day),
- L is the length of the river reach (ft),
- W is the width of river (ft), and
- M is the thickness of the riverbed material (ft).

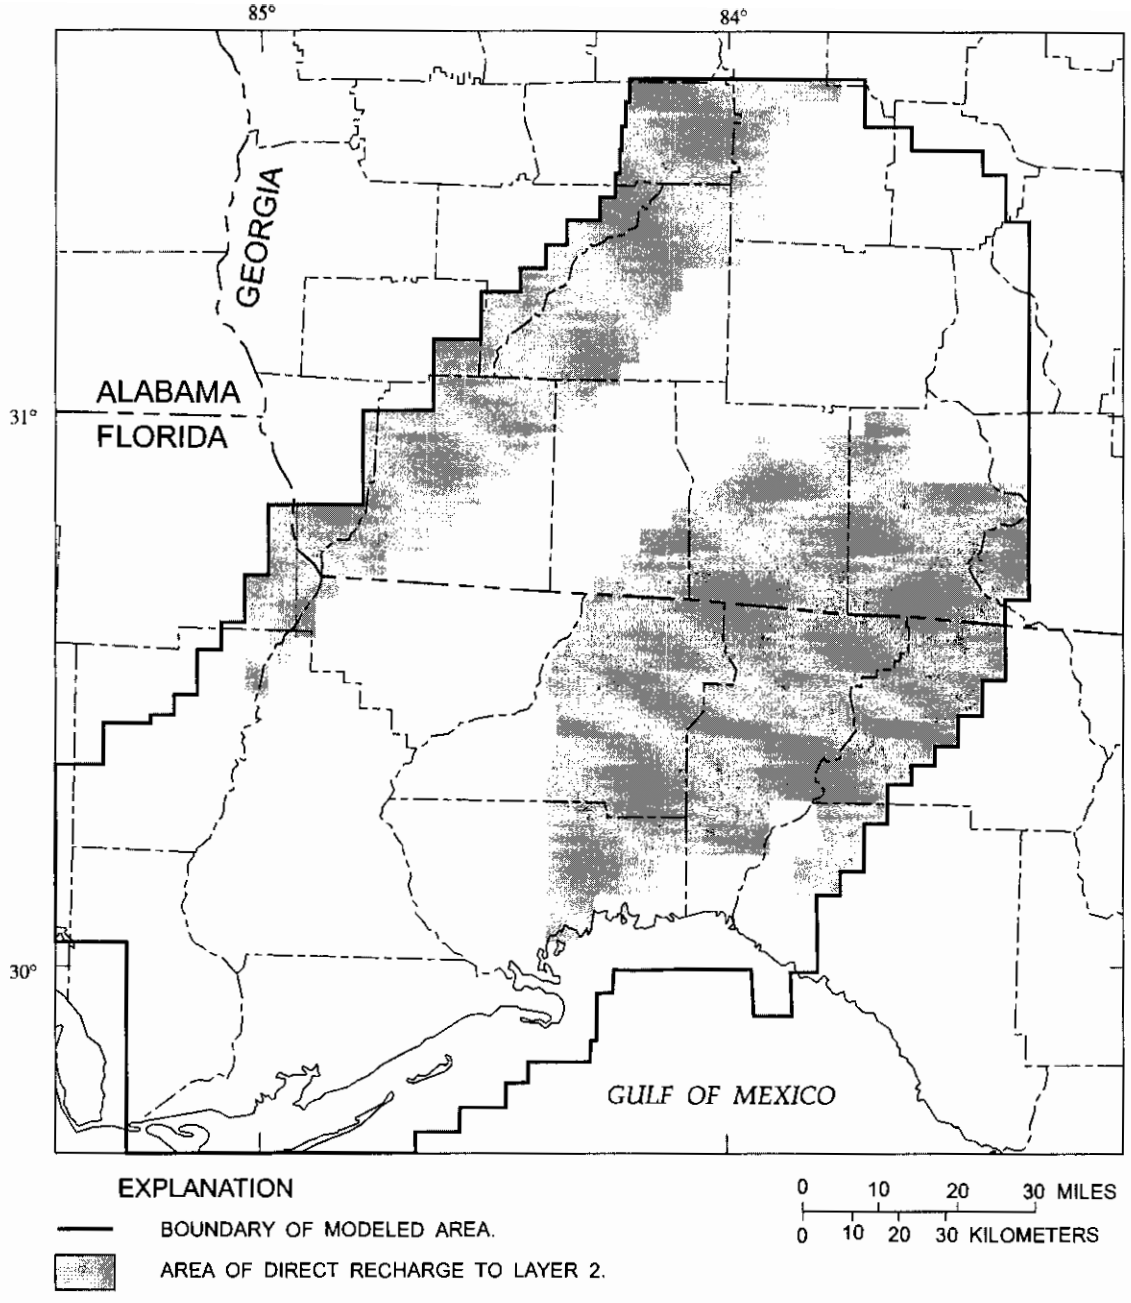

Figure 23. Areas of direct recharge to model layer 2.

Rivers in both the Ocala Uplift and Dougherty Plains are fed by springs. These springs, typically, are the terminal ends of conduit systems that extend for short distances (typically less than 2 miles) into the Upper Floridan aquifer. The riverbed conductances were calculated using a hydraulic conductivity equal to the conductivity of the aquifer material where the river cell resided. Rivers outside the karst areas are separated from the Upper Floridan aquifer by the low-permeability Miocene- and Pliocene-age sediments, do not interact directly with the aquifer, and were not simulated using river cells.

Municipal and industrial pumpage included in the simulation is listed in table 1. Generally,

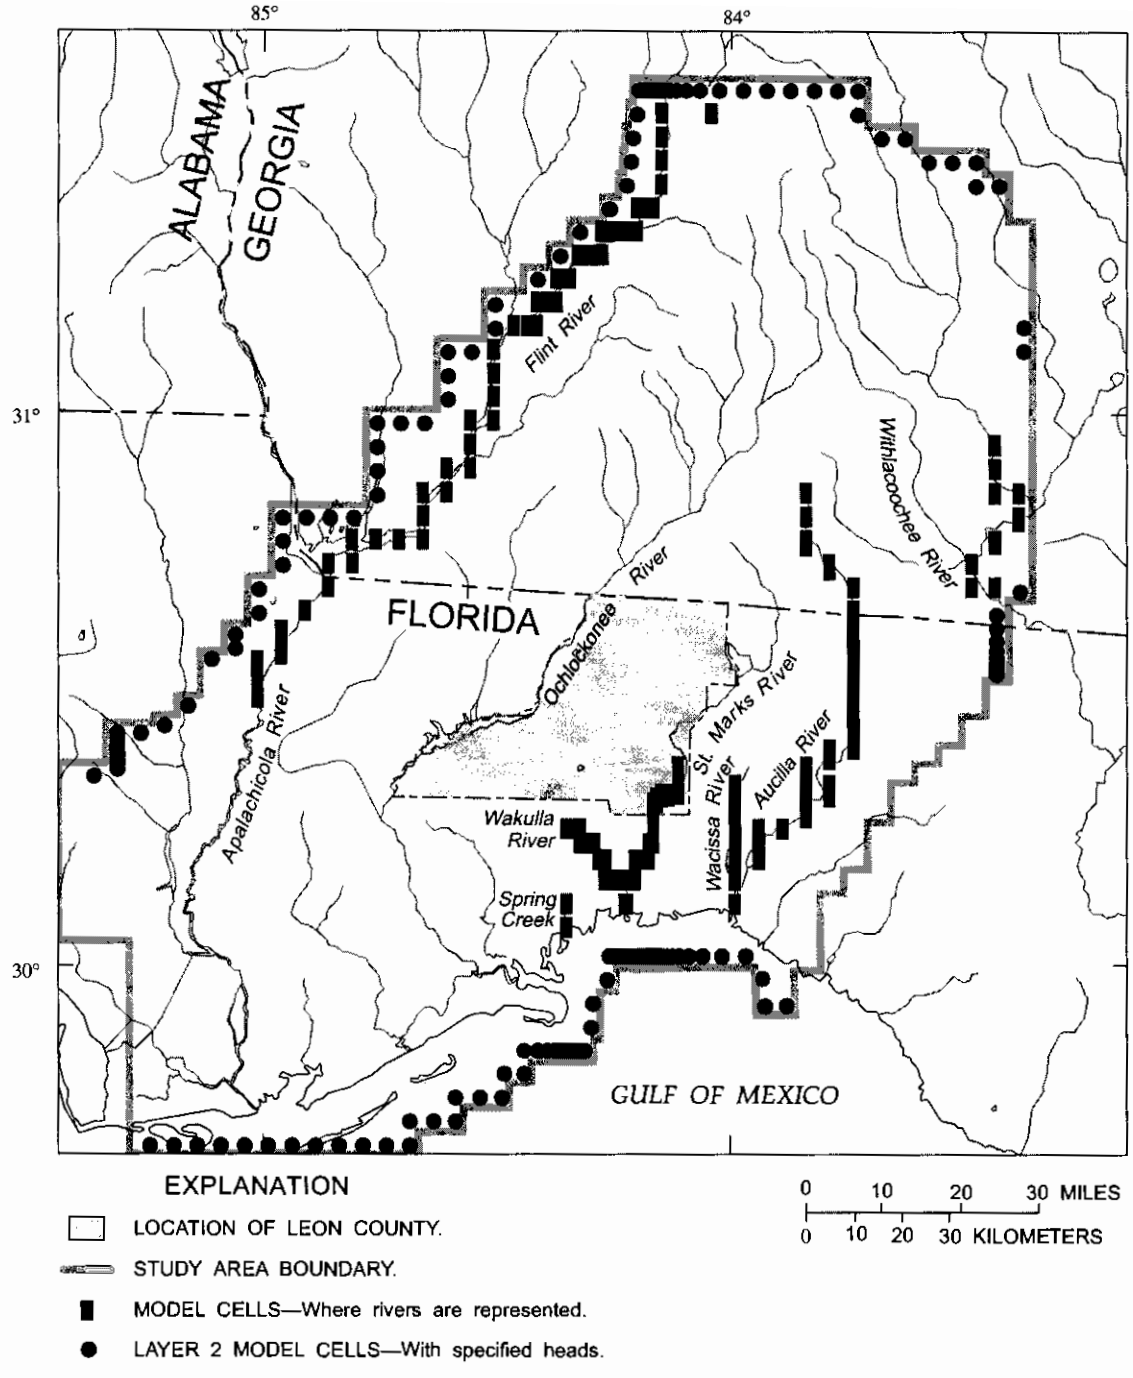

Figure 24. Location of model boundaries, specified-head cells, and cells representing rivers.

only wells at which average pumping is greater than 70 gal/min were included in the simulation; however, wells pumping lower rates were included if the information were readily available. The total pumpage used to calibrate the model was 53,000 gal/min (118 ft^3/s).

Model Calibration

The model calibration process consisted of 1) selecting input parameters, 2) simulating ground-water flow using MODFLOW, 3) comparing simulated heads with measured heads, 4) comparing simulated

river discharges with measured river discharges, and then 5) selecting new values for the input parameters aimed at minimizing the difference between simulated values and measured values. The calibration criteria established for simulated heads was arbitrarily chosen at plus or minus 10 feet of the measured values. The calibration criteria for simulated river gains was established as plus or minus 8 percent of the measured values, which is the accuracy of these measurements. The model was calibrated to the streamflow and water-level conditions observed during late October to early November 1991. Of the 274 water-levels measured to define the potentiometric surface of the Upper Floridan aquifer, 199 were within the boundary of the modeled area.

The input parameters varied during calibration were: transmissivity of the Upper Floridan aquifer, Vcont 1, and direct recharge to layer 2. The parameter Vcont 2 was changed as an artifact of changing the transmissivity of the Upper Floridan aquifer, but it was not independently changed during calibration. Riverbed conductance was recalculated between simulations using the same hydraulic conductivity as the Upper Floridan aquifer. The other input parameters were not varied because they were sufficiently constrained by measured values.

Calibration Results

After calibration, 197 simulated heads were within 10 ft of the 199 measured values and 132 of these were within 5 ft. Simulated and measured heads are compared in figure 25. Simulated and measured river discharge gains are listed in table 3 and shown on figure 26. All simulated river gains were within 6 percent of the measured values and well within the established calibration criteria of 8 percent. The simulated potentiometric surface of the Upper Floridan aquifer is shown in figure 27. Simulated conditions are considered equivalent to long-term average conditions.

The calibration-derived transmissivity distribution of the Upper Floridan aquifer (fig. 28) is the sum of the transmissivities for layers 2 and 3. The sum represents the transmissivity for the entire thickness of the Upper Floridan aquifer. The model-derived transmissivity distribution ranged from less than 5,000 ft^2/d in the region of the Apalachicola Embayment—Gulf Trough to greater than 10,000,000 ft^2/d in the area surrounding the large springs in extreme southern Leon County and west and south of Leon County. The low transmissivity applied to the Apalachicola Embayment—Gulf Trough was necessary to match the rapid potentiometric gradient change in the central and northern parts of the study area and to match the mounding of ground water in western Leon County and Gadsden County. Very high transmissivity values were necessary to match the very low potentiometric gradients in the areas around the large springs. The complex transmissivity distribution applied in and around Leon County was necessary to match the measured potentiometric surface changes which ranged from greater than 80 ft in western Leon County to less than 10 ft in the south.

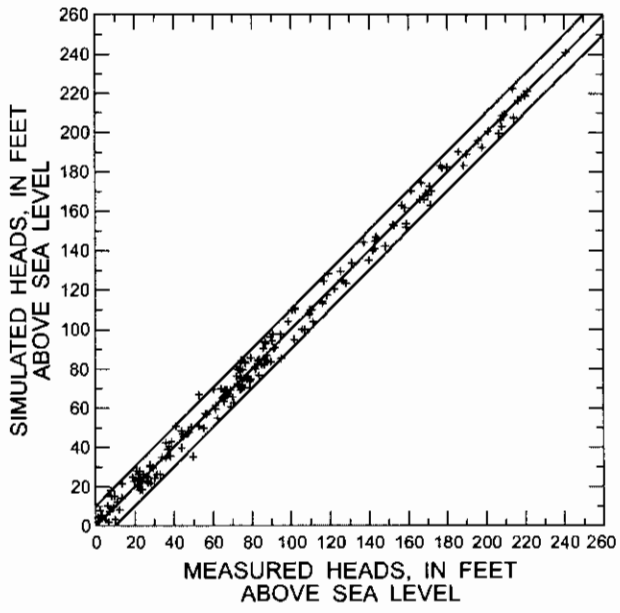

Figure 25. Simulated heads and measured heads.

Table 3. Comparison of measured net river gains, November 1991, and simulated net river gains

[ft^3/s, in cubic feet per second]

River	Measured gain in river reach, in ft^3/s	Model-derived gain in river reach, in ft^3/s	Difference, in percent
Aucilla	61	58	5
Wacissa	319	338	-6
St. Marks	602	601	0
Flint	490	499	-2
Wakulla	350	355	-1
Spring Creek	307	290	6

The calibration-derived vertical hydraulic conductivity distribution of the low-permeability Miocene- and Pliocene-age sediments is shown in figure 29. The vertical hydraulic conductivities were 2.0×10^{-3} ft/d and 2.0×10^{-2} ft/d in the southern part of the study area, 2.0×10^{-6} ft/d in the central part, and

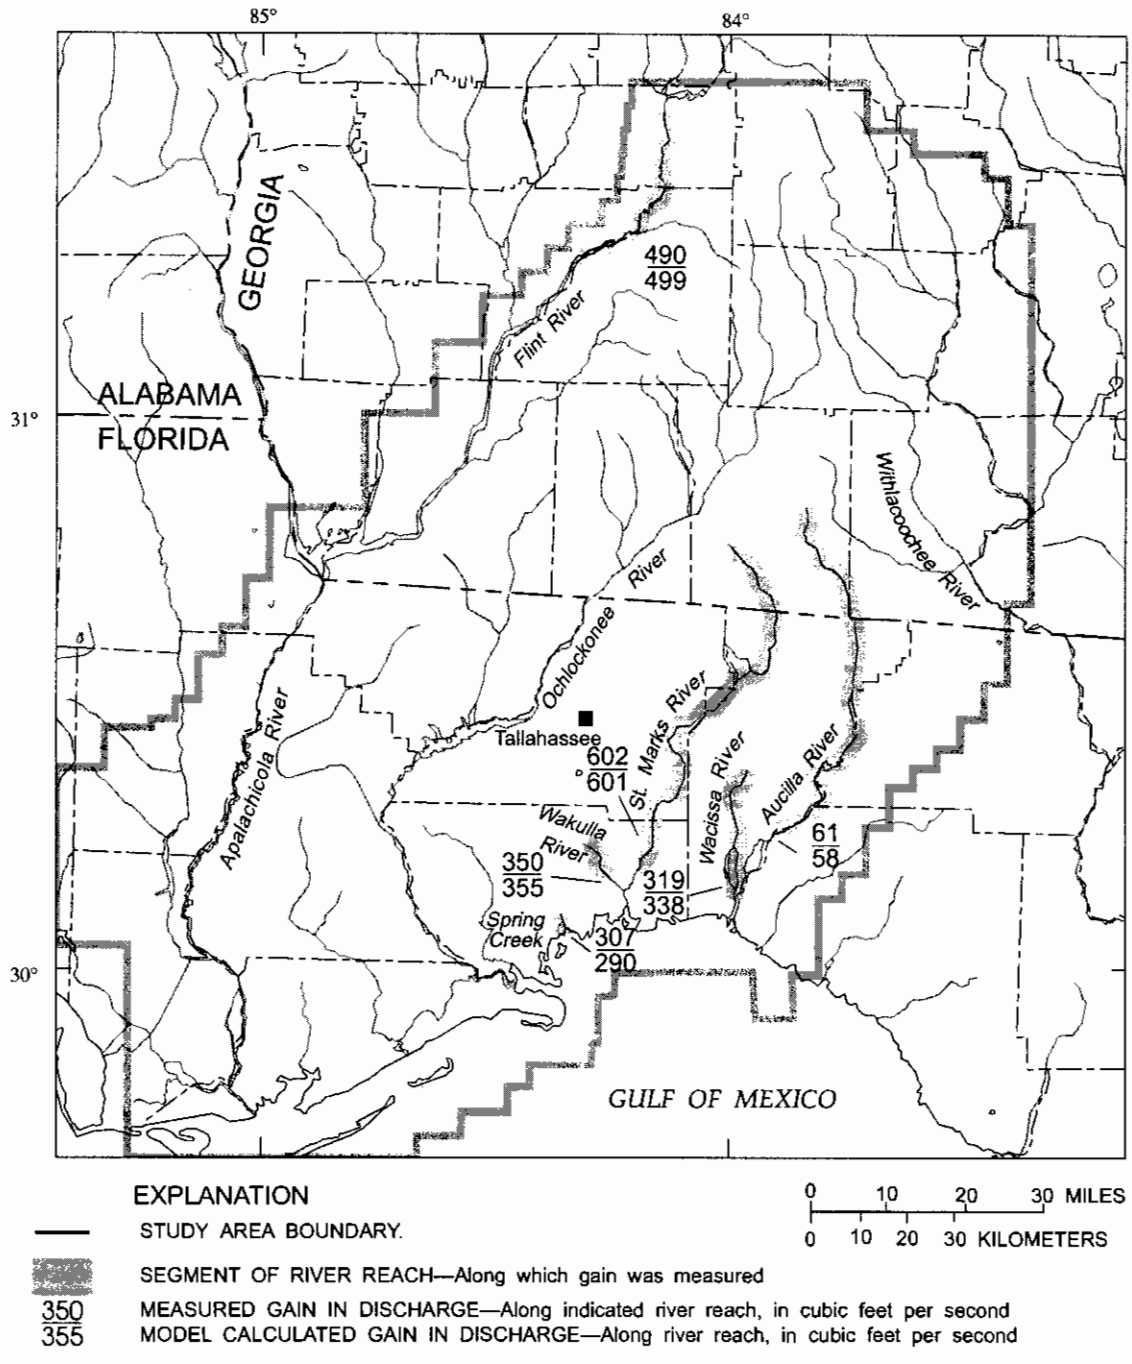

Figure 26. Measured net river gains, November 1991, and simulated net river gains.

7.8×10^{-4} ft/d in the northern part. The variability in the vertical hydraulic conductivity distribution is probably due to changes in the complex lithology of the sediments. In the two narrow zones in the southern part of the study area (darker areas in fig. 29) the vertical hydraulic conductivity is 2.0×10^{-2} ft/d. Rivers are present here, but are separated from the Upper Floridan aquifer by the low-permeability sediments. The relatively high vertical hydraulic conductivity allowed greater upward leakage in the vicinity of these rivers. The upward leakage rates were relatively small, a few cubic feet per second over distances of several miles.

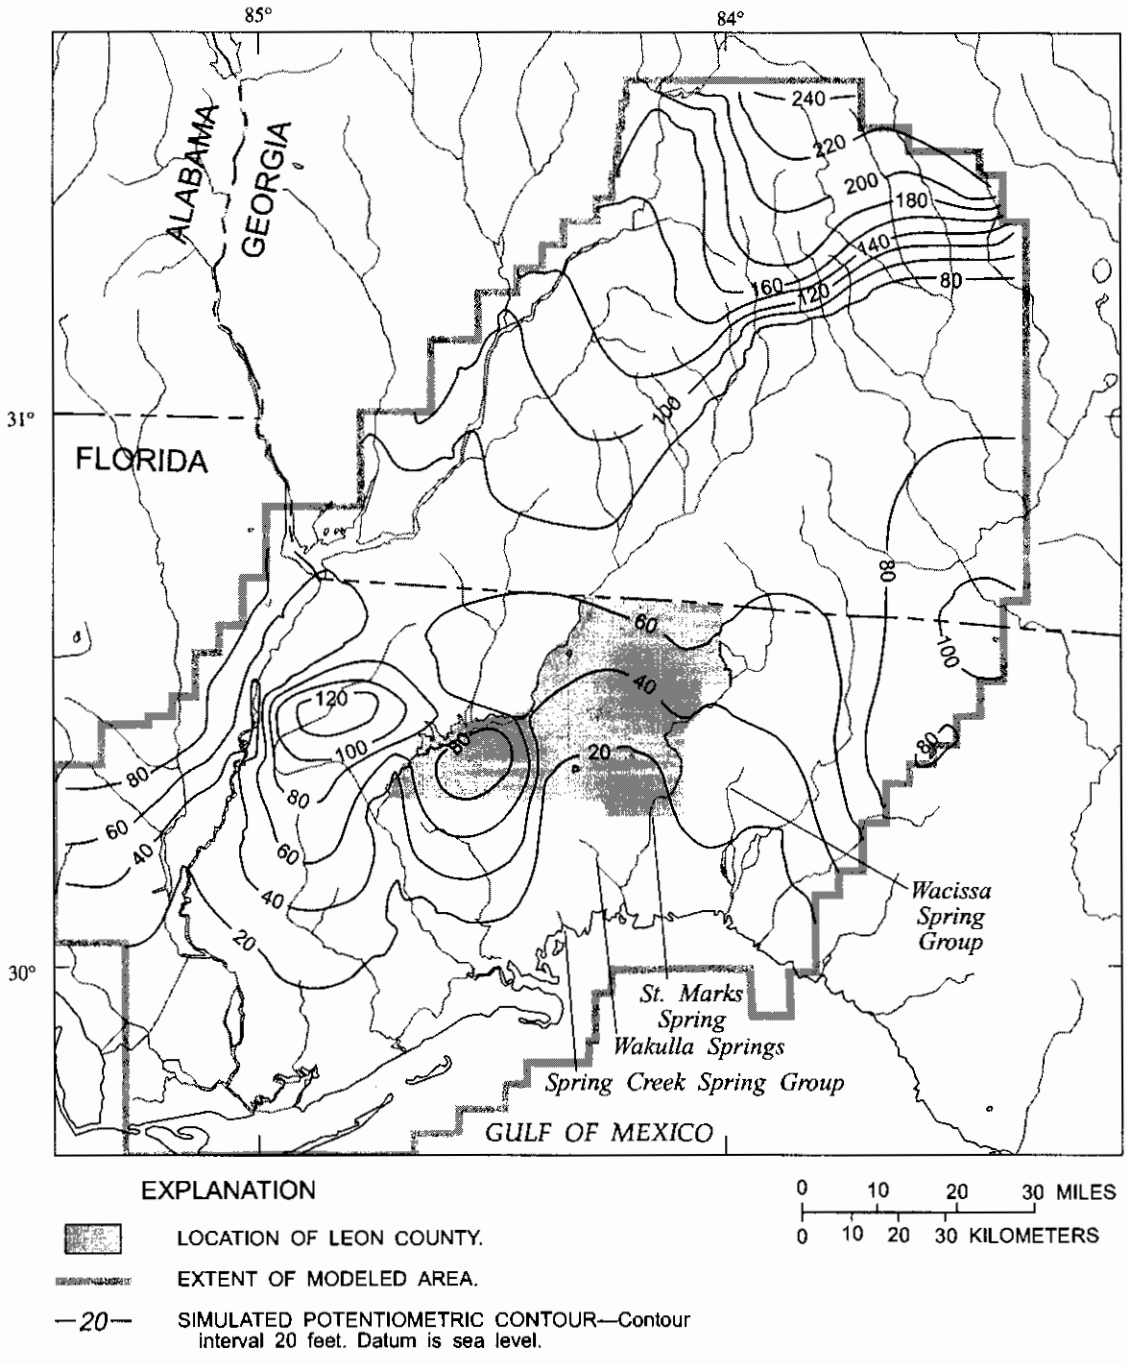

Figure 27. Simulated potentiometric surface of the Upper Floridan aquifer.

However, this leakage was needed to simulate the measured heads in the area. The calibration-derived vertical hydraulic conductivities fall within the range of expected values. The hydraulic conductivity of marine clay ranges from 3×10^{-7} ft/d to 3×10^{-4} ft/d and silt ranges from 3×10^{-4} ft/d to 3 ft/d (Freeze and Cherry, 1979).

The distribution of calibration-derived net recharge and leakage rates are shown in figure 30. The leakage rates between layers 1 and 2 were computed by MODFLOW and were dependent on Vcont 1 and the head difference between the layers. The relatively low rates of leakage were due to the low vertical hydraulic conductivities associated with the thick accumulations of

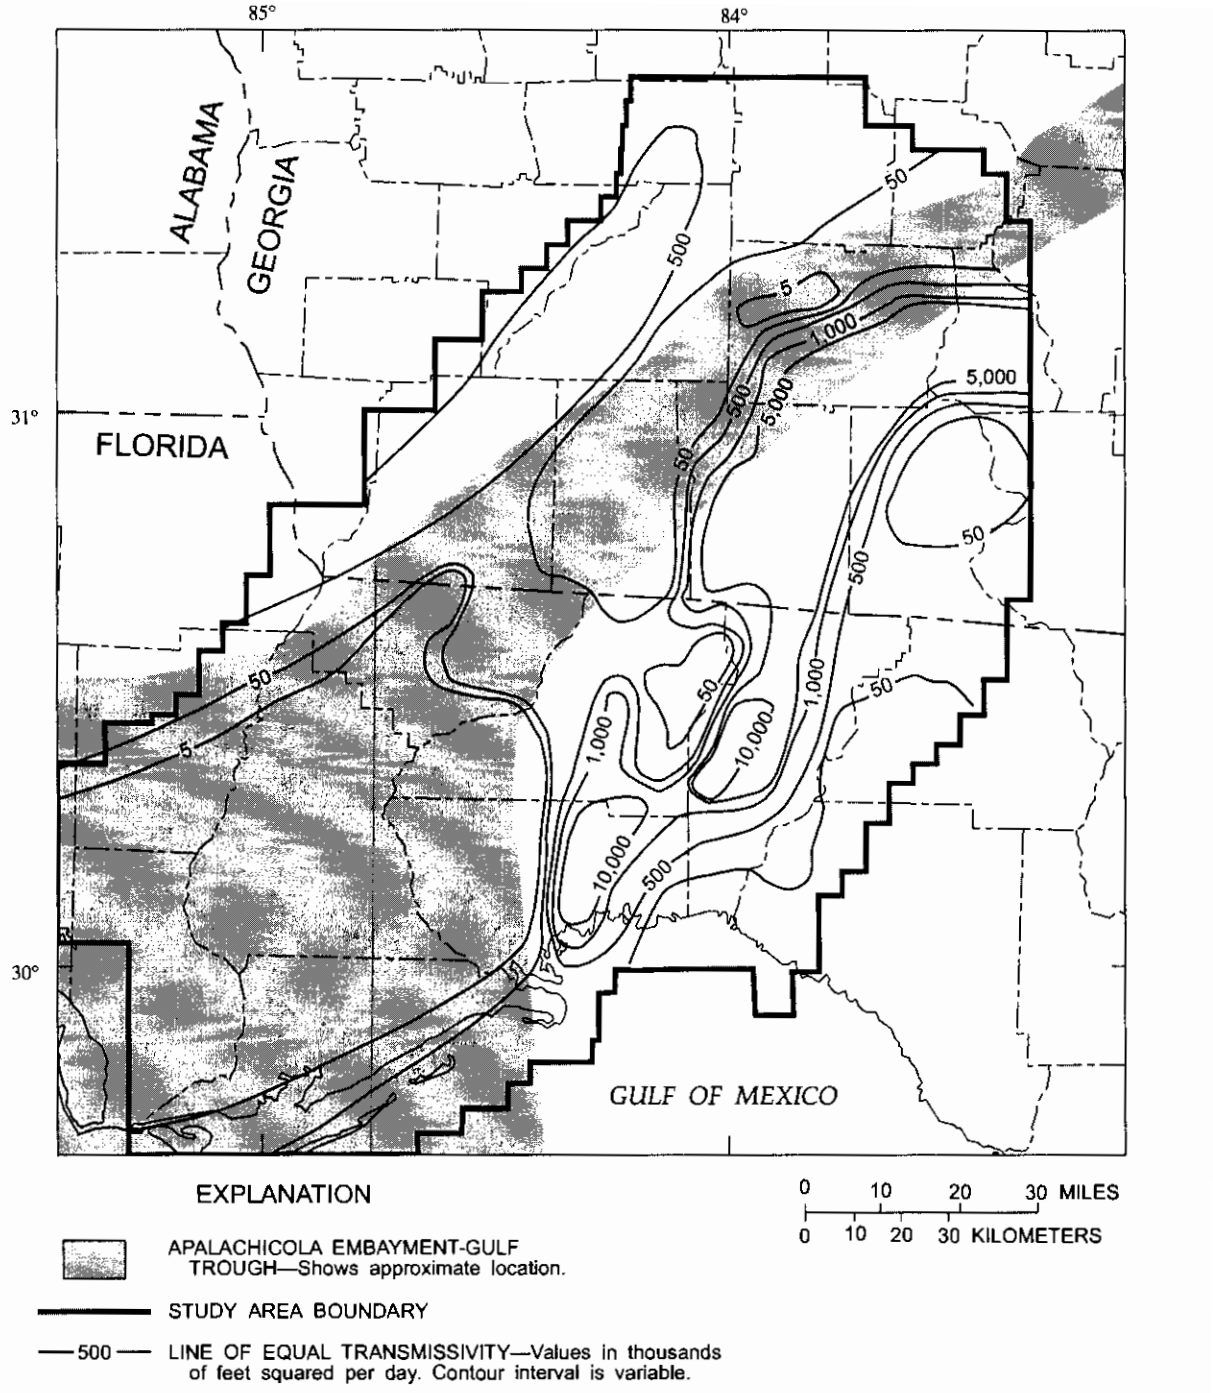

Figure 28. Calibration-derived transmissivities of the Upper Floridan aquifer.

low-permeability sediments in the Apalachicola Embayment - Gulf Trough area. The rates of direct net recharge were higher and occurred in karst areas and where the low-permeability Miocene- and Pliocene- age sediments were relatively thin. The highest rate was 62.0 in/yr and occurred at the Tallahassee wastewater sprayfields. The next highest net recharge rate of 18.0 in/yr occurred in the karst area in and south of Leon County. In this area, the Upper Floridan aquifer is covered by only a thin veneer of sand or directly exposed at land surface. The net recharge rate was 7.5 in/yr in the Dougherty Plain and 7.9 in/yr in most of the Ocala Uplift.

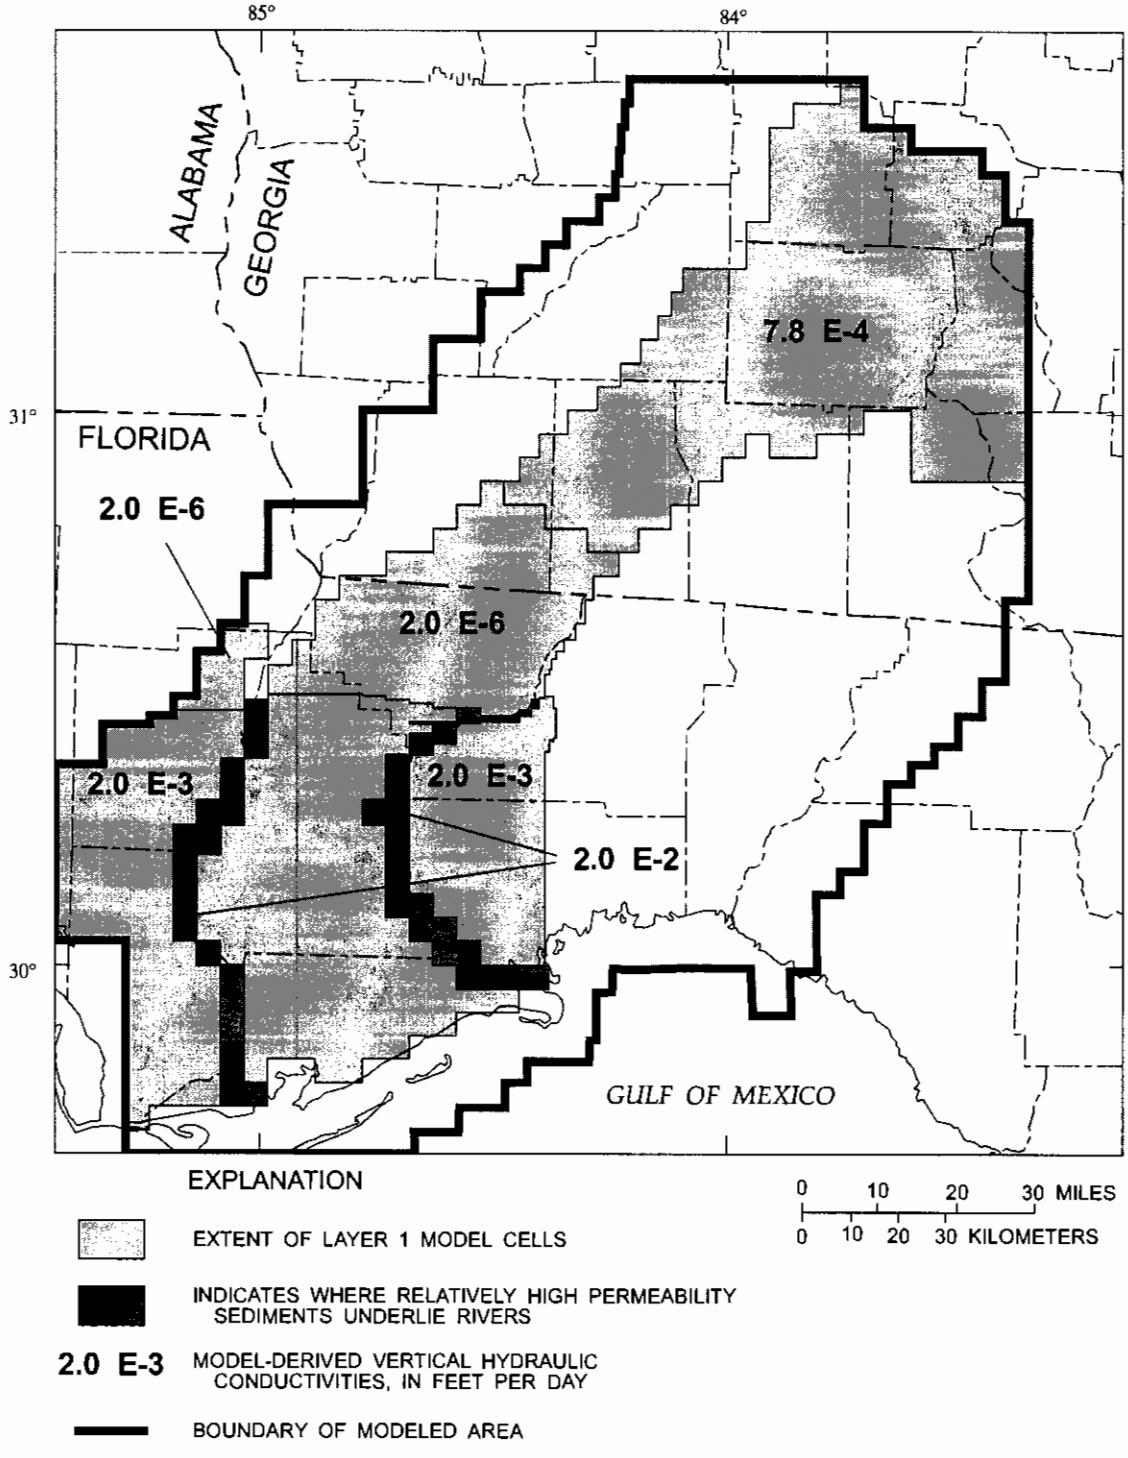

Figure 29. Calibration-derived vertical hydraulic conductivities for layer 1.

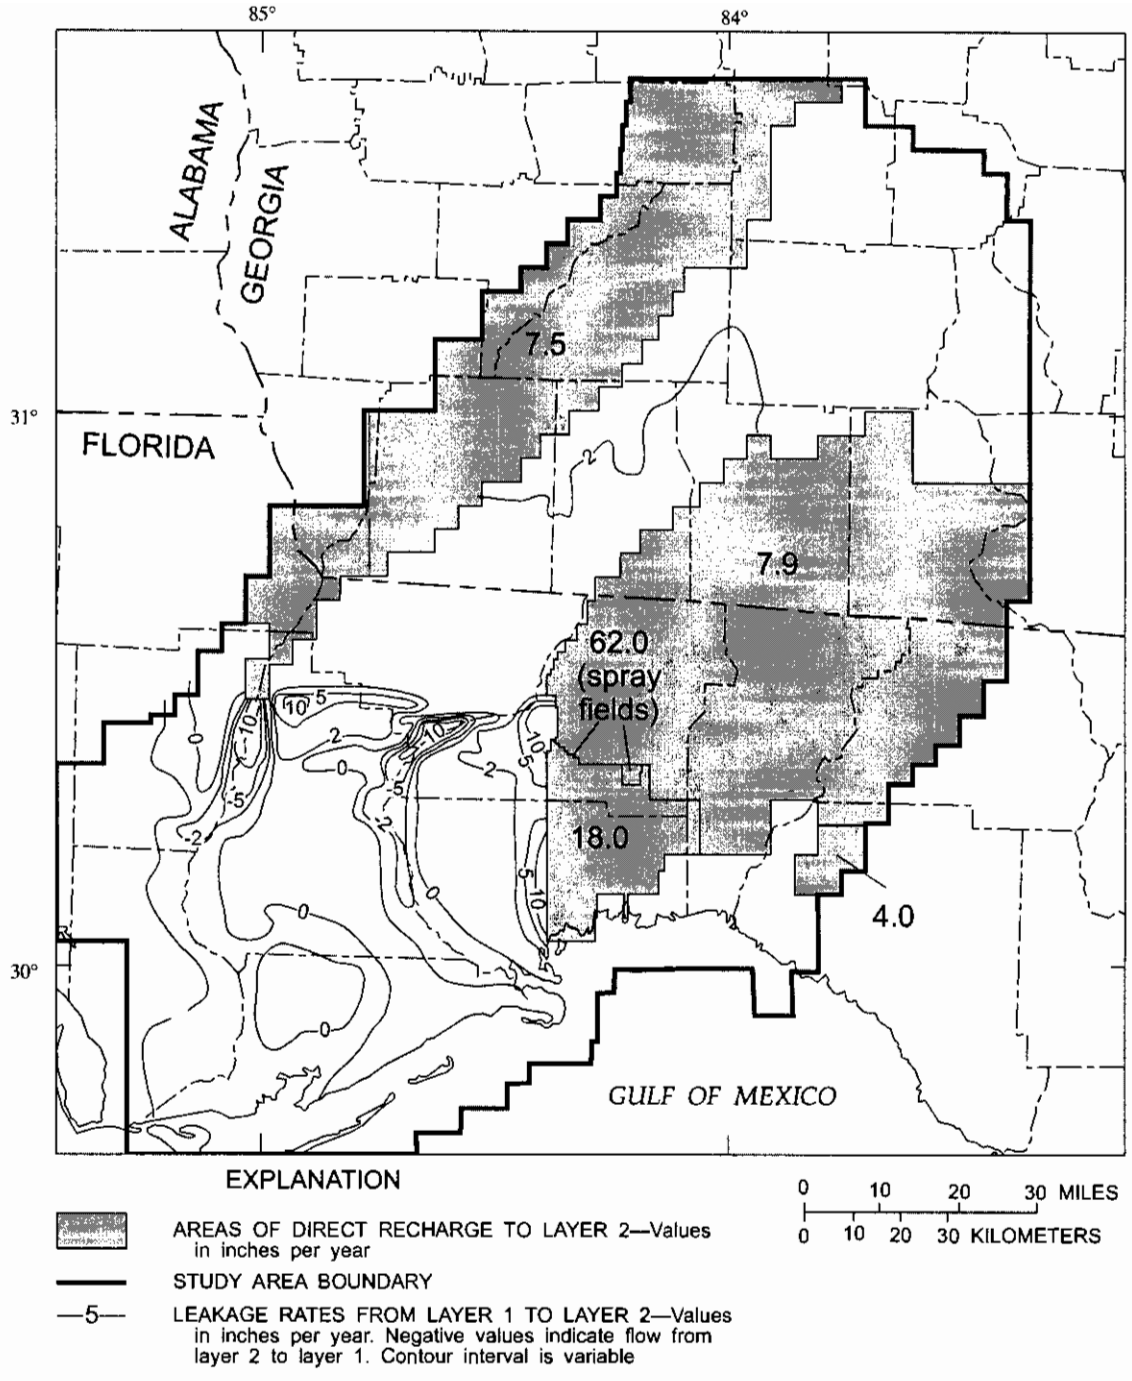

Figure 30. Calibrated leakage and recharge rates to the Upper Floridan aquifer.

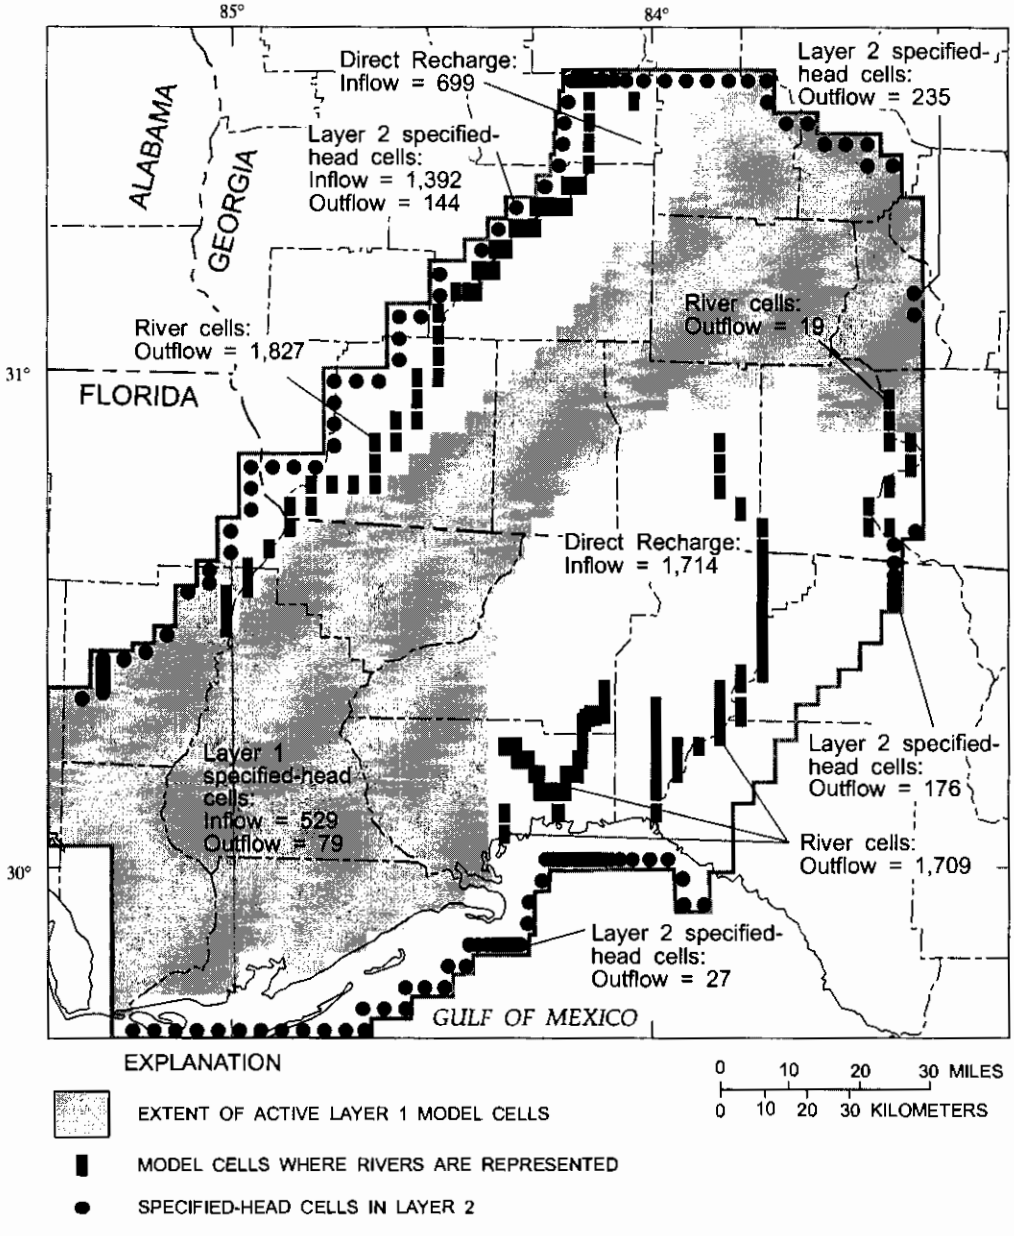
Simulation-Derived Water Budget

The ground-water flow simulation was steady state, so the rate of inflow to the Upper Floridan aquifer in the study area (4,334 ft^3/s) was equal to the outflow. The sources of inflow were: direct net recharge to layer 2 (2,413 ft^3/s), subsurface inflow from specified-head cells in layer 2 (1,392 ft^3/s), and vertical leakage from specified-head cells in layer 1 (529 ft^3/s). The outflows were: subsurface discharge to river cells (3,555 ft^3/s), subsurface outflow to specified-head cells in layer 2 (582 ft^3/s), pumpage (118 ft^3/s), and upward leakage to layer 1 (79 ft^3/s). Ground-water inflows and outflows were summed for subregions of the modeled area (fig. 31). Direct net recharge to layer 2 was the largest source of water to the Upper Floridan

BOUNDARY CONDITION TYPE (Values in cubic feet per second)	INFLOW	OUTFLOW
Direct recharge to layer 2	2,413	0
Leakage from specified-head cells in layer 1	529	79
Flow from specified-head cells in layer 2	1,392	582
River cells	0	3,555
Pumpage	0	118
Total	4,334	4,334



INFLOW = 529 - Rate of inflow to the Upper Floridan aquifer, in cubic feet per second.
OUTFLOW = 79 - Rate of outflow from the Upper Floridan aquifer, in cubic feet per second.

Figure 31. Simulated inflow and outflows in subregions of the study area.

aquifer with 1,714 ft^3/s occurring in the eastern part of the study area and 699 ft^3/s occurring in the Dougherty Plain. The specified-head cells in layer 2, located along the west and north perimeter of the modeled area, provided 1,392 ft^3/s to the aquifer. Almost all of this water later discharged to the Flint River. River cells accounted for most of the ground water discharged, with 1,827 ft^3/s being drained by rivers in the Dougherty Plain and 1,728 ft^3/s by rivers in the southeastern part of the modeled area. The northern set of specified-head cells on the eastern study area boundary drained 235 ft^3/s. The southern set of specified-head cells on the eastern boundary (in the vicinity of the Withlacoochee River) drained 176 ft^3/s. The rate of discharge to the Gulf of Mexico (27 ft^3/s) was relatively low because the large springs in the south-central part of the modeled area effectively drained ground water from the aquifer before it reached the coastline. Upward leakage from the Upper Floridan aquifer to layer 1 (79 ft^3/s) occurred in the southern areas of the Apalachicola Delta District.

Sensitivity Analysis

Sensitivity tests were conducted to assess the response of the calibrated model to a change in one input parameter while the calibrated values of other parameters were unchanged. The input parameters tested were the overall transmissivity of the Upper Floridan aquifer, direct net recharge to layer 2, Vcont 1, Vcont 2, and riverbed conductance. The sensitivity tests were conducted by: 1) changing an input parameter by plus or minus 50 percent from the calibrated value, 2) calculating the number of simulated heads exceeding the error criteria, and 3) comparing the simulated rate of ground-water discharge to rivers with the measured values. The greater the number of heads that exceeded the error criteria (by not being within 10 ft of the measured values) and the larger the difference between simulated-river discharges and measured discharges, the greater the sensitivity of the model to changes in that particular parameter. The results of the sensitivity analysis are listed in table 4.

The model was most sensitive to changes in transmissivity. A decrease in transmissivity of 50 percent caused the number of simulated heads exceeding the error criteria to increase from 2 to 85; simulated ground-water discharge to rivers also fluctuated substantially from the measured values. An increase in transmissivity of 50 percent caused the number of simulated heads exceeding the error criteria to increase to 25.

Table 4. Results of model sensitivity analysis

[trans, transmissivity; Vcont 1, layer 1 vertical conductance; river, river bed conductance; Vcont 2, layer 2 vertical conductance; %, percent]

Parameter changed	Number of cells where the difference between simulated head and measured head exceeded 10 feet	Difference between measured river gain and simulated ground-water discharge, in percent					
		Acuilla River	Wacissa River	St. Marks River	Flint River	Wakulla River	Spring Creek
Calibrated	2	-4	6	0	2	1	5
Trans - 50 %	85	--	29	--	--	--	--
Trans + 50 %	25	--	--	19	--	--	--
Vcont 1 - 50 %	14	-7	-2	2	-3	-2	-7
Vcont 1 + 50 %	18	-3	13	1	6	4	-4
Recharge - 50 %	28	--	--	--	20	--	--
Recharge + 50 %	35	--	--	--	--	--	--
River - 50 %	3	-13	8	-5	1	10	-6
River + 50 %	3	-2	5	2	2	-2	6
Vcont 2 - 50 %	3	--	7	--	--	--	--
Vcont 2 + 50 %	3	--	6	--	--	--	--

The model also was sensitive to changes in direct recharge to layer 2. A decrease in recharge of 50 percent caused the number of simulated heads exceeding the error criteria to increase from 2 to 28. The corresponding simulated ground-water discharge to rivers decreased substantially compared to the measured values. An increase in recharge of 50 percent caused the number of simulated heads exceeding the error criteria to increase to 35 and the simulated ground-water discharges to rivers increased substantially compared to the measured values. Simulations were sensitive to recharge rate because it is the largest source of water to the Upper Floridan aquifer.

Another source of water to the Upper Floridan aquifer was leakage from layer 1. A decrease in Vcont 1 of 50 percent caused the number of simulated heads exceeding the error criteria to increase from 2 to 14; an increase of 50 percent caused the number of simulated heads exceeding the error criteria to increase to 18. Simulated ground-water discharge to rivers did not fluctuate significantly from the measured values because leakage from layer 1 was not a substantial part of the overall water budget.

The model was not sensitive to changes in the riverbed conductance. Both an increase and decrease of 50 percent caused the number of simulated heads exceeding the error criteria to increase from 2 to 3. Simulated ground-water discharge to rivers was only slightly different than the measured values. The riverbed conductances were relatively high because they were calculated using the same hydraulic conductivity as the Upper Floridan aquifer (for reasons discussed earlier). With these high conductances, the simulated volume of ground water leaking into the rivers was controlled by the potentiometric gradients in the surrounding aquifer and not the riverbed conductance. Overall changing the riverbed conductance by plus or minus 50 percent did not greatly affect the simulation results.

The model also was not sensitive to changes in Vcont 2. A decrease of 50 percent caused the number of simulated heads exceeding the error criteria to increase from 2 to 3; an increase in Vcont 2 of 50 percent caused no change in the number of simulated heads exceeding the error criteria. Simulated ground-water discharges to rivers were not substantially different than the measured values. Vcont 2 values were calculated using a vertical hydraulic conductivity equal to the horizontal hydraulic conductivity (for reasons discussed earlier) resulting in relatively high values. The high Vcont 2 values allowed water to move easily from layer 2 to layer 3, and changing this value by plus or minus 50 percent did not sufficiently restrict the movement of water to affect the ground-water flow simulation.

PARTICLE-TRACKING ANALYSIS OF CONTRIBUTING AREAS

The calibrated model was used in combination with the post-processing-program MODPATH (Pollock, 1989) to delineate the contributing areas of five City of Tallahassee water-supply wells. The five wells were chosen because their locations span the range of transmissivities present in the Tallahassee area (fig. 32). Table 5 lists the characteristics of the wells, including the depth, open-hole interval, pumping rate, and relation of well depth and open-hole interval to the thickness of the Upper Floridan aquifer. All of the wells listed partially penetrate the aquifer, and the percent of penetration ranges from 19 percent for well 12 to 28 percent for well 23. The contributing areas were delineated assuming steady-state flow conditions. In reality, the City of Tallahassee operates its wells as needed to meet demand. Only one well was modeled at a time, thus the effects of well interference were not simulated.

Procedure for Delineation of Contributing Areas

The post-processing program MODPATH uses the intercell flow rates (the flow rate at the face of each cell in the model) calculated by MODFLOW to compute ground-water flow directions and velocities. The contributing area to a water-supply well was delineated by "seeding" the simulated pumping well location with particles and then tracking the particles backward toward areas of recharge. Particle tracking was arbitrarily stopped at a time-of-travel of 5 years, thus the time-related contributing area is a fraction of the overall contributing area. The contributing area includes only the time-of-travel within the Upper Floridan aquifer. The time-of-travel of a water particle from land surface, through the water-table aquifer and the low-permeability Miocene- and Pliocene-age sediments, was not included. MODPATH requires the same input parameters as MODFLOW and, additionally requires that porosity be specified for each active

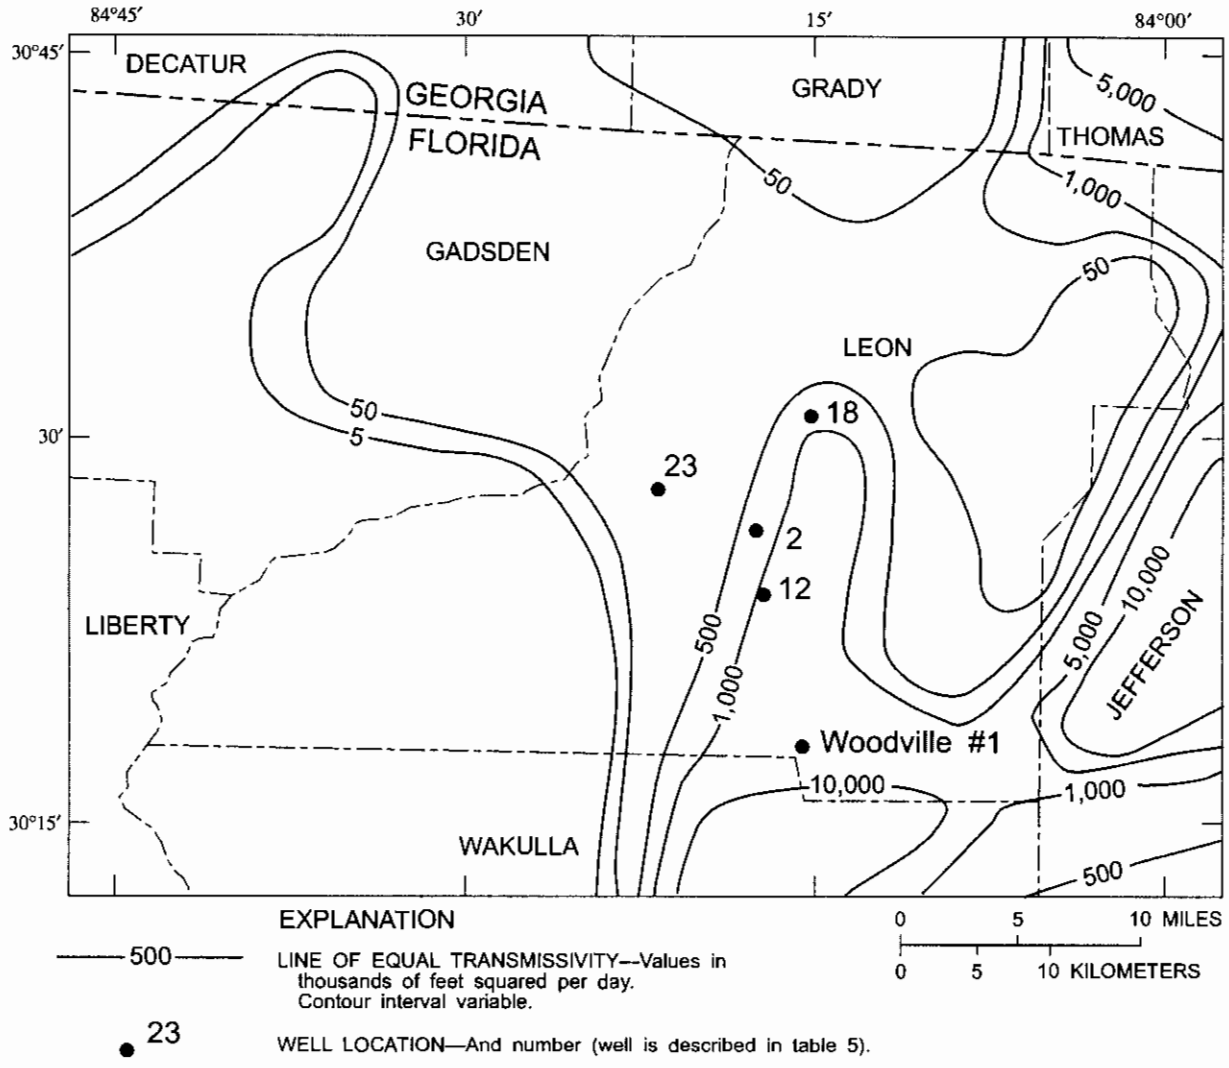


Figure 32. City of Tallahassee, Fla., water-supply wells for which contributing areas were delineated.

cell. The porosity is necessary for the calculation of ground-water velocity.

Porosity within the Upper Floridan aquifer is variable and the distribution is not accurately known. For this reason, the contributing areas were delineated twice, using porosities of 25 and 5 percent. The 25 percent porosity represents an approximate average value for the total porosity in a limestone. The porosity of 5 percent represents only the void space present in interconnected zones created by the dissolution of limestone along bedding planes and fractures. These interconnected zones would have a much higher permeability than the other, much larger, fraction of the aquifer that had not undergone dissolution. A pumping well would draw most of its water from the high-permeability zones where the resistance to ground-water flow is less than the remainder of the aquifer, which would be largely bypassed. The 5 percent porosity is not intended to represent the total porosity present in the Upper Floridan aquifer, but instead represents an estimate of the effective porosity where dissolution has occurred.

The contributing area for a 5 percent porosity is always much larger than the contributing area for a 25 percent porosity. For a lower porosity, the well has to draw water from greater distances to meet the pumping rate because there is less water per unit volume of aquifer. The contributing areas in Leon County are generally elliptical in shape, which reflects the influence of the slope of the potentiometric surface.

Simulated Contributing Areas

The two simulated contributing areas delineated for Tallahassee well 23 are shown in figure 33. The transmissivity in the vicinity of this well is about 100,000 ft^2/d, which is the lowest of the five wells (fig. 32). The pumping rate was 3,800 gal/min. This well penetrates approximately the upper 28 percent of the aquifer. However, because of the relatively low transmissivity and high pumping rate, ground water is drawn from the total thickness of the aquifer (fig. 34). The average ground-water velocity within the contributing area was 1.0 ft/d assuming a 25 percent porosity and 2.4 ft/d assuming a 5 percent porosity.

The two contributing areas simulated for the City of Tallahassee well Woodville 1 are shown in figure 35. The transmissivity in the vicinity of this well is about 10,000,000 ft^2/d, the highest of all the wells. The pumping rate was 575 gal/min. This well penetrates approximately the upper 21 percent of the aquifer. However, ground water is drawn from about the upper 25 percent of the aquifer (fig. 36), because of the high transmissivity and low pumping rate. The average ground-water velocity within the contributing area was 1.6 ft/d assuming a 25 percent porosity, and 7.4 ft/d assuming a 5 percent porosity.

The simulated contributing areas for wells 2, 12 and 18 are shown in figures 37, 38, and 39, respectively. The transmissivities at these wells are intermediate to that of the two wells previously discussed. The transmissivities at wells 2 and 12 are about 1,000,000 ft^2/d and the transmissivity at well 18 is about 750,000 ft^2/d. The pumping rates were 2,050 gal/min for well 2, 3,000 gal/min for well 12, and 2,900 gal/min for well 18. The ground-water velocities within the contributing areas of these wells were between those of well 23 and Woodville 1.

Comparison of Simulated and Analytically Derived Contributing Areas

Contributing areas to pumping wells can also be computed using analytical methods. This methodology is quick compared to the numerical modeling approach; however, the analytical method does not have the flexibility to incorporate a variety of hydrologic conditions. For this reason, simplifying assumptions about the aquifer must be made. For the purpose of comparison, the maximum upgradient width of the contributing area for each of the five Tallahassee wells was determined analytically and compared to the width delineated by particle tracking. The equation used to calculate the contributing area widths was (modified from Todd, 1980):

$$Y_L = Q / T\,i \qquad (3)$$

where:

- Y_L is the upgradient maximum width of the contributing area (ft),
- Q is the discharge rate of the well, (ft^3/s),
- T is transmissivity (ft^2/d), and
- i is the slope of the water table (dimensionless).

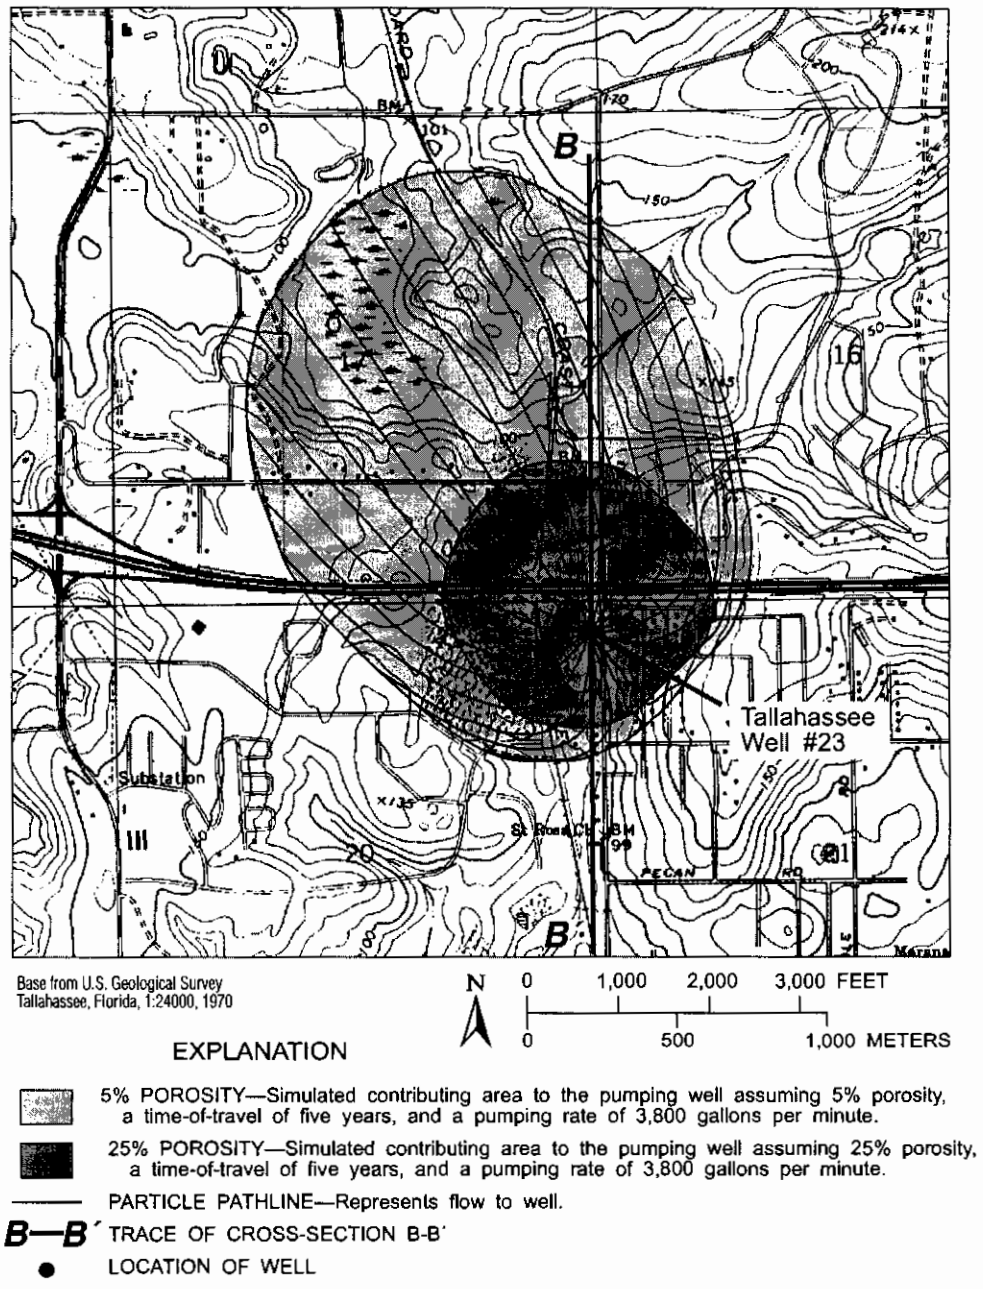

Figure 33. Simulated contributing areas to City of Tallahassee well 23.

This equation is commonly used to calculate contributing areas where a sloping water table is present (U.S. Environmental Protection Agency, 1987). The simplifying assumptions made when using this equation are: steady-state flow conditions, uniformly sloping potentiometric surface, constant pumping rate, uniform constant transmissivity, and a fully penetrating well. Over relatively small areas of 1 to 2 mi^2 within the Tallahassee area, all of these simplifying assumptions are probably valid except the last one.

Simulated and analytically derived contributing-area widths are listed in table 6. The analytically derived width for well 23 was 7,536 ft and the model-derived width was 7,500 ft. These values compare closely because well 23 draws water from the full thickness of the aquifer (even though the well was not fully penetrating, as discussed earlier). The analytically derived contributing-area width for Woodville 1 was 161 ft and the model-derived width was 900 ft. For this well, the analytical equation underestimates

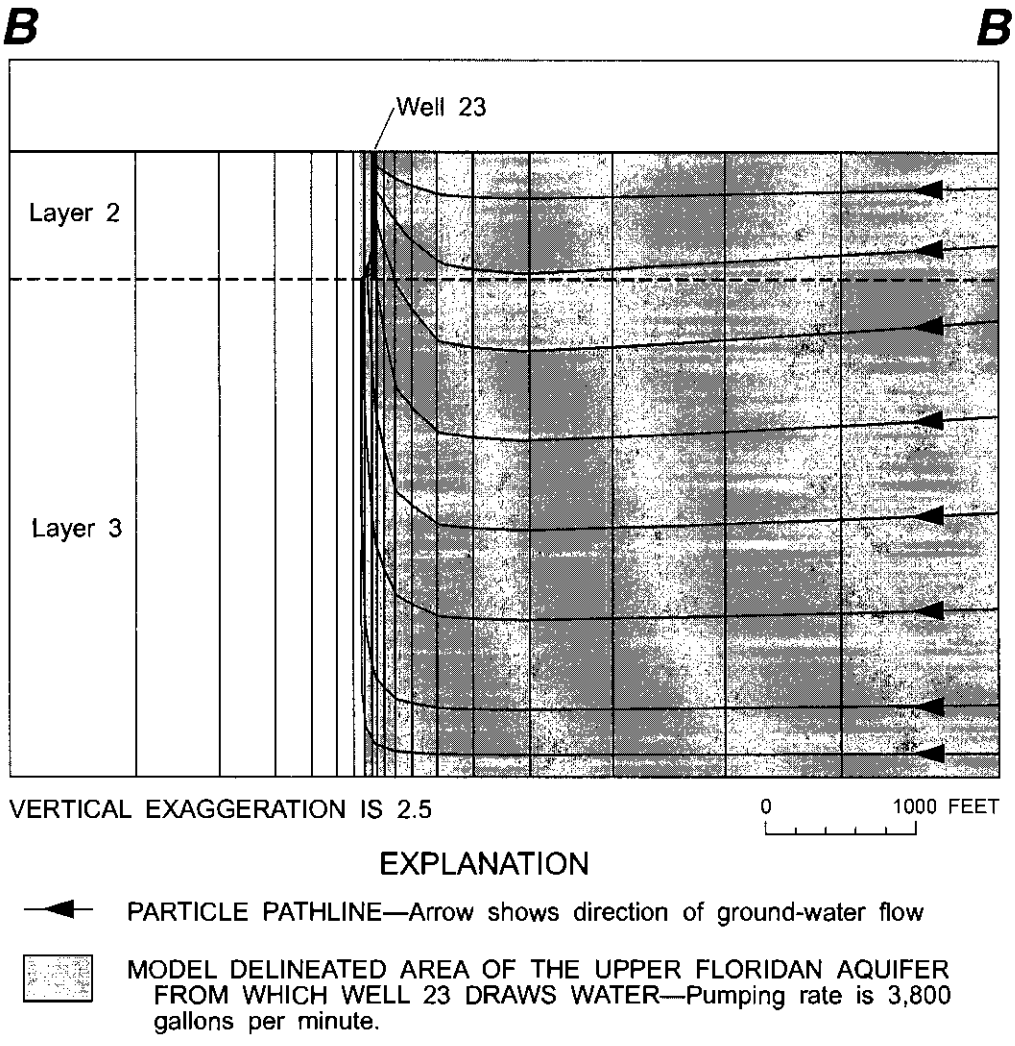

Figure 34. Particle pathlines showing the extent of the Upper Floridan aquifer from which City of Tallahassee well 23 draws water (line of section shown on figure 33).

the width of the contributing area because it assumes that ground water is drawn from the full thickness of the aquifer. The numerical model, which was able to simulate the well as partially penetrating, determined a shallower, wider contributing area which is more accurate. The vertical extent of the aquifer from which wells 2, 12, and 18 drew water was intermediate between those of well 23 and Woodville 1. Thus the differences between the simulated widths and the analytically derived widths were also intermediate between these two wells.

Determination of the contributing areas by model simulation is a more accurate method than analytical approaches because complex, three-dimensional aquifer characteristics can be incorporated into the solution. However, if the characteristics of a particular aquifer match the assumptions of the analytical methods, then these methods could produce good results for considerably less effort. The complexity of the ground-water system must be assessed to determine whether contributing areas should be calculated using numerical ground-water flow models or by simpler analytical methods.

SUMMARY AND CONCLUSIONS

Ground water from the Upper Floridan aquifer is the source of water supply for Tallahassee, Fla., and for many parts of the surrounding area. In most areas, the aquifer yields an ample supply of good quality water; however, in recent years low levels of tetrachloroethylene (PCE) have been detected in ground-water samples taken from seven City of Tallahassee water-supply wells. The PCE is attributed to past disposal practices of dry cleaners, service stations, and other businesses within the downtown area. The City of Tallahassee removes PCE from the water by passing it through granular-activated carbon units before distribution. To ensure that water-supply wells, presently free of contamination, remain clean, it is necessary to understand the ground-water flow system in sufficient detail to protect the contributing areas. The contributing area of a pumping well is the land area that has the same horizontal extent as that part of the aquifer from which ground-water flow is diverted. To gain an understanding of the ground-water flow system, a 4-year investigation of the Upper Floridan aquifer was conducted. The study area was centered in Leon County, Fla., and extended to surrounding counties in north-central Florida and southwestern Georgia.

The study area is underlain by sedimentary rocks of Tertiary through Quaternary age that consists of limestone, dolostone, clay, and sand of varying degrees of lithification. Aquifers in the study area include the water-table aquifer and Upper Floridan aquifer, which are separated by low-permeability sediments. The water-table aquifer yields only small amounts of water when pumped and generally is not used. The Upper Floridan aquifer is utilized for municipal, industrial, agricultural, and domestic water supply. The transmissivity of the Upper Floridan aquifer ranges over several orders of magnitude.

The potentiometric surface of the Upper Floridan aquifer was defined by measuring ground-water levels in a network of 274 wells. The rate of ground-water discharge from the Upper Floridan aquifer to rivers was quantified by measuring river-discharge rates in area rivers. One aquifer test was conducted that determined a transmissivity of 1,300,000 ft^2/d for the Upper Floridan aquifer in downtown Tallahassee.

A conceptual model describing ground-water flow was developed to aid in building a computer model that accurately simulates ground-water flow. The Upper Floridan aquifer is conceptualized as having the following characteristics: ground-water flow is at steady state; the aquifer acts as a single water-bearing unit; and recharge is by precipitation and discharge occurs as spring flow, leakage to rivers, leakage to the Gulf of Mexico, and pumpage. The recharge area for ground-water moving beneath Leon County extends to counties to the west and north.

Steady-state ground-water flow in the Upper Floridan aquifer was simulated using the USGS modeling software MODFLOW. The model was calibrated to hydrologic data collected from late October to early November 1991. The model grid consisted of 176 rows, 162 columns, and 3 layers with 28,512 model cells per layer. Cell size was variable with the smallest cells being near the center of the study area and larger cells being near the perimeter. Row and column spacing was chosen so that water-supply wells, in which contributing areas were to be determined, would be positioned in the smallest model cells. The smallest cells are 30 ft on each side and the largest cells are 3 mi on each side.

The calibrated model was used in combination with the post-processing program MODPATH to simulate the contributing areas of five Tallahassee water-supply wells. The five wells were chosen because their locations spanned the range of transmissivities present in the Tallahassee area. All of the wells partially penetrated the aquifer and penetration ranged from 19 to 28 percent. The contributing area was delineated by "seeding" the simulated pumping well location in the model with particles and then tracking the particles backward toward areas of recharge.

Porosity within the Upper Floridan aquifer is variable and the distribution not accurately known. For this reason, the contributing areas were simulated twice, using a porosity of 25 and 5 percent. The

Hydrogeology and Analysis of Aquifer Characteristics in West-Central Pinellas County, Florida

Hydrogeology and Analysis of Aquifer Characteristics in West-Central Pinellas County, Florida

By James C. Broska *and* Holly L. Barnette

ABSTRACT

The U.S. Geological Survey, in cooperation with Pinellas County, Florida, conducted an investigation to describe the hydrogeology and analyze the aquifer characteristics in west-central Pinellas County. A production test well and four monitor wells were constructed in Pinellas County at Walsingham Park during 1996-97. Water-quality sampling, static and dynamic borehole geophysical surveys, and hydraulic tests were conducted at the wells to delineate the hydrogeology at Walsingham Park. A 9-day aquifer test was conducted to determine the hydraulic characteristics of the aquifer system and observe the changes in water quality due to pumping.

A numerical model was constructed to simulate the aquifer test and calculate values for hydraulic conductivity and storage coefficient for permeable zones and confining units at Walsingham Park. Final calibrated values for hydraulic conductivity for the different permeable zones and confining units at the test site were 18 feet per day for Upper Zone A, 750 feet per day for Lower Zone A, 1 foot per day for Zone B, $1x10^{-4}$ feet per day for the intermediate confining unit, and 10 feet per day for the semiconfining unit separating Upper Zone A and Lower Zone A. Final calibrated values for storage coefficient were $3.1x10^{-4}$ for Upper Zone A, $8.6x10^{-5}$ for Lower Zone A, $2.6x10^{-5}$ for Zone B, $3.1x10^{-4}$ for the intermediate confining unit, and $4.3x10^{-5}$ for the semiconfining unit separating Upper Zone A and Lower Zone A. Estimates of transmissivity for Upper Zone A and Lower Zone A were about 2,500 and 37,500 feet squared per day, respectively.

INTRODUCTION

Pinellas County, located in west-central Florida, has limited potable water supplies and is dependent on water delivered from Tampa Bay Water (formerly called the West Coast Regional Water Supply Authority) which withdraws water from neighboring inland counties to meet the water demands of a large population. Although the population of Pinellas County has not increased significantly since 1990, during the period from 1970 to 1990 the population of Pinellas County increased from 552,329 to 851,659 (University of Florida, 1991). In 1990, the county received a total of 78 Mgal/d of water from Hillsborough and Pasco Counties (Marella, 1992). To alleviate some of the demand for this delivered water, Pinellas County is exploring the possibility of using the brackish-water resources within the Upper Floridan aquifer underlying the county.

Brackish waters (water with dissolved-solids concentrations between 1,000 and 10,000 mg/L) are found in the Upper Floridan aquifer at depths ranging from about 100 to 400 ft below land surface in central Pinellas County (Cherry and others, 1970). The development of these brackish-water resources through low-pressure reverse osmosis could provide a source of potable water. Low-pressure reverse osmosis is a process of forcing water through a membrane to remove dissolved solids, thus purifying the water; however, the process is economically practical only when dissolved-solids concentrations are less than 7,000 mg/L (D. Slonena, Pinellas County Utilities, written commun., 1998).

A production test well and four monitor wells were constructed in 1996-97 at Walsingham Park in west-central Pinellas County. The wells were subjected to various geologic investigation methods to determine the hydrogeology at the test site and the viability of brackish-water development in the area.

Purpose and Scope

This report presents the results of a study by the U.S. Geological Survey (USGS), in cooperation with Pinellas County, to evaluate the brackish-water resources underlying the Walsingham Park study area in west-central Pinellas County. Results from the field investigation and numerical simulation to determine aquifer characteristics at the Walsingham Park test site could provide valuable information for future development of brackish water in Pinellas County and in other coastal counties in west-central Florida. The report includes: descriptions of the hydrogeologic framework of the study site, hydraulic characteristics of the aquifer system, and description of the ground-water quality.

The objectives of this report are to
1.) describe the hydrogeology at the test site, and
2.) evaluate an aquifer test conducted in the Upper Floridan aquifer at the test site.

Description of the Study Area

Pinellas County is a peninsula in west-central Florida bounded by Tampa Bay to the east and the Gulf of Mexico to the west (fig. 1). The county is part of the Gulf Coastal Lowlands physiographic region described by White (1970) which consists of low angle scarps and terraces formed during several Pleistocene sea-level stands. The climate of Pinellas County is subtropical with an average rainfall of 53 inches per year (in/yr). Most rainfall occurs during the summer months between June and September (Causseaux and Fretwell, 1983). Land surface elevation at the Walsingham Park test site is about 55 ft above sea level.

HYDROGEOLOGIC FRAMEWORK

The geology of Florida consists of a pre-Mesozoic igneous and metamorphic basement and an overlying thick sequence of sedimentary units deposited during transgressive and regressive episodes (Heath and Smith, 1954). The hydrogeologic framework underlying the study area consists of Eocene or younger-age rocks and makes up the surficial aquifer system, the intermediate confining unit, and the Floridan aquifer system (fig. 2). This multilayered system consists of several permeable zones interbedded with zones of variable permeability that function as either confining units or semiconfining units. A semiconfining unit in this report refers to lower-permeability carbonate units that do not produce large quantities of water to wells when pumped (Knochenmus and Swenson, 1996). The hydrogeologic information compiled from wells at the test site was correlated with hydrogeologic information from previous studies in west-central Pinellas County. A generalized hydrogeologic section, oriented north-south, was constructed from natural-gamma geophysical logs (fig. 3).

Surficial Aquifer System

The surficial aquifer system (SAS) in Pinellas County is the shallowest water-bearing formation in the study area and consists of undifferentiated sands and clays which change in composition laterally and vertically (Causseaux, 1985). The post-Miocene age surface deposits in Pinellas County lie unconformably above the Hawthorn Group. Surface deposits are characterized by a base of marginal marine beds overlain by sandy, marine terrace deposits and capped by aeolian sand deposits. The thickness of the SAS, which ranges from a few feet to 50 ft, restricts the amount of potable water the aquifer supplies; however, the nonpotable water is utilized for irrigation (Gilboy, 1985). The SAS at the Walsingham Park site is about 35 ft thick. Throughout Pinellas County, the water table is less than 15 ft below land surface during dry periods and close to land surface during wet periods. Precipitation is the main source of recharge.

Hydraulic properties of the SAS are highly variable due to the diversity in physical characteristics of the sediments. Grain size, sorting, and thickness vary throughout the system and greatly influence the permeability and porosity of the system. Values for specific yield range from 0.1 to 0.35 (Causseaux, 1985). Horizontal hydraulic conductivity is estimated to range from 13 to 33 ft/d (Cherry and Brown, 1974; Sinclair, 1974) and vertical hydraulic conductivity is estimated to range from 0.36 to 13 ft/d (Sinclair, 1974; Hutchinson and Stewart, 1978).

Intermediate Confining Unit

The surficial and Floridan aquifer systems are separated by the low-permeability intermediate confining unit (ICU). The ICU occurs within the upper Miocene undifferentiated Arcadia Formation of the Hawthorn Group. The formation consists of interbedded quartz sands, clays, and carbonates. The clay beds in the Arcadia Formation act as confining beds

Figure 1. Location of the study area in west-central Pinellas County, well names, and hydrogeologic section *A-A′*.

throughout Pinellas County (Heath and Smith, 1954). The thickness of the ICU averages about 90 ft and ranges from 50 to 140 ft. At the Walsingham Park site, the ICU is about 100 ft thick. Due to the heterogeneous nature of the unit, a wide range of hydraulic properties has been reported. Vertical hydraulic conductivity for the ICU ranges from 1.3×10^{-4} to 6.9×10^{-3} ft/d (Sinclair, 1974; Black, Crow and Eidness, Inc., 1978). Leakance values reported in previous investigations range from 1×10^{-5} to 1.5×10^{-2} (ft/d)/ft (Black, Crow and Eidness, Inc., 1978; Seaburn and Robertson, Inc., 1983; Brown and Associates, Inc., 1986).

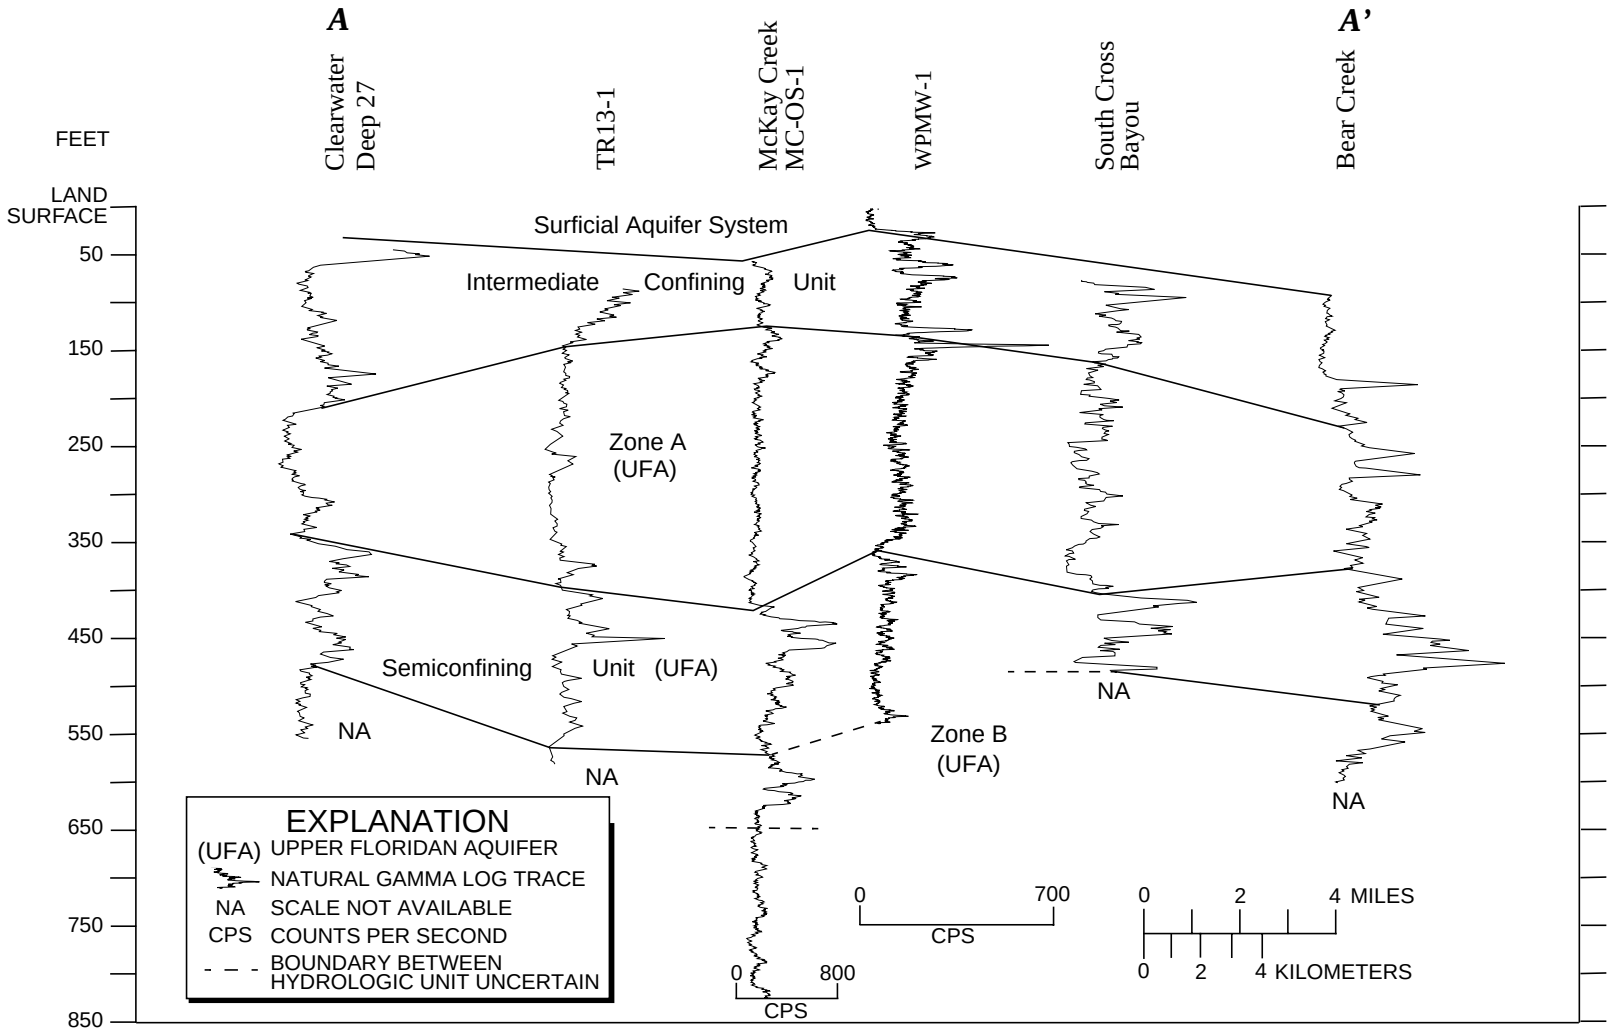

Figure 3. Hydrogeologic units underlying the study area correlated to natural-gamma ray log traces for section *A-A'* in Pinellas County (location of section shown in fig. 1).

Floridan Aquifer System

The Floridan aquifer system consists of limestones and dolomites and includes the Upper Floridan aquifer, the middle confining unit, and the Lower Floridan aquifer. The Upper Floridan aquifer in Pinellas County is composed of the Avon Park Formation, the Ocala Limestone, the Suwannee Limestone, and the Tampa Member of the Arcadia Formation (fig. 2). The Avon Park Formation consists of marine limestones interbedded with dolostones. The limestones are predominantly well indurated packstones which are highly fossiliferous. Overlying the Avon Park Formation is the Ocala Limestone. The Ocala Limestone consists of moderately indurated grainstones and packstones. The foraminiferal limestones in the unit commonly contain benthic foraminifera, bryozoan, echinoid, and mollusk fossils. The Ocala Limestone has a gradational contact with the overlying Suwannee Limestone. The Suwannee Limestone is predominantly foraminiferal packstone to grainstone with abundant mollusk and microfaunal remains (Miller, 1986). Overlying the Suwannee Limestone is the Tampa Member of the Arcadia Formation, which is the lower Miocene unit of the Hawthorn Group (Miller, 1986). The Tampa Member lies unconformably on the Suwannee Limestone and consists of limestone with dolostone, sands, and clays present in minor amounts. Mollusks, foraminifera, and algae are the common fossil molds present in the unit. The unit varies from mudstones to packstones, but is predominately wackestones.

In Pinellas County, the Upper Floridan aquifer is subdivided into four permeable zones generally separated by semiconfining units as defined by Hickey (1982). The zones are labeled alphabetically with increasing depth from A to D. The focus of this report is the uppermost part of the Upper Floridan aquifer, specifically the Tampa Member of the Arcadia Formation of the Hawthorn Group (Zone A) and the Suwannee Limestone (Zones A and B) because these are the only zones that contain brackish water at concentrations suitable for low-pressure reverse osmosis. Further discussions will be restricted to Zones A and B.

Zone A

Zone A, the shallowest and freshest permeable zone in the Upper Floridan aquifer, is made up of the Tampa Member and the upper part of the Suwannee Limestone. In Pinellas County, the thickness of Zone A averages 180 ft and ranges from approximately 115 to 250 ft. Reported transmissivities for Zone A throughout Pinellas County range from 10,000 to 40,000 ft^2/d (Hickey, 1982; Seaburn and Robertson, Inc., 1983; Brown and Associates, Inc., 1986). Values for storativity range from $4x10^{-4}$ to $8x10^{-4}$ (Hickey, 1982). Hickey (1982) divided Zone A into Upper Zone A (UZA) and Lower Zone A (LZA), separated by a discontinuous semiconfining unit. At the Walsingham Park site, a 25-ft thick semiconfining unit consisting of an abundance of marine clay separates the 140 ft thick UZA from LZA, which is about 50 ft thick (fig. 2).

Zone B

In Pinellas County, Zone B underlies Zone A. Thickness of Zone B averages about 150 ft and ranges from about 125 to 170 ft. The upper part of Zone B functions as a semiconfining unit in some parts of Pinellas County and is considered a nonproducing zone in these areas (Hickey, 1982; Knochenmus and Swenson, 1996). Reported hydraulic properties for this sequence are $1.3x10^{-3}$ to 2 ft/d for vertical hydraulic conductivity, 0.1 ft/d for horizontal hydraulic conductivity, and $7x10^{-3}$ (ft/d)/ft for leakance (Hickey, 1982; Seaburn and Robertson, Inc., 1983; and Brown and Associates, Inc., 1986). The lower part of Zone B is more permeable and is comprised of the lower part of the Suwannee Limestone. Thickness of this section of Zone B averages about 62 ft and ranges from 50 to 75 ft. Transmissivity estimates by Hickey (1982) suggest a value of about 5,000 ft^2/d. At the study site, Zone B was encountered between 350 and 547 ft below land surface. However, no apparent changes in permeability in the upper and lower parts of Zone B could be determined during drilling.

Delineation of Hydrogeologic Units Underlying the Study Area

The delineation of hydrogeologic units and their associated hydraulic properties at the Walsingham Park test site was accomplished through the collection and interpretation of lithologic and stratigraphic data, water-quality data, borehole geophysical data, and hydraulic data. During the well construction, rock core description, discrete water-quality sampling, borehole geophysical logging, and specific capacity tests were performed. Upon completion of the well construction, a 9-day aquifer test was performed. In total, one test production well 3 and four monitor wells were installed at the test site (fig. 4).

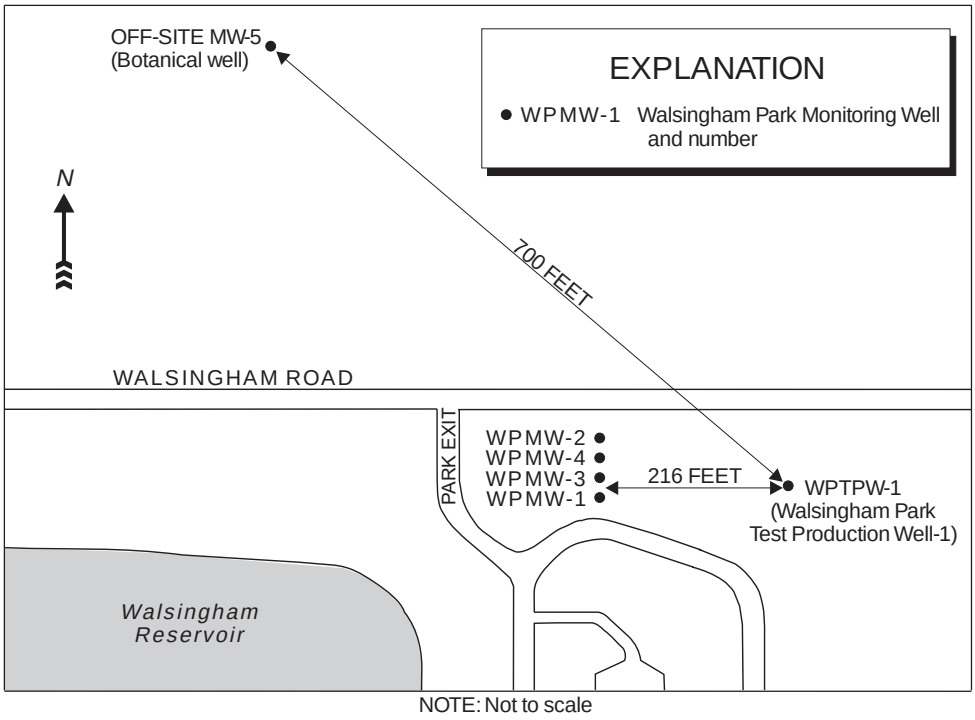

Figure 4. Walsingham Park test site, including location of wells drilled during the field investigation, and location of off-site monitor well (general location is shown in fig. 1).

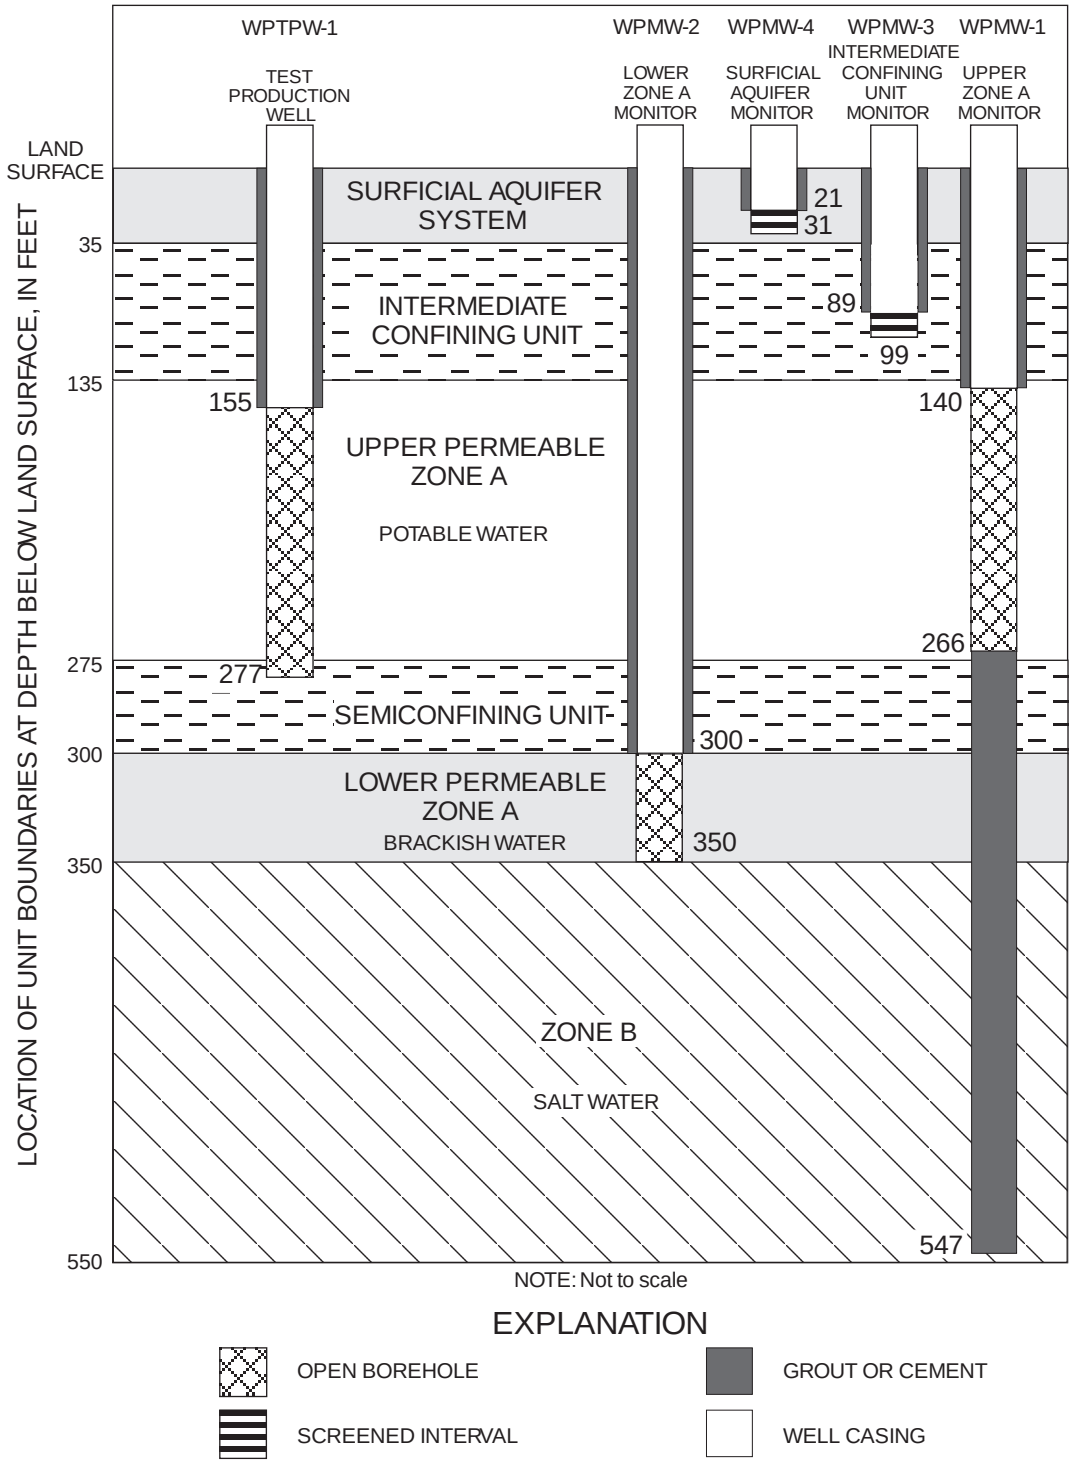
A production test well and four monitor wells were drilled by using a dual-wall reverse-circulation rotary drilling method. With this drilling method, pressurized air is forced down between the inner and outer barrels of the drilling stem. Rock and/or sediment is cut by the drill bit, and core samples rise to land surface through the inner barrel. The first well drilled was originally designed to function as a deep exploratory well and was drilled to a depth of 547 ft. This well was drilled to define the geology, water quality, and vertical distribution of producing zones and confining units at the test site. Data collected from the deep exploratory well were used to determine the total depths and casing depths of the test production well and monitor wells. After drilling and data collection, the deep exploratory well was backplugged to a depth of 266 ft and converted into the Walsingham Park UZA monitor well 1 (WPMW-1). The WPMW-1 and all other monitor wells were constructed to monitor a specific producing zone or lower permeability unit to evaluate the responses of various zones to pumping. The other wells drilled as part of this study are hereafter referred to as the test production well 1 (WPTPW-1), the LZA brackish-water monitor well 2 (WPMW-2), the intermediate confining unit monitor well 3 (WPMW-3), and the surficial aquifer system monitor well 4 (WPMW-4). Total depths and casing depths of all the wells constructed during this study are provided in figure 5.

Water-Quality Sampling

Water-quality samples were collected by the USGS and Pinellas County personnel during drilling of WPMW-1 to determine vertical distribution of water quality at the site. Water samples were collected at discrete intervals every 10 ft during drilling and tested onsite for specific conductance, temperature, and pH. When abrupt changes in field measurements occurred, water samples were collected and analyzed for major ions and physical properties at the Pinellas County Utilities laboratory. A vertical water-quality profile showing variations in dissolved solids with depth during drilling of WPMW-1 is presented in figure 6. As illustrated, the dissolved-solids concentration begins increasing approximately 350 ft below land surface. Although some water samples collected between 360 and 425 ft below land surface contained a lower concentration of dissolved solids, this anomaly may have been caused by drilling constraints as water samples were collected over a period of 3 consecutive days.



NOTE: Before backplugging to 266 feet, WPMW-1 was referred to as the deep exploratory well.

Figure 5. Generalized section view of casing depths and final depths of wells at the Walsingham Park test site.

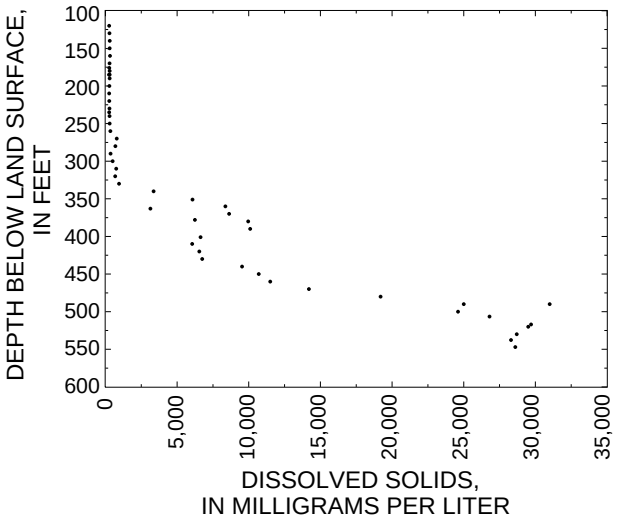


Figure 6. Relation of dissolved solids and depth from water samples collected during drilling of Walsingham Park deep exploratory well (WPMW-1).

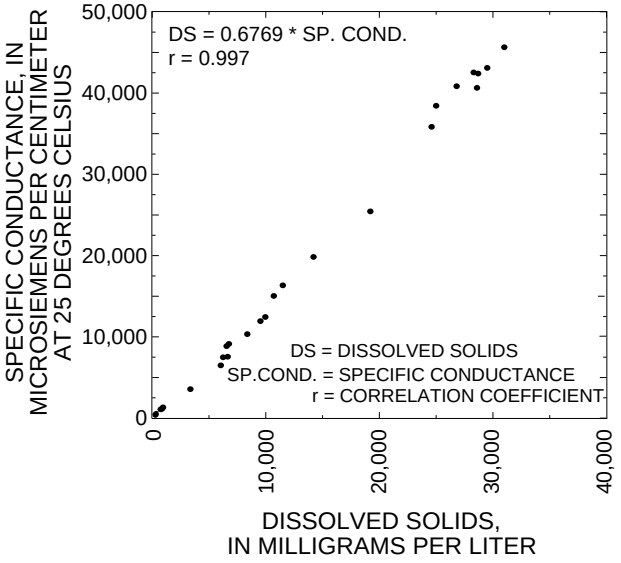

Figure 7. Relation between dissolved solids and specific conductance of selected water samples collected during drilling of Walsingham Park deep exploratory well (WPMW-1).

The freshening of water samples between drilling days may have been the result of mixing of waters in the borehole. However, previous investigations in northern Pinellas County have shown that layering of water with higher dissolved-solids concentrations can occur over water with lower dissolved-solids concentrations (Knochenmus and Swenson, 1996). The nature of this water-quality anomaly at the Walsingham Park test site could not be determined upon completion of drilling.

Additionally, selected samples were used to show the correlation between specific conductance and dissolved-solids concentrations for ground water representative of the study site (fig. 7). The linear regression closely fits a straight line with a correlation coefficient (r) of 0.997. The correlation of the two parameters was later used to estimate changes in dissolved-solids concentration under pumping conditions; however, the relation of dissolved solids to specific conductance would not be constant for the entire range of samples (Hem, 1985). As figure 7 illustrates, the slope of the linear regression is different for specific ranges of conductance values. Changes in water quality that occurred during hydraulic testing are discussed further in the aquifer test section of this report.

Geophysical Logging

Borehole geophysical logging was used to delineate hydrogeologic units, flow zones, and water-quality changes at the test site. Geophysical logs were collected by a Pinellas County contractor under static and pumping conditions on WPMW-1. A lithologic log from WPMW-1 was also compiled during drilling. Logs collected during static conditions included caliper, natural-gamma radiation, fluid resistivity, and fluid temperature. Logs collected under pumping conditions included ascending and descending flow meter with the pump placed 120 ft below land surface. A schematic of the geophysical logs collected from WPMW-1 is shown in figure 8.

Interpretations of the geophysical logs in conjunction with the lithologic log were used to determine the distribution of flow zones and semiconfining units. Natural-gamma radiation logs are used to delineate clay and phosphate-bearing deposits by recording the naturally occurring radiation coming from the formation adjacent to the borehole. The natural-gamma log, when correlated with the WPMW-1 lithologic log, confirmed the presence of clay and phosphate deposits from 35 to 135 ft below land surface. This sequence corresponded to the ICU at the study site. The decrease in the natural-gamma values at about 340 ft below land surface indicates a region of low phosphate content within the Suwannee Limestone.

Flow logs measured under pumping conditions are used in conjunction with caliper logs to delineate flow zones. Within a relatively uniform borehole diameter, an increase in counts per second indicates an increase in fluid velocity, thus an increase in flow. The flow meter logs collected at WPMW-1 indicate the presence of a major flow zone from around 300 to 350 ft below land surface, corresponding to LZA.

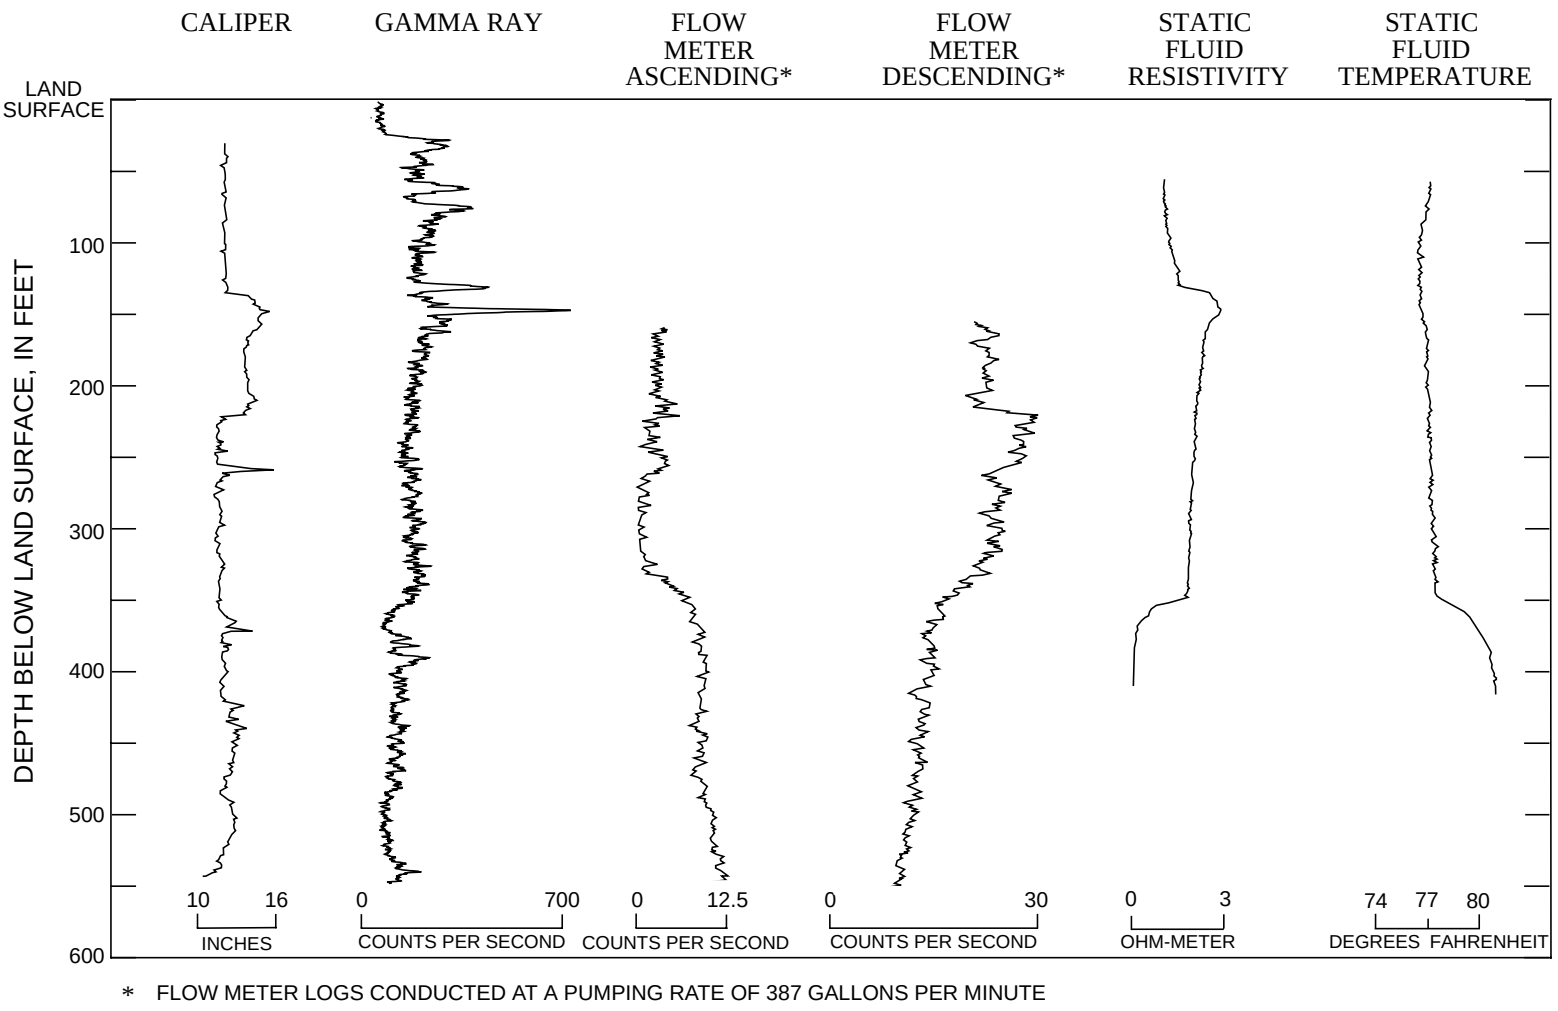

Figure 8. Geophysical logs of Walsingham Park deep exploratory well (WPMW-1).

Fluid resistivity and temperature logs are used to identify zones of water-quality change. The fluid resistivity and fluid temperature logs indicate a rapid water-quality change approximately 350 ft below land surface as fluid resistivity decreases and fluid temperature increases. The change in water quality at 350 ft below land surface was noted in the water-quality profile developed from water samples taken during drilling. However, unlike the water-quality profile, neither the fluid resistivity nor temperature logs suggest a freshening of water from 360 ft below land surface to the lowest extent of the logs at about 415 ft below land surface (fig. 8).

Specific-Capacity Tests

Specific-capacity tests were performed on WPMW-1 to evaluate the various hydrogeologic units at the study site. Water-level data, collected under a range of pumping rates, were analyzed to estimate hydraulic parameters of the system. Specific-capacity tests measure well yield per unit of drawdown for specific intervals of individual hydrogeologic units. Results were used to estimate hydraulic properties of specific intervals, locate permeable zones, and determine the well and casing depths of the monitor and production wells. In addition to specific-capacity tests, packer tests were performed upon completion of WPMW-1 (prior to backplugging) to further identify permeable zones at the site. Transmissivity and hydraulic conductivity values, estimated from specific-capacity and packer tests performed on the deep exploratory well (WPMW-1), are listed in table 1.

Table 1. Results from specific capacity and packer tests from the deep exploratory well

[ft, feet; ft^3/d, cubic feet per day; (gal/min)/ft, gallons per minute per foot; ft^2/d, feet squared per day; ft/d, feet per day]

Depth interval below land surface (ft)	Pump rate (ft^3/d)	Total change in head (ft)	Specific capacity (gal/min)/ft	Transmissivity (ft^2/d)	Hydraulic conductivity (ft/d)
135-185	11,744	9.73	6.3	1,675	34
135-235	11,934	8.87	7.0	1,870	19
135-235	59,864	59.64	5.2	1,400	14
205-235	9,336	9.59	5.1	1,350	45
230-282[a]	17,901	13.74	6.8	1,810	35
268-285[a]	9,182	4.63	10.3	2,750	162
288-340[a]	18,289	14.50	6.6	1,750	34
338-355[a]	9,624	4.31	11.6	3,100	182
385-542[a]	9,124	5.77	8.2	2,195	33

[a]Packer test interval.

The values were estimated by applying specific-capacity and packer-test data to empirical equations developed from the modified Jacob nonequilibrium equation for a single-well test (Driscoll, 1986, p. 1021). Due to the difficulty in placing packers in the borehole and leakage problems detected around the packers, confidence in the packer-test data was low for determining hydraulic parameters. However, UZA from about 135 to 270 ft below land surface and LZA from about 300 to 350 ft below land surface were determined to be the primary flow zones contributing ground water to the wells. Although LZA had a higher specific capacity, it was located directly above a highly mineralized water-quality zone. Therefore, UZA was more suitable for a longer-term aquifer test.

Aquifer Test

A 9-day aquifer test was conducted at the test site from July 29 to August 7, 1997, to estimate the hydraulic parameters of Zone A and determine changes in water quality due to long-term pumping. The four onsite and one offsite monitor wells were used to observe responses in various zones to pumping from UZA at WPTPW-1. Background water-level data collected before and after pumping showed that head differences between zones at the test site reflected a downward head gradient (fig. 9). At the onset of the aquifer test, the water level in the SAS monitor (WPMW-4) was about 2.5 ft above the water level in the ICU monitor (WPMW-3), whereas the water level in the ICU monitor was more than 36 ft higher than the water level in the UZA monitor (WPMW-1). Moreover, the water level in the UZA monitor was 0.15 ft higher than the water level in the LZA monitor (WPMW-2). The test production well (WPTPW-1) was pumped at a rate of 220 gal/min for the length of the test. After the initiation of pumping, responses were noted for the various monitor wells. WPMW-1 responded immediately with a lowering of water level in the first minute of pumping. WPMW-2 also responded quickly with the first drawdown noted after 4 minutes of pumping. Contrasting the changes in water levels at these two wells, the water level in WPMW-1 decreased by 1.0 ft, whereas the water level in WPMW-2 decreased by 0.02 ft after 4 minutes of pumping. Furthermore, a “reverse water-level fluctuation” (Andreasen and

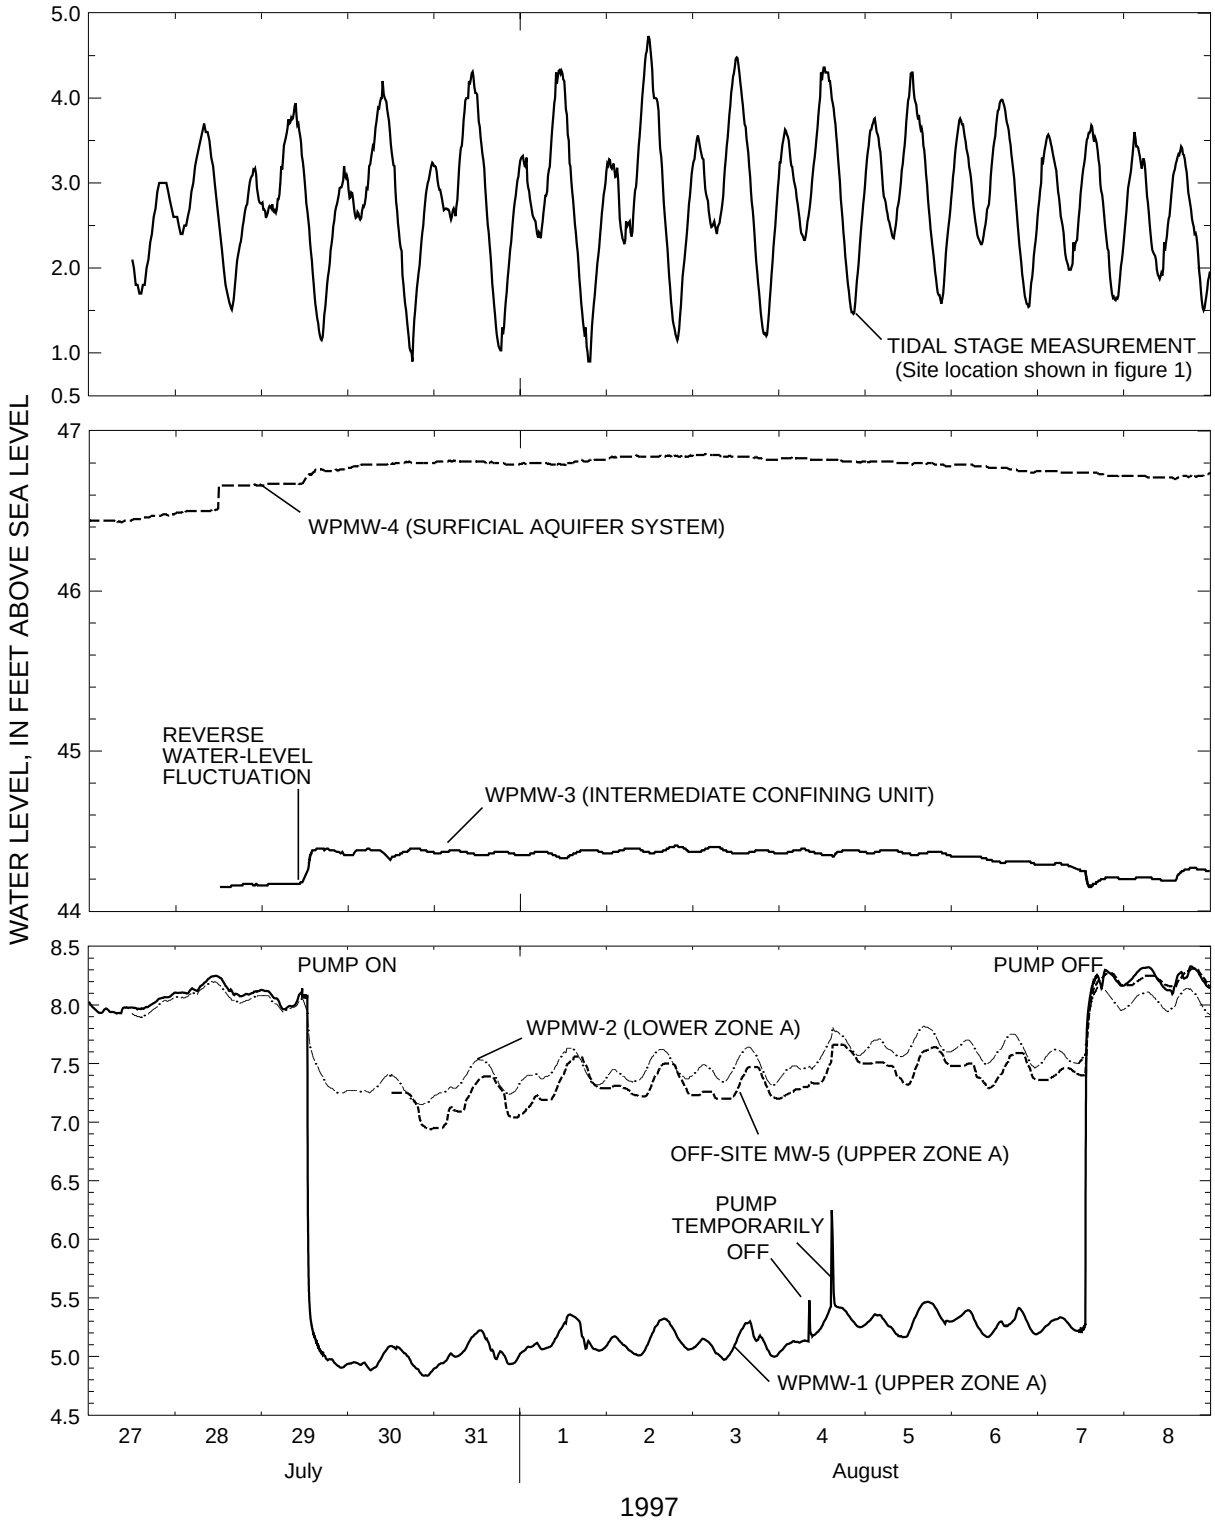

Figure 9. Water levels in all monitor wells before, during, and after the 9-day aquifer test.

Brookhart, 1963) was observed in the ICU monitor well WPMW-3. The water level in the ICU began to rise immediately after pumping began and declined when pumping ended (fig. 9). A possible explanation for this occurrence is that the release of water from compressive storage produced by pumping in UZA caused a reduction in aquifer volume of UZA, which in turn caused both horizontal and vertical deformations in the overlying ICU. These deformations of the ICU subsequently induced the measured water-level rise. This phenomenon has been documented and is often referred to as the Noordbergum Effect (Hsieh, 1996). No response due to pumping was denoted in the surficial aquifer system monitor well WPMW-4. Although water levels were monitored in the five wells for the duration of the test, drawdowns reached steady-state within the first 3 hours of pumping when tidal effects began to interfere with drawdown measurements (fig. 9).

Water-quality data were collected for the duration of the 9-day aquifer test. Specific conductance probes were placed in WPMW-1 and WPMW-2 at depths of 250 ft and 330 ft, respectively. Discharge water from WPTPW-1 was monitored hourly for specific conductance for the duration of the aquifer test. The changes in specific conductance measured during the test are shown in figure 10. Interestingly, water-quality changes noted in the UZA and the LZA monitor wells exhibited opposite trends. By using the relation between dissolved solids and specific conductance developed earlier (fig. 7), an inference can be made regarding the changes in dissolved solids concentrations during the aquifer test. The specific conductance in WPMW-1 in UZA increased from about 1,050 to 1,600 µS/cm corresponding to an increase in dissolved- solids concentration of about 372 mg/L. By contrast, the specific conductance in WPMW-2 in LZA decreased from about 11,900 to 11,200 µS/cm corresponding to a decrease in dissolved-solids concentrations of about 440 mg/L over the 9 days of the test. The specific conductance of the composite sample collected from WPTPW-1 increased from 470 to 488 µS/cm. Although this slight increase in measured specific conductance can be considered to be within the error of measurement of the conductance probe, the data showed a consistent trend (fig. 10).

The opposite trends in water-quality changes noted between the UZA and the LZA monitor wells during the 9-day aquifer test are difficult to explain. The upward hydraulic gradient between LZA and UZA induced during the aquifer test may have resulted in upward movement of more saline water. However, the freshening of water in the LZA monitor well (WPMW-2) during the aquifer test is anomalous. As figure 10 illustrates, the rate of change of measured specific conductance appears to decrease from the time pumping began. It is possible that mineralized water may have invaded LZA during drilling of the deep exploratory well and may have evacuated LZA during the aquifer test, thus returning to native conditions. Since the aquifer test lasted only 9 days, no data are available to determine the specific conductance values at longer pumping times.

Data and the results of the aquifer test are on file and available at the USGS Tampa office. Because analytical methods are constrained by limitations in the simplification of a flow system into one- or two-dimensional flow, the 9-day aquifer test was analyzed by using numerical methods. Numerical methods can simultaneously calculate changes in head and advective transport in a variable-density flow system for multiple observation points.

ANALYSIS OF AQUIFER CHARACTERISTICS

A numerical modeling approach was used to simulate the effects of pumping the variable-density ground-water flow system at the test site. The model was constructed to simulate the 9-day aquifer test conducted at the site and to refine estimates of hydraulic parameters such as hydraulic conductivity and storage coefficient determined from specific-capacity tests and previous investigations.

Numerical Methods

The USGS computer code HST3D (Kipp, 1987) was used to solve the equation for ground-water flow and solute transport using backward-in-space and backward-in-time finite-difference approximation methods. Mass-fractional concentrations and total fluid pressures were simulated using the model. The reader is referred to the original report that documents the computer code (Kipp, 1987) for a complete discussion of the numerical methods and model code.

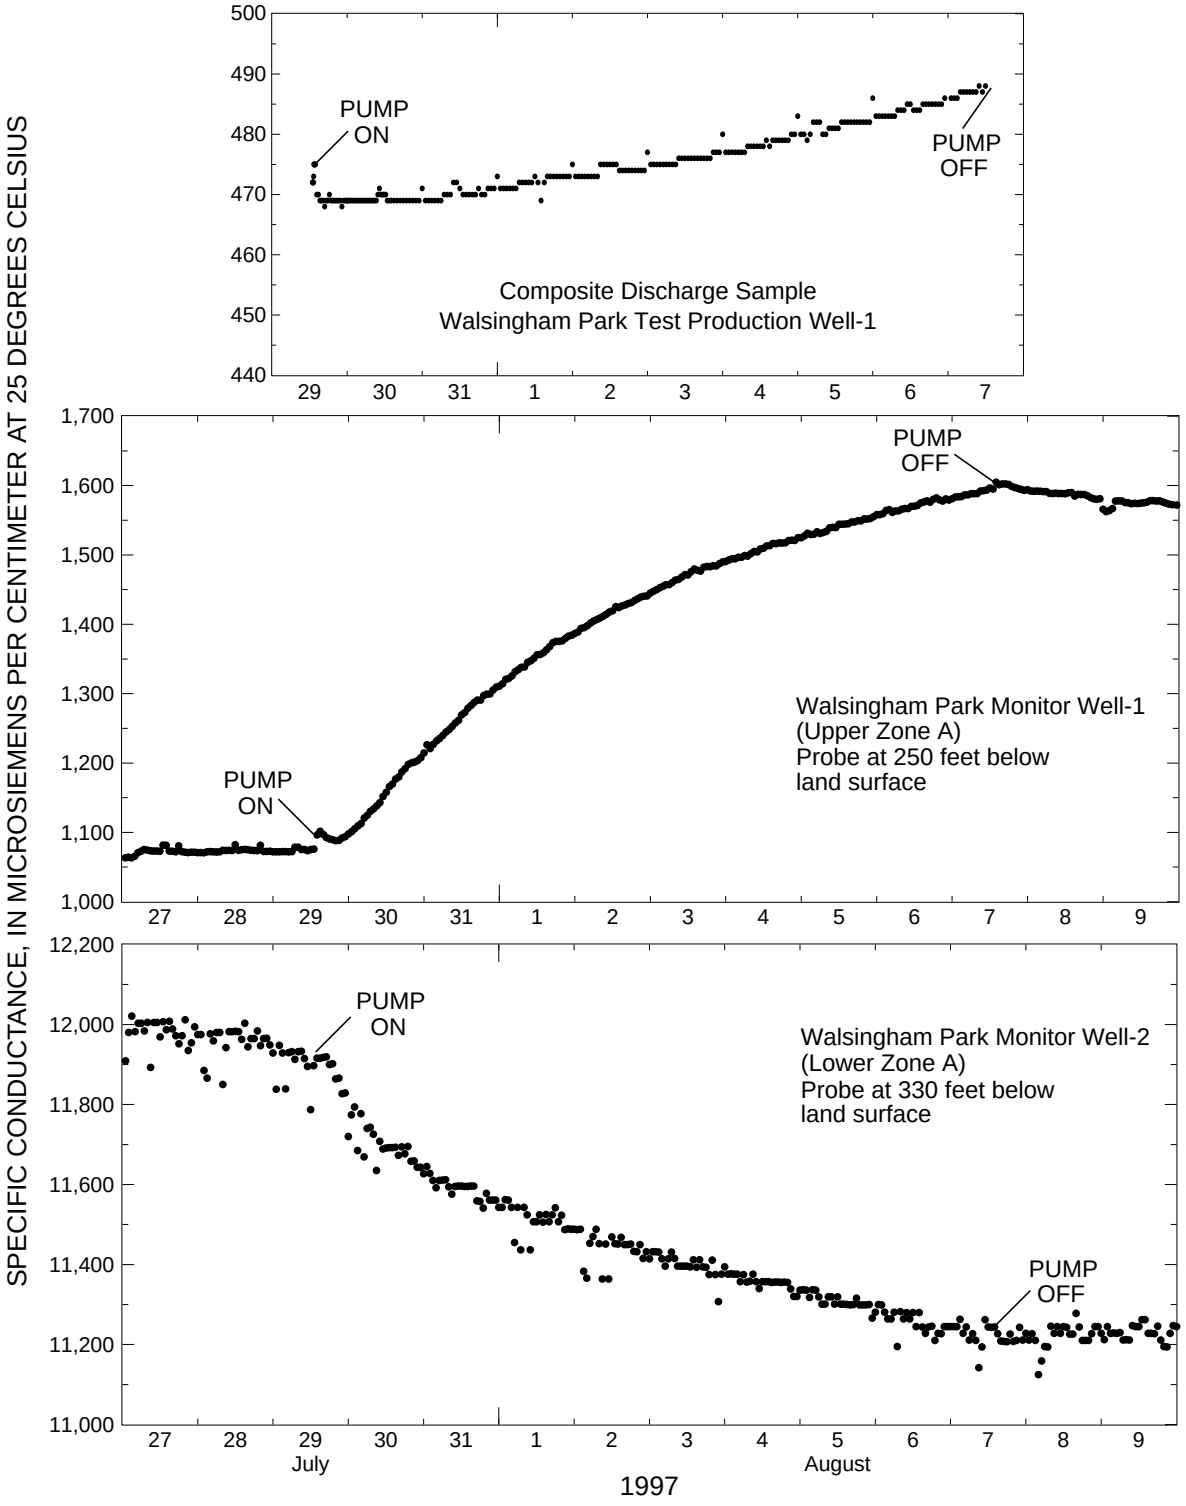

Figure 10. Changes in specific conductance during the 9-day aquifer test at Walsingham Park Test Production Well and Walsingham Park Monitor Wells 1 and 2.

Conceptual Model

The hydrogeologic system of the study area is conceptualized as a multilayered aquifer system encompassing various permeable zones separated by confining and semiconfining units extending from the surficial aquifer system downward through the Suwannee Limestone of the Upper Floridan aquifer (fig. 2). Ground-water flow is considered to be lateral in permeable zones and vertical in confining and semiconfining zones. Ground-water quality changes from fresh to saline with depth as ground water becomes increasingly dense with higher concentrations of dissolved solids. Several assumptions were made regarding the conceptualized hydrogeologic system to effectuate numerical simulation:

1. The aquifer system is assumed to act as an equivalent porous medium,
2. All aquifer layers are homogeneous and isotropic,
3. Initial conditions are hydrostatic,
4. Initial fluid density is constant in each model row, and
5. The water-quality profile is laterally homogeneous for the entire model area.

Design of Numerical Model

The numerical model subdivides the conceptualized hydrogeologic system from the ICU through Zone B at the test site into an organized network of grid blocks, each with assigned fluid and matrix properties representing a 500-ft thick section underlying the test site. The model was constructed by using a cylindrical-coordinate grid of 124 columns and 12 rows (fig. 11), and was designed to simulate the responses of UZA and LZA to brackish-water development. The columns are variable in width with radial spacing expanding logarithmically from 0.3 ft at the test production well up to a maximum width of 328 ft extending out to 11,500 ft. Radial widths extending to 12,500 and 14,500 ft were also simulated, but the additional simulation area in the horizontal direction had no affect on model results. The 12 model rows were grouped together as five distinct hydrogeologic layers. Layer 1 corresponds to model rows 1-3, is 175 ft thick, and represents Zone B of the Upper Floridan aquifer. Layer 2 corresponds to model rows 4 and 5, is 50 ft thick, and represents LZA of the Upper Floridan aquifer. Layer 3 corresponds to model row 6 and represents a discrete, 25-ft section within Zone A with an increased occurrence of green clays. This section was modeled to determine the hydraulic properties of the unit separating UZA and LZA. Layer 4 corresponds to model rows 7-9, is 150 ft thick, and represents UZA of the Upper Floridan aquifer. Layer 5 corresponds to model rows 10-12, is 100 ft thick, and represents the ICU.

Initial and Boundary Conditions

Initial conditions refer to pressure and fluid property distributions established prior to the initiation of the model simulation. Hydrostatic conditions are established in HST3D from a distribution of dissolved solids and fluid densities for each model row. Values for dissolved-solids concentrations and fluid densities, based on water-quality parameters defined from samples taken during drilling, were used to establish initial conditions (table 2). The model calculates the starting fluid pressures based on the user-specified fluid property distribution for all model rows as well as at model boundaries. Under these hydrostatic conditions, the aquifer response to pumping is determined by model simulated changes in pressure relative to the initial hydrostatic conditions (Anderson and Woessner, 1992).

Boundary conditions delimit the model domain by constraining the lateral and vertical extent of the simulated flow system at the model periphery. The inner cylindrical boundary represents the production well and was defined by allocating well information to the various rows that represent the open-hole interval of the pumped well. Model rows not open to the production well were assigned a no-flow condition, whereas the outer cylindrical boundary was defined as a specified-pressure condition (fig. 11). The assigned pressure distribution along the vertical plane of the outer boundary was calculated by using water-level and dissolved-solids concentration data obtained during drilling of the test production well. The lower model boundary was defined as a specified-pressure boundary equivalent to the pressure exerted by a column of stratified saltwater and freshwater in the overlying strata determined from the density of water samples acquired during drilling (fig. 11). The outer and lower specified-boundaries were used to simulate an infinitely extensive aquifer while eliminating the modeling of indefinite regions outside the study area. The upper model boundary was assigned a no-flow boundary coinciding with the top of the ICU. Because no drawdown occurred in either the SAS or the ICU monitor wells during the aquifer test, a no-flow boundary condition at the top of the ICU was deemed appropriate. However, row 11 (corresponding to the

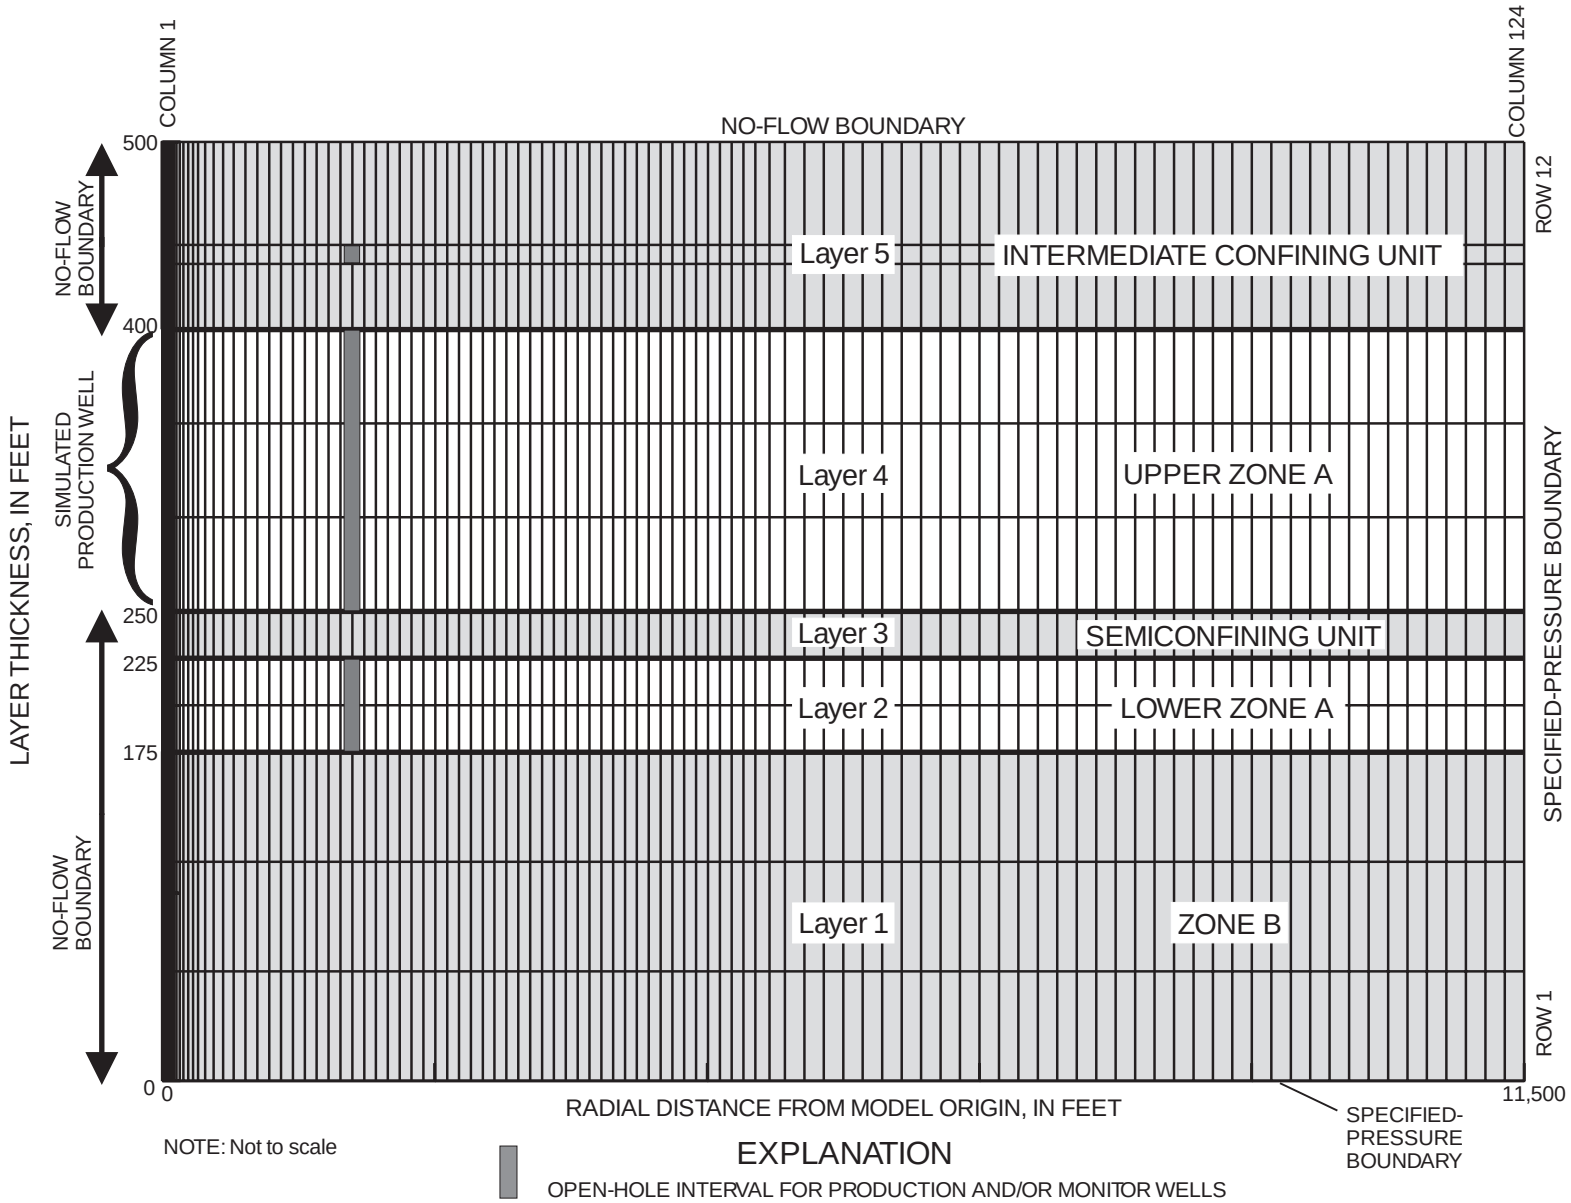

Figure 11. Model grid, simulated open-hole intervals, and boundary conditions used in the HST3D simulation.

Table 2. Values for model parameters used to establish initial conditions and values for calibrated model parameters

[lb/ft^3, pound per cubic foot; mg/L, milligrams per liter; ft^2, feet squared; ft/d, feet per day]

Hydrogeologic unit	Initial conditions		Calibrated model		
	Density (lb/ft^3)	Scaled-solute mass fraction / dissolved solids (mg/L)	Intrinsic permeability (ft^2) / hydraulic conductivity (ft/d)	Storage coefficient	Effective porosity (percent)
Intermediate confining unit	62.38	0.0089 / 250	$3.9x10^{-15}$ / 0.0001	$3.1x10^{-4}$	35
Upper Zone A	62.38	0.0098 / 275	$7.0x10^{-11}$ / 18	$2.6x10^{-4}$	30
Semiconfining unit	62.41	0.0250 / 700	$3.9x10^{-11}$ / 10	$4.3x10^{-5}$	35
Lower Zone A[a] (Row 6)	62.61	0.1786 / 5,000	$2.9x10^{-9}$ / 750	$8.6x10^{-5}$	30
Lower Zone A (Row 5)	62.72	0.2679 / 7,500	$2.9x10^{-9}$ / 750	$8.6x10^{-5}$	30
Zone B	63.65	1.0 / 28,000	$3.9x10^{-12}$ / 1	$2.6x10^{-5}$	30

[a] Input parameters varied between the two rows representing Lower Zone A.

open-hole interval of WPMW-3) was used as an indictor for the upper limit of hydraulic parameters that would simulate a no-response condition in the ICU. Although the lack of a drawdown in the ICU made it impossible to accurately estimate hydraulic properties of the unit, model parameters in rows representing the ICU were adjusted to eliminate drawdown during the simulation.

Model Parameters

Model parameters including bulk matrix properties, fluid properties, and well information were defined for the five hydrogeologic units simulated (table 2). Although some adjustments were made to the parameters during calibration, initial values were carefully selected based on data collected during this investigation and previous studies (Hickey, 1982, 1989; Knochenmus and Swenson, 1996; Yobbi, 1996). Each model parameter is discussed in detail below:

1. *Bulk matrix properties.*—Bulk matrix properties include effective porosity, hydraulic conductivity (as a function of intrinsic permeability), storage coefficient (as a function of matrix compressibility), and dispersivity. Bulk matrix properties (except dispersivity) for each hydrogeologic layer are listed in table 2. Because values of dispersivity are poorly known within the study area, a conservative approach was used by setting longitudinal and transverse dispersivity to zero.

2. *Fluid properties.*—Fluid properties include viscosity, density, compressibility, temperature, and dissolved-solids concentration. Dissolved-solids concentration is expressed as a scaled-solute mass fraction ranging from 0 to 1 in HST3D. A value of 0 represents pure freshwater whereas a value of 1 represents water with the highest dissolved-solids concentration (28,000 mg/L) in the model. Values for density and dissolved solids for each hydrogeologic layer are summarized in table 2. Fluid viscosity was held constant for the entire model at $1.0x10^{-3}$ centipoise. Likewise, fluid temperature and fluid compressibility were held constant with values of 77 ^{o}F, and $3.03x10^{-6}$ in^2/lb, respectively.

3. *Well information.*—Well information needed for model input includes the withdrawal rate of the pumping well and is distributed equally over the three rows representing the pumped zone. The test production well open to UZA was simulated in model rows 7-9. The simulated pumpage was discretized with a constant withdrawal rate assigned to each of the three rows. The total pumpage assigned for all three rows for the aquifer test simulation equaled 220 gal/min. Pumpage was varied thereafter from 200 to 700 gal/min during the brackish-water development simulations.

Simulation of Aquifer Test

Numerical analysis of the 9-day aquifer test data provided a method for calculating hydraulic properties of various hydrogeologic units at the test site. The numerical model was calibrated by simulating the aquifer system's response to pumping UZA during the aquifer test. The model analysis of the 9-day aquifer test consisted of meeting two calibration objectives within acceptable limits: (1) simulate the drawdown and recovery of water levels in selected wells measured during the test, and (2) simulate the overall response of the system to pumping.

The first objective involved matching the initial drawdown part of the aquifer test. The initial 139 minutes of the aquifer test was used because nearly all drawdown effects occurred during this time and monitor well drawdowns could be separated from tidal effects. Tidal effect corrections were made by calculating the tidal efficiency for the monitor zone and adjusting drawdown and recovery data accordingly. Tidal efficiency is the ratio of the water-level amplitude measured in a well to the oceanic tidal amplitude (Ferris and others, 1962). Tidal data were collected at a gage located on the intracoastal waterway at Indian Rocks Beach, 2 mi west of the study site (fig. 1). The calculated tidal efficiency for Zone A averaged 10 percent for ebbing tides and 16 percent for flooding tides. After tidal corrections were made to the observed data, the corrected drawdowns were compared to simulated drawdowns.

Model parameters were adjusted until a reasonable match was derived where simulated drawdowns closely paralleled the observed drawdowns. A reasonable match was considered less than 0.10 ft difference between simulated and observed drawdown data. Final calibrated values for hydraulic conductivity were 18 ft/d for UZA, 750 ft/d for LZA, 1 ft/d for Zone B, $1x10^{-4}$ ft/d for the ICU, and 10 ft/d for the semiconfining unit separating UZA and LZA. Final calibrated values for storage coefficient were $3.1x10^{-4}$ for UZA, $8.6x10^{-5}$ for LZA, $2.6x10^{-5}$ for Zone B, $3.1x10^{-4}$ for the ICU, and $4.3x10^{-5}$ for the semiconfining unit separating UZA and LZA. Calibrated model parameters were further checked by comparing the observed recovery data of the aquifer test to the simulated recovery water levels (fig. 12). Values of the corrected, observed drawdown and recovery and simulated values are provided in table 3.

Table 3. Simulated and corrected observed drawdown and recovery for selected monitor wells during the 9-day aquifer test

[UZA, upper zone A; LZA, lower zone A; NA, data not available; all values are in feet]

Zone and well	Corrected observed drawdown[a]	Simulated drawdown	Corrected observed recovery[b]	Simulated recovery
UZA WPMW-1	2.69	2.66	2.79	2.66
LZA WPMW-2	0.29	0.30	0.36	0.31
UZA Botanical Well	NA	0.59	0.54	0.60

[a]Corrected drawdown for first 139 minutes of pumping.
[b]Corrected recovery for first 136 minutes of recovery in WPMW-1 and Botanical Well, and first 192 minutes of recovery in WPMW-2.

The second objective involved matching the long-term pattern of drawdown and recovery for the length of the 9-day aquifer test. As figure 9 shows, after the initial 139 minutes of pumping, observed drawdowns stabilized (excluding tidal effects) for the remainder of the 9-day test until the pump was turned off and recovery effects occurred. A reasonable match was accomplished when simulated drawdowns functioned in a similar fashion with drawdowns decreasing after the initial drop in water levels and stabilizing throughout the simulation until the recovery part of the test (fig. 13). It should be noted that the simulated hydrographs are superimposed over the uncorrected field hydrographs. No attempt was made to simulate the variations in water levels due to tidal effects.

Sensitivity Analysis

Sensitivity analysis was used to determine the effect of each parameter on the calibrated model results. Input parameters were individually varied over a reasonable range of values to determine the sensitivity of the model to that particular parameter over the entire simulation period. Ranges were based on values from previous investigations discussed in the hydrogeologic framework section of this report. Changes in certain parameters had no effect on the model, whereas others noticeably affected the model results. For example, a one order of magnitude increase and decrease in the value of matrix compressibility in model rows representing both UZA and LZA had no effect on the model results. Furthermore, a one order of magnitude increase and decrease in the intrinsic permeability of model rows representing the ICU had

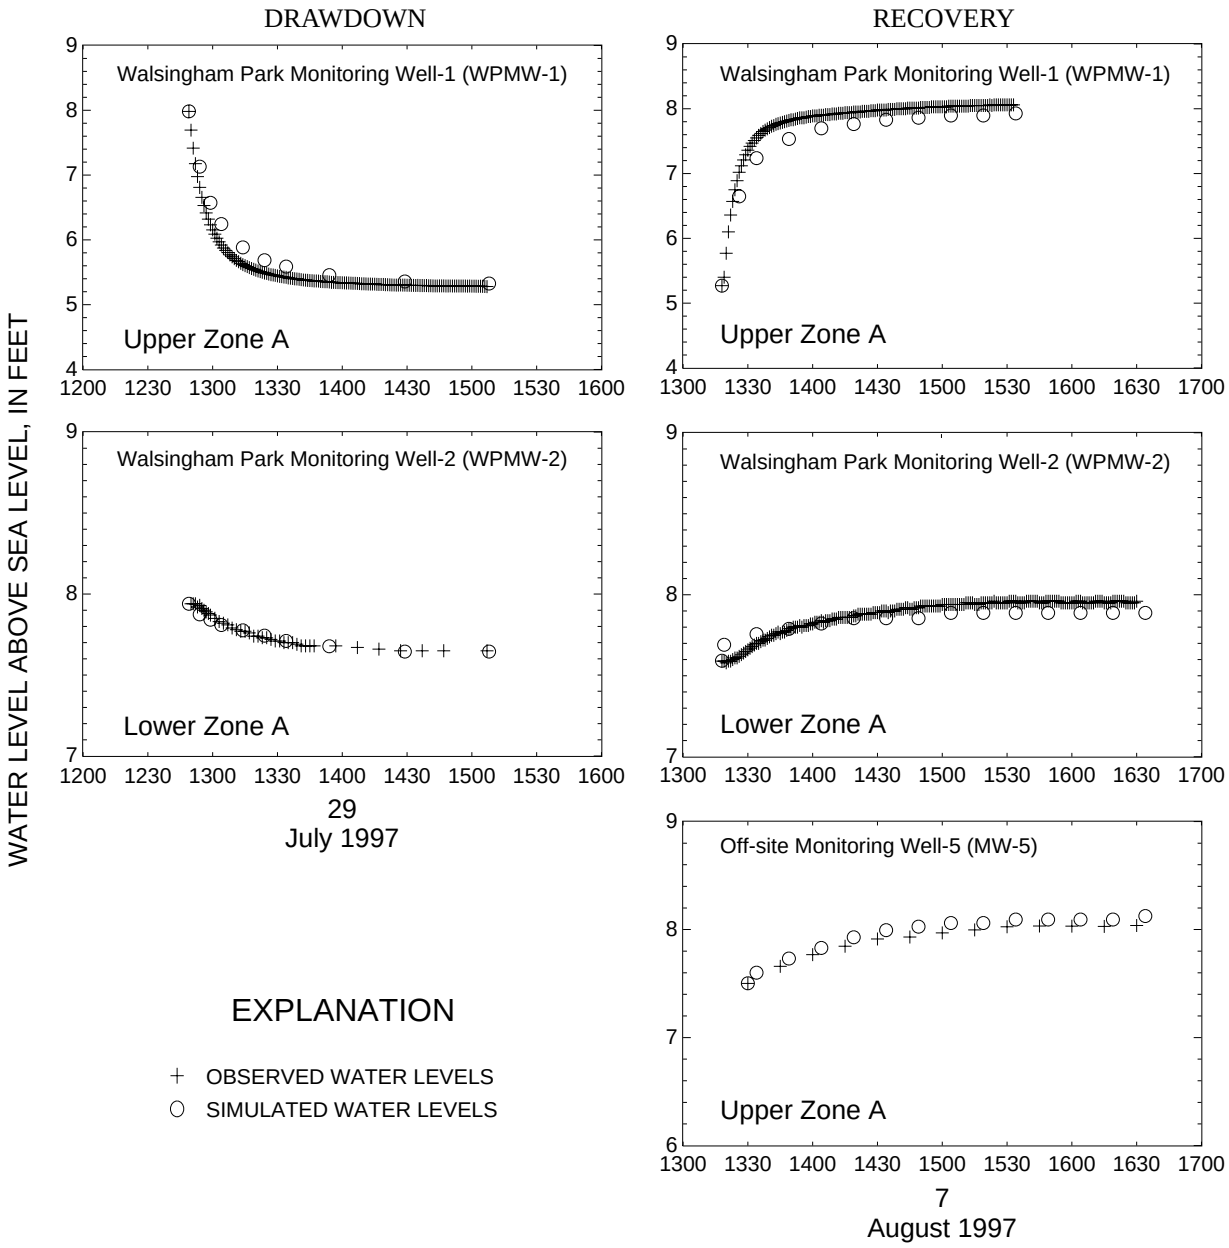

Figure 12. Simulated and observed water levels during drawdown and recovery periods at selected wells during the 9-day aquifer test.

no effect on the model results. Conversely, the largest changes to the model results occurred from changes in intrinsic permeability values assigned to both UZA and LZA (figs. 14a thru 14d). Model rows representing UZA were increased and decreased by one order of magnitude, whereas model rows representing LZA were changed by a factor of 2 and 0.5. Additionally, the value of matrix compressibility assigned to model rows representing the ICU were increased and decreased by one order of magnitude (figs. 14e and 14f). An increase in the matrix compressibility of the ICU resulted in a slight response in only UZA. Furthermore, this response occurs in the early part of the drawdown graph, but the overall magnitude of drawdown in UZA did not change. The model was generally sensitive to changes of intrinsic permeability and insensitive to changes of matrix compressibility; therefore, more confidence was placed on estimates of transmissivity than on estimates of storativity.

Model Limitations

Results from model simulations outlined in this report are approximations of the actual hydrogeologic system. Confidence in model results is dependent on the assumptions outlined earlier in this report and the extent that the hydrogeologic system is simplified for mathematical representation. Simplification of the conceptual model is necessary to simulate a very complex natural system; however, the extent to which the system is simplified represents a source of error in model results. The major limiting factor in the model simulations is that the hydrogeologic system was simulated as a five-layered system with isotropic, homogeneous, and porous-medium individual layers. The actual hydrogeologic system may, however, be anisotropic, heterogeneous, and possess properties of secondary porosity due to dissolution and fracturing. Although alternate combinations of model parameters may provide similar results to those outlined in this report, the model incorporated the best estimates of the unknown parameters, the local geology, and hydrologic conditions.

SUMMARY

This report presents the results of a study to evaluate the brackish-water resources in the Upper Floridan aquifer underlying west-central Pinellas County, Florida. A production test well and four monitor wells were constructed at a location in Walsingham Park in 1996-97. The wells were sampled for water-quality parameters and investigated using borehole geophysical methods and hydraulic testing. The data collected were analyzed by using numerical techniques to delineate the hydrogeologic framework at the test site.

Collected data indicate that a multilayered aquifer system consisting of two permeable zones underlies Walsingham Park. One zone extends from about 135 to 275 ft below land surface and corresponds to UZA of the Upper Floridan aquifer. Another permeable zone extends from about 300 to 350 ft below land surface and corresponds to LZA of the Upper Floridan aquifer. Analysis of water-quality data indicates that LZA may not provide water of consistent quality because of rapidly increasing dissolved-solids concentrations occurring around 350 ft below land surface. UZA was deemed more appropriate for production pumping and was tested during a 9-day aquifer test.

A numerical model was developed to simulate the 9-day aquifer test performed at the Walsingham Park test site. The model was calibrated to the drawdown and recovery water levels of selected monitor wells at the test site. Final calibrated values for hydraulic conductivity were 18 ft/d for UZA, 750 ft/d for LZA, 1 ft/d for Zone B, $1x10^{-4}$ ft/d for the ICU, and 10 ft/d for the semiconfining unit separating UZA and LZA. Final calibrated values for storage coefficient were $3.1x10^{-4}$ for UZA, $8.6x10^{-5}$ for LZA, $2.6x10^{-5}$ for Zone B, $3.1x10^{-4}$ for the ICU, and $4.3x10^{-5}$ for the semiconfining unit separating UZA and LZA.

Hydrogeology of Effluent Disposal Zones, Floridan Aquifer, South Florida

by Joseph L. Haberfeld[a]

Abstract

The increasing population of south Florida is creating a need for greater waste-water disposal capacity. The people of Florida are dependent on ground water for drinking, irrigation, and other uses. The emphasis on preservation of surface-water quality means that many surface waters are not allowed to receive effluent from municipal or industrial sources. Since the 1940s, the highly transmissive zones of the nonpotable portion of the Floridan aquifer have served as disposal zones for oil field brine and later for industrial and municipal effluent.

The Floridan aquifer of south Florida is a carbonate Cenozoic age aquifer. Transmissivities between 0.5 and 21 million gpd/ft exist in cavernous and fractured sequences in the aquifer. Confining zones that overlie the disposal intervals have transmissivities and hydraulic conductivities one to three orders of magnitude less than the injection intervals. These confining zones prevent low density municipal effluent from rising upward through the overlying saline waters.

This paper provides an integration of previously published work with recent site-specific data collected from deep injection wells drilled in the last two decades.

Introduction

The Floridan aquifer is the principal aquifer in the southeastern United States. It is comprised of rocks of Paleocene through Miocene age and is found in Florida, Georgia, Alabama, and South Carolina. Although its major resource is a potable-water supply, the nonpotable part of the aquifer in south Florida serves as a disposal zone for municipal and industrial waste water. The hydrogeologic setting of the Floridan aquifer is generally favorable for the disposal of effluent in south Florida. The construction and testing of deep injection wells provides hydrogeologic information on the portions of the aquifer containing saline water, leading to a better understanding of aquifer and confining zone properties and flow dynamics. The types of data that yield important information include water quality analyses, geophysical logs, cores, packer tests, and withdrawal and injection tests.

Previous Studies

Numerous characteristics of the disposal zones in south Florida have been studied over the past three decades. Flow characteristics were studied by Meyer (1988), Hickey (1989a, 1989b), Smith and Griffin (1977), and Kohout (1965). General aquifer properties and geologic setting were discussed by Meyer (1989), Puri and Winston (1974), Puri et al. (1973), and Vernon (1970). In addition, numerous studies of individual wells are on file with the Florida Department of Environmental Regulation as support of operating permit applications.

History of Deep Well Injection in Florida

The injection of liquid waste into the Floridan aquifer in south Florida began in 1943. Brine produced from the Sunniland oil field was disposed of in the cavernous zone of the lower Floridan aquifer of Eocene age. This interval is referred to as the "Boulder Zone" due to the difficulty oil field drillers had getting through this zone in search of oil at greater depths. Drillers typically encountered boulders dislodged by the drill bit from cavities, lost circulation, or had

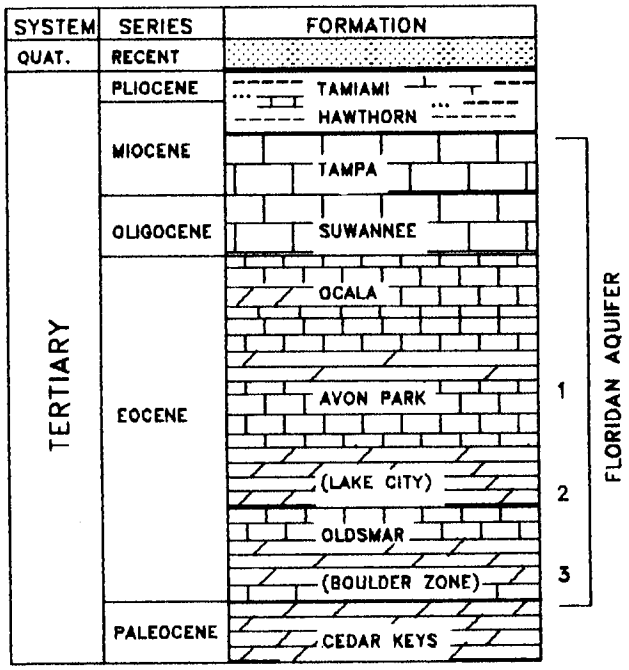

Fig. 2. General stratigraphic column, south Florida (adapted from Puri and Winston, 1974). Standard symbols are shown for lithology. St. Petersburg, Sarasota and North Port areas inject into zone 1; Ft. Myers area injects into zone 2; all other wells inject into zone 3.

the drill string drop several feet through a cavern (Puri and Winston, 1974). The first injection of municipal (domestic) effluent began in 1959 into the upper Floridan aquifer. This zone was abandoned in the 1970s when waste-water treatment plants disposed of their effluent in the more transmissive "Boulder Zone." The majority of effluent now disposed of into deep injection wells in Florida is secondarily treated municipal waste water. Finally, smaller volumes of industrial (nonpetroleum related) waste water have been disposed of in the "Boulder Zone" since 1966.

The establishment and implementation of U.S. Environmental Protection Agency regulations have resulted in the accumulation of data on the Floridan aquifer in south Florida (Figure 1). The municipal wells, as expected, are located in population centers near the coasts. Oil field disposal wells are located between Ft. Myers and Miami.

Hydrogeologic Setting

The Cenozoic section of Florida is dominated by carbonate rocks, particularly in south Florida (Meyer, 1989). The general stratigraphic column shows the vertical extent of the Floridan aquifer, formation names, and lithologies (Figure 2). Limestones and dolomites comprise nearly the entire aquifer. The upper boundary of the Floridan aquifer is defined by the top of the Tampa or Suwannee Formation. The lower boundary is defined by the base of the Oldsmar Formation, although part of the Cedar Keys Formation may be included in the aquifer (Meyer, 1989).

While the occurrence of injection and confining zones is relatively predictable within each highlighted area of Figure 1, there is stratigraphic variation within each area and especially between areas (Figure 3). The "Boulder Zone" of the Oldsmar Formation is the injection interval for the area on the east coast between Miami and Melbourne and for the oil fields of south Florida. On the west coast between St. Petersburg and Ft. Myers, the "Boulder Zone" loses its highly transmissive development, but the younger Avon Park Formation develops both cavernous and fractured characteristics. Hence, injection intervals are between approximately 2,000-3,500 feet on the southeast coast, and are between approximately 600-2,000 feet on the southwest coast.

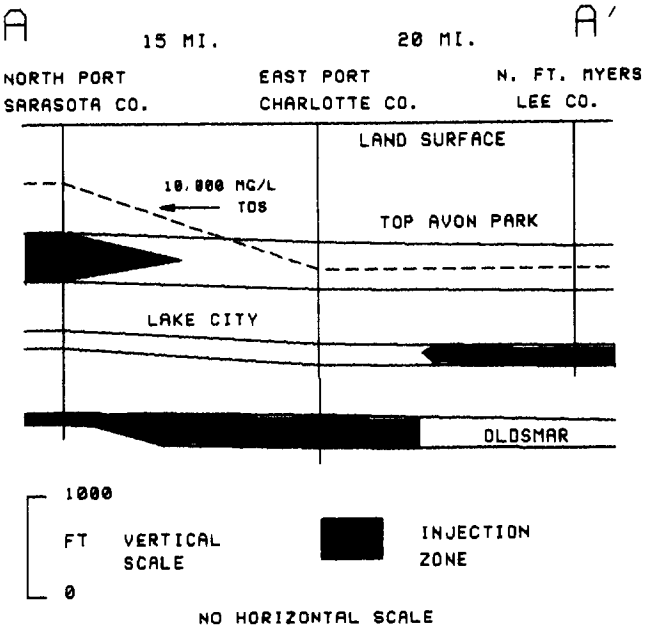

Fig. 3. Cross section A-A' showing stratigraphic variability of permeable injection zones in southwest Florida. Salinity gradually increases from surface to 10,000 mg/l interface. Each well encountered only one usable injection zone. Location of section shown on Figure 1.

Hydrogeologic Characteristics

Aquifer Properties

Withdrawal and injection tests reveal that the cavernous and fractured injection zones of the Floridan aquifer have extremely high transmissivities, ranging from 0.5 to 21 million gpd/ft. The "Boulder Zone" of Eocene age has transmissivities ranging from 1.0 to 4.0 million gpd/ft on the east coast based on injection test data (Geraghty and Miller, 1988). The only "Boulder Zone" well with available data on the west coast, near Ft. Myers, has a transmissivity of 0.51 million gpd/ft. This well, along with available geophysical logs of other southwest coast wells, indicates "Boulder Zone" transmissivity is less on the southwest coast. Quantitative data from oil field disposal wells between Ft. Myers and Miami are unavailable, but transmissivity is very high in this region (Vernon, 1970).

Transmissivity of the Avon Park Formation greatly increases from the east coast to the west coast. This formation serves as a confining sequence on the east coast while serving as the primary disposal zone on the west coast. Avon Park wells in the St. Petersburg area have transmissivities ranging from 9 to 21 million gpd/ft (CH2M Hill, 1987), while Avon Park wells in the Sarasota area have values from 0.5 to 2.8 million gpd/ft (CH2M Hill, 1988). Storage coefficients for the Avon Park in the St. Petersburg area are typical for confined aquifers, from .0002 to .00003 (CH2M Hill, 1987). Storage coefficients are unavailable at nearly all other injection sites owing to the lack of observation wells in the disposal zone.

Several million gallons of effluent per day are injected into the disposal zones with only a minimal increase in wellhead pressure (recorded on a gauge at the wellhead). Most of the increase is due to frictional loss as the effluent travels through the casing down into the injection zone (CH2M Hill, 1988). A typical well in southeast Florida injecting into the "Boulder Zone" might have a static (shut-in) wellhead pressure of 25 psi and an injection wellhead pressure of 30 psi at a rate of 2,000 gpm. Bottom hole pressure (recorded at the top of the injection zone) typically rises only a few psi during injection even at high rates. Figure 4 shows a typical time-drawdown plot for an injection well and the aquifer characteristics at the site.

The highly permeable zones are recognized on geophysical logs by greatly enlarged hole sizes on the caliper log, exceedingly long sonic (acoustic) transit times beyond measurable limits, very low resistivity indicating high porosity and saline water, changes on temperature logs, and flow into or out of zones on flowmeter (fluid velocity) logs (Figure 5). In addition, television video inspections show the caverns and fractures. Cavities are usually 2 to 6 feet high, but can be larger (Puri and Winston, 1974). The caverns alternate vertically with dense, noncavernous limestone and dolomite.

While previous studies emphasized cavern development, there is strong evidence suggesting the disposal zones are highly fractured, and that cavities develop after drill bit penetration (Hickey, 1990). Fractures are evident on television surveys, and drillers often do not report bit drops as would be expected in cavernous zones. The Avon Park injection zone in Pinellas County (St. Petersburg) is dominated by high concentrations of small aperture fractures which "shatter" and collapse during drilling (Hickey, 1989b).

Confining Zone Properties

The municipal effluent has a specific gravity (about 1.000 g/cc) less than the formation water in the injection zones (about 1.025 g/cc, approximately the same as sea water), which causes an additional force of upward flow. Confining rocks must offset this effect. The confining rocks of the Floridan aquifer typically have transmissivities less than 5,000 gpd/ft, and selected short intervals (approximately 10 feet thick) have transmissivities less than 50 gpd/ft (CH2M Hill, 1988). Vertical hydraulic conductivity ranges from .03 to .0003 ft/d. Transmissivity is determined by withdrawal tests or straddle packer pumping tests (Figure 6), and hydraulic conductivity is obtained from cores. Porosity is typically greater than 30%. Lack of interconnection between pore spaces, resulting in lower vertical hydraulic conductivity than might be expected, is how confining beds counteract the effluents' buoyancy in the injection zone.

When injection zones are pumped or used for injection, there are corresponding responses in the potentiometric surfaces of overlying zones in the confining unit. Monitor wells completed in intervals from 560-600 feet and 730-750 feet and located about 80 feet from the North Port injection well in Sarasota County exhibited an average of 0.42 and 0.78 feet of change in water levels respectively during withdrawal and injection tests of the injection well, which is completed open hole from 1,105-3,200 feet (CH2M Hill, 1988). Injection caused a rise in overlying water levels, while pumping caused a fall in water levels. Monitoring of long-term injection has shown no changes in water quality of overlying aquifers. Pressure in overlying aquifers changes because the confining zone rocks are compressible (porosity is about 30%), and a low vertical hydraulic conductivity

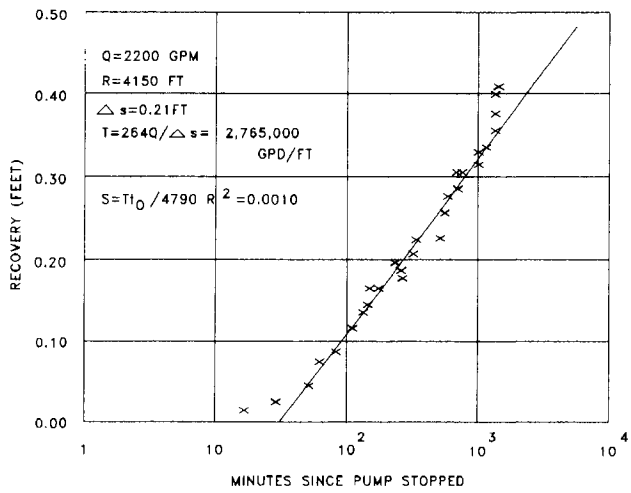

Fig. 4. Plot of observation well recovery data after 24-hour withdrawal test, North Port injection site, Sarasota County. Observation well is 4,150 feet from pumped well and both are completed in the injection zone at a depth of approximately 1,100 feet. (Modified from CH2M Hill, 1988).

prevents chemical contamination of overlying aquifers (Post, Buckley, Schuh and Jernigan, 1989).

Water Chemistry

South Florida is surrounded by bodies of sea water, which induces a fresh-water/salt-water interface along the Florida coast. Excessive fresh-water withdrawal leads to salt-water intrusion along the coast. The bulk of the population near the coasts makes maintenance of the hydrologic balance a delicate matter.

The federal and state programs allow deep wells for the injection of water not meeting drinking-water standards only if the receiving zone has a total dissolved solids (TDS) concentration greater than or equal to 10,000 mg/l. Such conditions exist beneath the fresh-water/salt-water interface but vary depending on distance from the coast.

The water of the upper Floridan aquifer is generally brackish (between 1,000-5,000 mg/l TDS) and grades downward to become chemically similar to sea water (35,000 mg/l TDS) in the middle or lower Floridan aquifer (Meyer, 1989). Confining rocks overlying the injection zones, located within these saline portions, serve to keep effluent out of brackish and potable waters.

Native formation water and typical secondarily treated

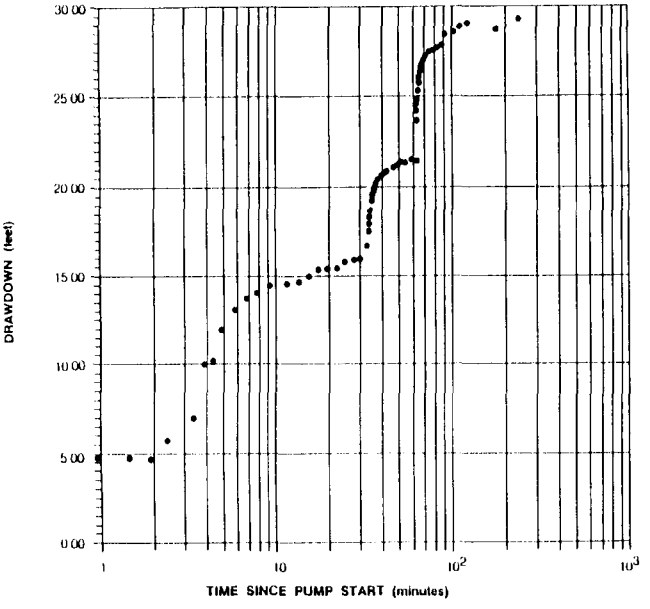

Fig. 6. Time-drawdown plot of confining interval from 560-1,100 feet during variable rate pump-out test, North Port injection well, Sarasota County. Estimated transmissivity of 65,000 gpd/ft reflects influence of thin permeable zones within confining sequence. (From CH2M Hill, 1988).

Table 1. Comparison of Injected Municipal Effluent and Native Formation Water (Data from North Port well, Sarasota County)

Concentrations (mg/l unless stated otherwise)		
Parameter	*Effluent (sampled 7/6/88)*	*Formation water (sampled 11/6/87)*
Sodium	82	9,870
Chloride	87	17,200
Sulfate	175	3,590
Total dissolved solids	604	29,300
Conductivity (μmhos/cm)	863	37,900
pH	7.25	7.15
Fluoride	0.29	1.4
Iron	0.06	0.41

Gross alpha (pCi/l)	<0.5	8.3
Turbidity (NTU)	0.9	0.63
Specific gravity (g/cc)	0.99	1.02

municipal effluent are compared in Table 1. The waters of the injection zone are dominated by the sodium and chloride ions, and to a lesser extent by sulfate, calcium, and magnesium. The infiltration of ocean water into the Floridan aquifer at the edge of the Floridan Plateau accounts for the sodium and chloride dominance (Smith and Griffin, 1977; Vernon, 1970; Kohout, 1965). Magnesium is derived from the solution of dolomite. Injection zone water chemistry does not vary significantly from east coast to west coast or from the "Boulder Zone" to the Avon Park Formation. The effluent is typically fresh to very slightly brackish water, depending on the water-supply source. The only significant constituents are elevated levels of nitrogen and phosphorus, and sometimes elevated biochemical oxygen demand and coliform bacteria concentrations. The municipal effluent has no significant effect upon either the native formation water or the carbonate rocks. However, the low density effluent rises to the top of the injection zone and spreads laterally. Modeling done by the U.S. Geological Survey shows circular convection and mixing of the two different liquids (Hickey, 1989b).

Summary

Numerous studies of individual deep injection wells have provided information on hydrogeological characteristics of injection zones in the Floridan aquifer of south Florida and also the confining characteristics of overlying intervals. Site-specific data agree with and add to previous studies. The highly permeable zones of the Floridan aquifer continue to be favorable for effluent disposal as long as each site has an effective confining bed.

Joseph L. Haberfeld has worked in the Underground Injection Control section of the Florida Department of Environmental Regulation (FDER) since 1987. His current interests include the hydrostratigraphy and geophysical log interpretation of injection and confining intervals in the Floridan aquifer. He earned a B.S. degree in Geology at the State University of New York, Fredonia (1975) and an M.S. degree in Geology at Southern Illinois University, Carbondale (1977). Before working at FDER he worked for nine years as a petroleum geologist for Gulf Oil and Chevron.

ground water

Important Observations and Parameters for a Salt Water Intrusion Model

by W. Barclay Shoemaker[1]

Abstract

Sensitivity analysis with a density-dependent ground water flow simulator can provide insight and understanding of salt water intrusion calibration problems far beyond what is possible through intuitive analysis alone. Five simple experimental simulations presented here demonstrate this point. Results show that dispersivity is a very important parameter for reproducing a steady-state distribution of hydraulic head, salinity, and flow in the transition zone between fresh water and salt water in a coastal aquifer system. When estimating dispersivity, the following conclusions can be drawn about the data types and locations considered. (1) The "toe" of the transition zone is the most effective location for hydraulic head and salinity observations. (2) Areas near the coastline where submarine ground water discharge occurs are the most effective locations for flow observations. (3) Salinity observations are more effective than hydraulic head observations. (4) The importance of flow observations aligned perpendicular to the shoreline varies dramatically depending on distance seaward from the shoreline. Extreme parameter correlation can prohibit unique estimation of permeability parameters such as hydraulic conductivity and flow parameters such as recharge in a density-dependent ground water flow model when using hydraulic head and salinity observations. Adding flow observations perpendicular to the shoreline in areas where ground water is exchanged with the ocean body can reduce the correlation, potentially resulting in unique estimates of these parameter values. Results are expected to be directly applicable to many complex situations, and have implications for model development whether or not formal optimization methods are used in model calibration.

Introduction

Numerical models that account for the effects of fluid density on ground water flow are being used more frequently to address scientific, engineering, and water resource management problems (Voss and Wood 1993; Voss 1999; Voss and Andersson 1993; Simmons et al. 1999; Simmons et al. 2002; Shoemaker and Edwards 2003; Langevin 2001). Also being used more frequently are inverse modeling routines based on nonlinear regression methods documented by Hill (1992, 1998), Hill et al. (2000), Poeter and Hill (1998), and Doherty (1990, 2002). However, there has been little application of inverse modeling sensitivity methods to density-dependent ground water flow simulators because of limitations in computing power and the unique technical skills individuals must learn. As computing power increases and expertise grows, modeling studies will likely use both inverse methods and density-dependent ground water flow simulations to solve complicated water resource or ground water contamination problems. Both technologies contain powerful capabilities that can help modelers better understand complex flow systems and make better use of available data.

A practical problem that could benefit from the combined use of these methods is salt water intrusion. Salt water intrusion is important because (1) ~70% of the earth's population lives near a coast, and (2) ~95% of the earth's water lies in the oceans and seas at high levels of salinity (Freeze and Cherry 1979). To study salt water intrusion, density-dependent ground water flow dynamics are needed to simulate flow in the transition zone between fresh water and salt water. Nonlinear regression methods for calibrating and

evaluating models offer many advantages over trial and error methods (Hill 1998). For example, in the context of salt water intrusion models, these methods can be used to (1) estimate flow and transport parameter values that provide the best fit to simulated heads, flows, and salinity to their observed equivalents; (2) calculate sensitivity measures for determining the flow and transport parameters most important to reproducing salt water intrusion observations and for assessing whether the observations are sufficient to estimate parameters of interest; and (3) compute measures of parameter and predictive uncertainty.

The work in this paper is partly motivated by a recent salt water intrusion investigation in which inverse modeling methods were applied to a density-dependent ground water flow simulation. In this study, the U.S. Geological Survey (USGS), in cooperation with the South Florida Water Management District (SFWMD), examined the physics of salt water intrusion in southwestern Florida (Shoemaker and Edwards 2003). During this study, the universal inverse modeling routine UCODE (Poeter and Hill 1998) was applied to the flow model to accomplish the following. (1) Identify flow and transport parameters representing aquifer properties and boundary conditions that could not be estimated accurately and uniquely with the available observations. (2) Determine parameter values that produced the best fit between observations and their simulated equivalents. (3) Quantify uncertainty in parameter estimates through linear confidence intervals. In addition, prediction-scaled sensitivities (Hill 1998) suggested that the extent of salt water intrusion, as reflected by salinity predictions, was most affected by recharge, followed in order of declining importance by ground water pumpage, sea level, and the salinity of the Gulf of Mexico. This insight was more quickly and clearly obtained than would have been possible using traditional calibration and sensitivity methods.

The initial success of the combined use of inverse modeling sensitivity methods with a density-dependent ground water flow simulator was encouraging, but motivated further investigation. For example, the SFWMD/USGS cooperative project did not directly consider potential extreme correlations between flow and transport parameters given observations typically available for calibration of salt water intrusion models. Parameter correlation is measured using correlation coefficients calculated as the covariance between two parameters divided by the product of their standard deviations (Hill 1998). Parameter correlation coefficients with values of +1.00 or –1.00 indicate parameter values that are extremely correlated and generally cannot be estimated uniquely with the observations involved; values < ~0.95 indicate that unique estimates can likely be obtained.

The purpose of this paper is to investigate what insight and understanding of salt water intrusion calibration problems can be attained by combined use of the sensitivity analysis methods suggested by Hill (1998) with a density-dependent ground water flow simulator, and what numerical difficulties are to be expected. This is accomplished using results from five simulations based on a simple two-dimensional, cross sectional model (Langevin 2001) that represents coastal ground water flow within the transition zone between fresh water and salt water. The five simulations differ in the number and type of observations used to compute sensitivities and correlation coefficients. The simple model and approach also demonstrate (1) some challenges of attempting to calibrate a density-dependent ground water flow model with various types of observations, (2) the relative importance of some flow and transport parameters in simulating the types of quantities commonly observed in coastal aquifer systems, and (3) observation types and locations within the transition zone between fresh water and salt water that provide the most information for estimating important flow and transport parameters. Though a simple model is used for the analysis, results are expected to be applicable to more complex situations because the simple model captures the basic dynamics.

Methods

Two modeling codes were selected for this study. SEAWAT–2000 (Langevin et al. 2003) was chosen as the density-dependent ground water flow simulator and UCODE (Poeter and Hill 1998) was chosen as the inverse modeling routine.

SEAWAT–2000 is a new version of the SEAWAT program (Guo and Bennett 1998; Guo and Langevin 2002) that combines MODFLOW–2000 (Harbaugh et al. 2000; Hill et al. 2000) and MT3Dms (Zheng and Wang 1999) to solve the coupled ground water flow and solute transport equations. SEAWAT–2000 contains considerably more functionality than the prior release of the code. This code was chosen primarily because it compares well with other density-dependent flow models in terms of accuracy and execution time. In fact, new solvers for the flow equation (Harbaugh et al. 2000; Mehl and Hill 2001) that may reduce model execution times are available. In addition, the model selected for experimentation in this paper (Langevin 2001) was built and run with a prior version of SEAWAT (Guo and Bennett 1998). As such, little reformatting of model input datasets was necessary.

The UCODE inverse modeling routine was used in this study to compute sensitivities and parameter correlation coefficients. MODFLOW–2000 (Hill et al. 2000) capabilities were not used because they do not support the transport parameters and salinity observations being considered. This was a disadvantage because the sensitivities computed by MODFLOW–2000, which uses the sensitivity-equation method, are more accurate than those computed by UCODE, which uses a perturbation approach. The perturbation sensitivities are expected to be sufficiently accurate to produce robust scaled sensitivity measures for evaluating observation and parameter importance. However, Hill and Østerby (2003) show that the less accurate perturbation sensitivities can affect the utility of the correlation coefficients. In particular, values that should be near +1.00 or –1.00 may be smaller in absolute value, so that extreme parameter correlation may not be detected when actually present. Extreme correlation means coordinated linear changes in parameter values would produce the same simulated results at observation locations (Poeter and Hill 1997). In this situation, estimating unique values of extremely correlated parameters using nonlinear regression will likely be

problematic. Thus, in this work, parameter correlation coefficients that are smaller than +1.00 in absolute value may reflect a lack of correlation, or may reflect the inaccuracies in the perturbation sensitivities. Absolute values that round to +1.00, however, clearly indicate extreme parameter correlation.

Because calculating and interpreting sensitivities and correlation coefficients are an important part of this paper, the equations that compute these quantities (Hill 1998; Poeter and Hill 1998) are presented here. Dimensionless-scaled sensitivities (ss_{ij}) are computed as

$$ss_{ij} = \left(\frac{\partial y_i'}{\partial b_j}\right)\left|\underline{b}\right|\left|b_j\right|\omega_i^{1/2} \quad (1)$$

where y_i' is the simulated value associated with the ith observation; b_j is the jth estimated parameter; $(\partial y_i'/\partial b_j)$ is the sensitivity of the simulated value associated with the ith observation with respect to the jth parameter, and is evaluated at the set of parameter values in $\underline{b}$ is a vector that contains parameter values for which the sensitivities are evaluated; and ω_i is the weight of the ith observation.

Dimensionless-scaled sensitivities are used to determine observation types and locations likely to be most effective for estimating a given parameter value. Composite-scaled sensitivities (css_j) are computed as

$$css_j = \left[\sum_{i=1}^{ND}\left(ss_{ij}\right)^2\Big|_{\underline{b}}/ND\right]^{1/2} \quad (2)$$

where ND is the number of observations. Composite-scaled sensitivities are used to determine the relative importance of various flow and transport parameters for reproducing observed values, and as a measure of the amount of information provided by the set of observations for estimating a parameter value. Correlation coefficients, $cor(i, j)$, are calculated as

$$cor\left(i, j\right) = \frac{cov\left(i, j\right)}{var\left(i\right)^{1/2}\, var\left(j\right)^{1/2}} \quad (3)$$

where cov(i, j) is the covariance between parameter i and j; var(i) is the variance of parameter i; and var(j) is the variance of parameter j.

Correlation coefficients are used to identify parameters that are extremely correlated given the observations used in experimental simulations.

Experimental Density-Dependent Model and Observations

The model used in this study was designed to simulate local submarine ground water discharge to Biscayne Bay in southwestern Florida, and is described in detail by Langevin (2001). The model has one row, 149 columns, and 33 layers (Figure 1). Boundary conditions were assigned to the model domain (Figure 1, Table 1) based on general knowledge, field data, and results from some regional ground water models. Boundary conditions include a constant flux of ground water to each cell in column 1 (Q/m) representing the general flow of ground water toward the coast that originates from recharge on inland areas not represented by the model grid. The constant-flux was computed using hydraulic conductivities and hydraulic gradients similar to those observed in the Biscayne Aquifer (Merritt 1996; Sonenshein and Koszalka 1996). Net recharge (rch) is applied to the inland portion of layer 1. In the context of this model, net rch is the amount of rainfall that exceeds evapotranspiration and runoff and reaches the water table. Net rch was assigned a reasonable value of 38 cm/yr based on studies of rainfall, evapotranspiration, and runoff in a coastal area (Parker et al. 1955; Merritt 1996; German 2000). A no-flow boundary exists along the base of model layer 33 representing a less permeable clastic confining or semiconfining unit that underlies more permeable limestone. This type of hydrostratigraphic sequence is common in coastal environments due to changes in sea level. Constant-head and constant-salinity boundaries are used to represent an ocean body. The constant-head and constant-salinity boundaries were assigned values roughly equal to sea level (0 m), and the salinity of sea water (35 kg/m^3), respectively.

Aquifer permeability and transport properties (Table 1) also were assigned to the cross sectional model based on general knowledge, field data, and prior calibration results. These aquifer properties were initially assigned using results from previous studies (Fish and Stewart 1991; Merritt 1996) and were adjusted by Langevin (2001) while calibrating to match hydraulic head and salinity observations. These properties include longitudinal dispersivity, transverse vertical dispersivity, effective porosity, and horizontal and vertical hydraulic conductivity. Diffusion was assumed to be negligible. The model has one stress period, and initial conditions of head and salinity were used to compute a steady-state distribution of hydraulic head, flow, and salinity within the model domain (Figure 2).

An important modification to the model documented in Langevin (2001) was made for the purposes of this study. During preliminary simulations, the implicit finite difference transport solver (GCG) in MT3Dms produced slightly inaccurate solutions due to the time length of transport steps. This time length is computed internally by the program using various stability criteria. The small inaccuracies in the transport solution resulted in large inaccuracies in perturbation sensitivities calculated for horizontal and vertical hydraulic conductivity. Setting the time length of transport steps to 0.5 the value computed by MT3Dms resulted in more accurate transport solutions and perturbation sensitivities. This was confirmed using the highly accurate, mass conservative total-variation-diminishing (TVD) scheme in MT3Dms. With this change in time step length, transport solutions and sensitivities calculated using the GCG solver were essentially the same as those calculated using the TVD scheme. The GCG solver produced results twice as quickly as the TVD solver and therefore was used for the experimental simulations described hereafter.

Hydraulic head, salinity, and flow observations were generated using the final steady-state results from the cross

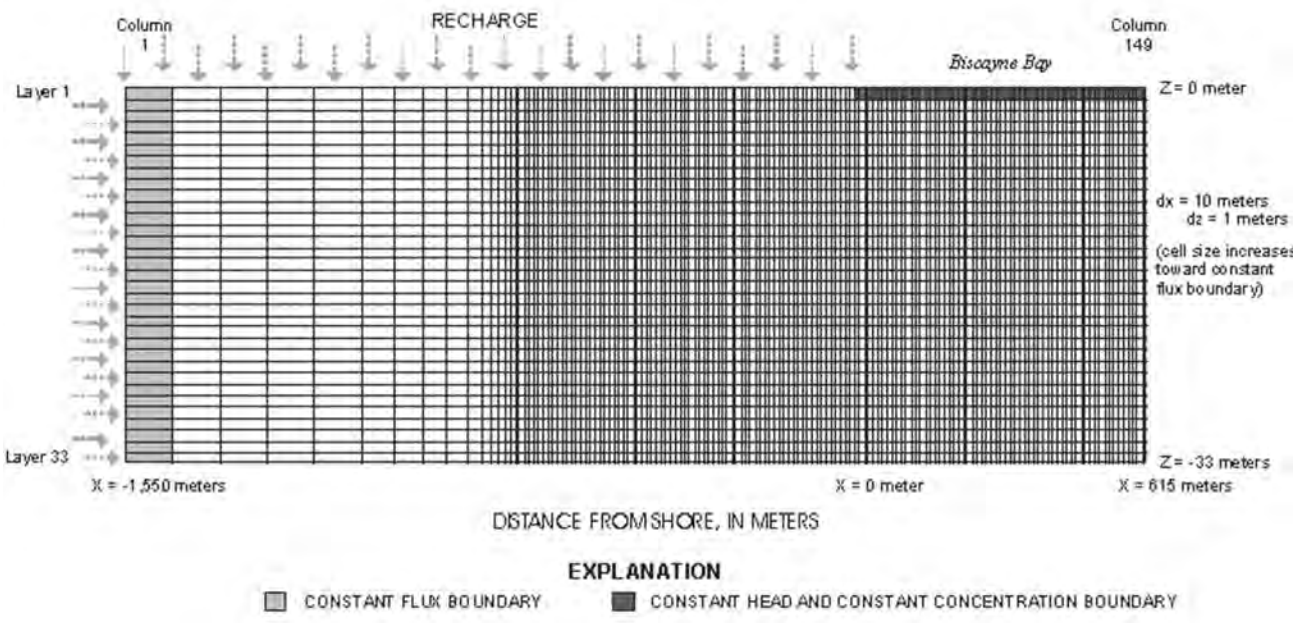

Figure 1. Cross section showing model grid and boundary conditions.

sectional model (Table 2). Measurement error that would likely occur in the field was added to these observations. The measurement error is necessary to calculate the observation weights, which, in turn, are used to calculate the scaled sensitivities and correlation coefficients (weights are used in the calculation of the variance and covariance terms in Equation 3) (Hill 1998). In this study, weights are calculated as the inverse of the variance of likely measurement error. This variance can be computed from the standard deviation or coefficient of variation of measurement error.

For the 23 hydraulic head observations, measurement error was assumed to be normally distributed with a mean of zero (Hill 1992; Cooley 1997) and a standard deviation of ~0.003 m. This standard deviation was based on standard error estimates for water levels measured in wells by the USGS in southern Florida (Prinos et al. 1996). For the 23 salinity observations, measurement error was assumed to be normally distributed with a mean of zero and a standard deviation of ~0.1 kg/m^3. Salinities range from ~3 to 35 kg/m^3, and for this range using a 0.1 kg/m^3 standard deviation was thought to be appropriate based on discussions with USGS water quality personnel. For the five flow observations, measurement error was assumed to be normally distributed with a mean of zero and a coefficient of variation of 30%. These observations are likely to be obtained by seepage meters, which are known to produce relatively large measurement errors (Shinn et al. 2002). Measurement error was randomly sampled from these distributions and added to the simulated results to create the values used as observations in this work (Table 2). For all of the observations used, the errors imposed may be lower than normally expected in field situations in which many types of errors can occur. Their value relative to one another, however, is thought to be representative of field problems, so that the results of the sensitivity analysis conducted in this work should be applicable to most field studies.

The five experimental simulations differed only by the observations used by UCODE to compute correlation coefficients, dimensionless-scaled sensitivities, and composite-scaled sensitivities. The observation sets included 23 hydraulic heads (simulation 1), 23 salinities (simulation 2), 23 hydraulic heads and 23 salinities (simulation 3), 23 hydraulic heads and five flows (simulation 4), and 23 hydraulic heads, 23 salinities, and five flows (simulation 5). All of the observations were located within the transition zone (Figure 3) because this region of the flow system has proven to be particularly difficult to understand based on previous studies (Konikow and Reilly 1999).

Execution time is often a problem when considering density-dependent, ground water flow and transport simulations. A single forward run of this simple model required ~30 min of execution time on a personal computer, with a Pentium II 550 MHz processor and 384 MB RAM. To solve for sensitivities took ~1 h for each defined parameter.

Table 1
Parameter Values and Boundary Stresses Assigned to the Model Domain

Parameter/ Stress	Value (Units)
Q/m[a]	15 (m/d)
dsp[b]	dsp = α L = 10: α T = α L/10 (both in m)
por[c]	0.2 (dimensionless)
Kh[d]	1000 (m/d)
Kv[e]	100 (m/d)
rch[f]	38 (cm/day)

[a](Q/m) is regional ground water flow.
[b](dps) is dispersivity.
[c](por) is effective porosity.
[d](Kh) is horizontal conductivity.
[e](Kv) is vertical hydraulic conductivity.
[f](rch) is recharge.

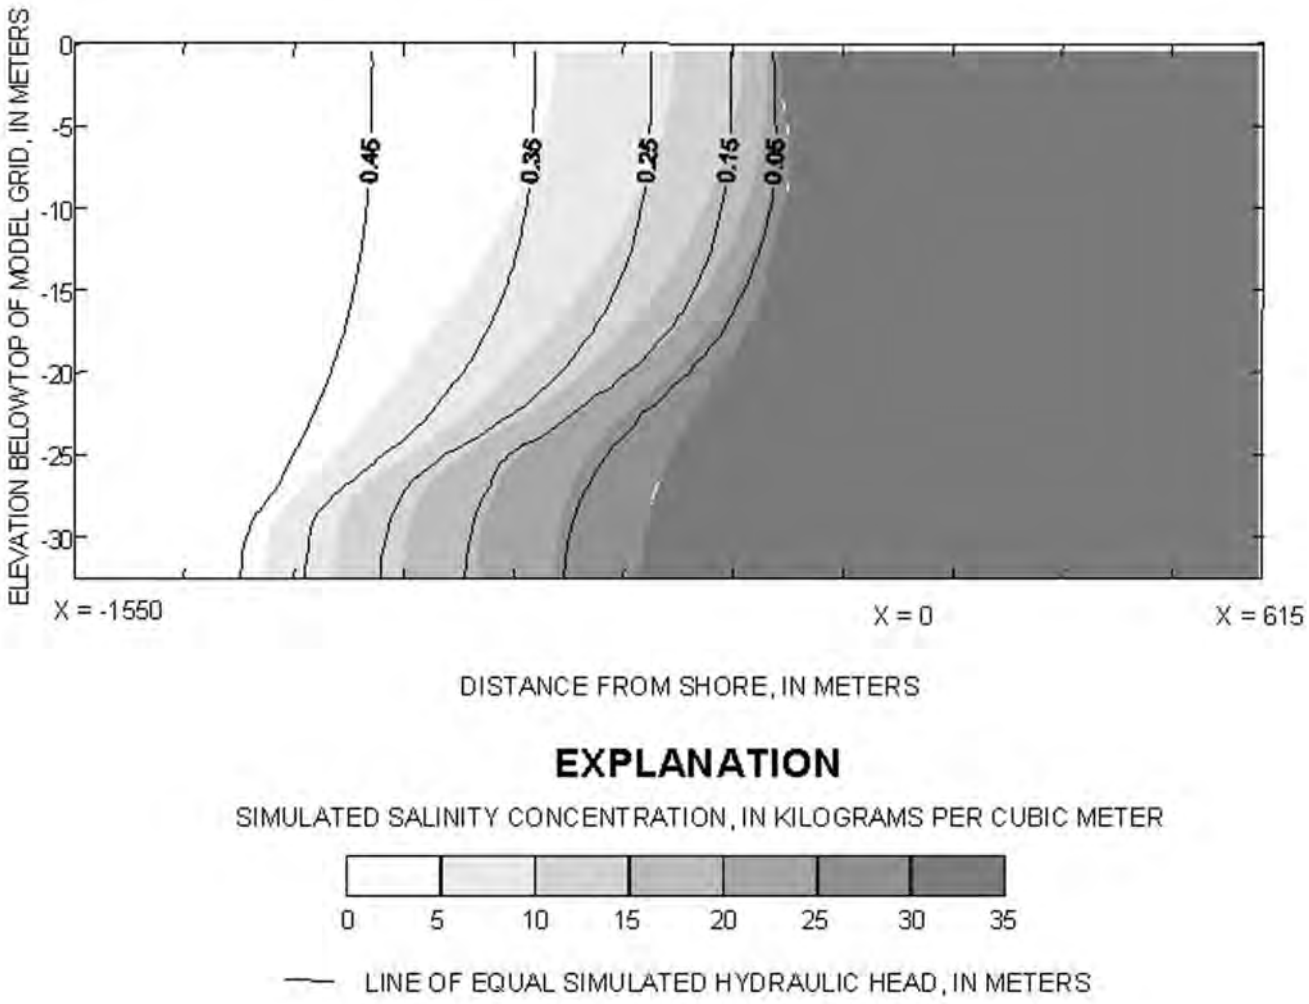

Figure 2. Cross section of steady-state hydraulic heads and salinity in the model domain.

Thus, ~6 h of execution time was necessary for the parameters considered in this paper. To attain this execution time, the longitudinal and vertical components of dispersivity were grouped together by setting the vertical dispersivity equal to 0.1 of the longitudinal dispersivity (Table 1).

Souza and Voss (1987, 1989), Voss and Souza (1998), and Langevin (2001) indicate that simulated hydraulic heads, salinities, and flow are more sensitive to transverse dispersivities (in either the vertical or horizontal directions) than to longitudinal dispersivities because ground water flows mostly parallel to lines of equal solute concentration in the transition zone. The latter makes the density-dependent flow model insensitive to longitudinal dispersivities, but highly sensitive to transverse dispersivities. Additionally, although sea level can be very important for reproducing head, salinity, and flow observations in the transition zone between fresh water and salt water, this parameter is not included. Sea level is typically less uncertain than the other parameters considered in this study (Table 1). For example, sea level and tides are generally well known relative to aquifer properties, recharge, and ground water flow. Composite and dimensionless-scaled sensitivities and correlation coefficients were computed for each experimental simulation for the six parameters listed in Table 1. The sensitivities were calculated by perturbing the parameter value by 1% of its value.

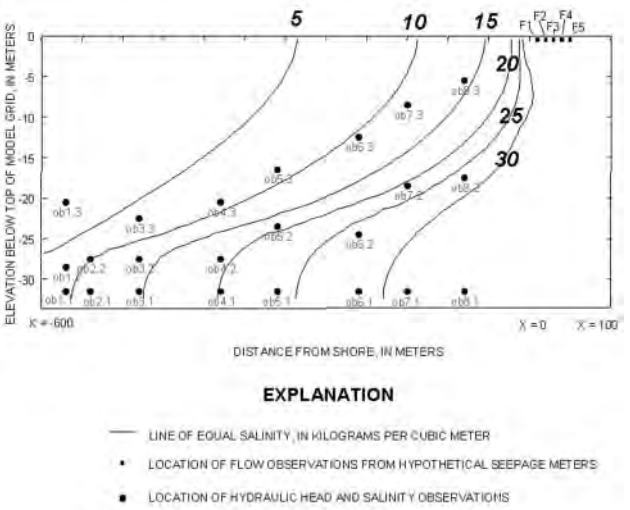

Figure 3. Cross section of observation types and locations in relation to the transition zone between fresh water and salt water.

Results and Discussion

Composite-Scaled Sensitivities

Composite-scaled sensitivities for the five experimental simulations are shown in Figure 4. This figure shows that

(Q/m) is regional ground water flow, (dsp) is dispersivity, (por) is effective porosity, (kh) is horizontal hydraulic conductivity, (kv) is vertical hydraulic conductivity, (rch) is recharge.

Figure 4. Bar graph of composite-scaled sensitivity for each experimental simulation.

the hydraulic head observations alone provide little information about any of the model parameters. When salinity observations are included (experimental simulations 2 and 3), a consistent pattern is evident. Dispersivity is most important, followed by regional ground water flow, horizontal hydraulic conductivity, recharge, vertical hydraulic conductivity, and effective porosity. Vertical hydraulic conductivity becomes the most important parameter in experimental simulations 4 and 5, which use flow observations. This means the flow observations provide substantial information about vertical hydraulic conductivity.

Dispersivity is clearly a very important parameter in this study, being either the most sensitive or second most sensitive when flow observations are used in the analysis. The importance of dispersivity to the different type of observations is discussed next using dimensionless-scaled sensitivities.

Dimensionless-Scaled Sensitivities

Dimensionless-scaled sensitivities for dispersivity are plotted in Figure 5. Two aspects of these results are discussed in the following sections—(1) the implications of a positive or negative dimensionless-scaled sensitivity value, and (2) observation locations and types likely to be most effective for estimating dispersivity.

Sign Implications of Dimensionless-Scaled Sensitivities

Dimensionless-scaled sensitivities of hydraulic head observations to dispersivity are all positive (Figure 5), meaning that increasing dispersivity increases heads and decreasing dispersivity decreases heads. This reflects the underlying physics. Increasing dispersivity increases the process of salt water mixing with fresh water. This causes the salt water to become less dense and to rise toward the sea, and causes the transition zone to be more vertically oriented and to have a somewhat broader top and a much less pronounced "toe" (Figure 6a). The latter allows more fresh water from recharge to move seaward, resulting in higher hydraulic heads in the vicinity of observation locations. Decreasing dispersivity decreases the mixing process, which produces a much more pronounced salt water toe and allows less fresh water from recharge to move seaward (Figure 6b), resulting in lower hydraulic heads in the vicinity of observation locations.

Dimensionless-scaled sensitivities of salinity observations to dispersivity are negative in most of the transition zone and are positive only at the top of the seaward part of the zone (Figure 5). This means increasing dispersivity decreases salinity in most of the transition zone and increases salinity at the top of the transition zone. Conversely, decreasing dispersivity increases salinity in most of the transition zone and decreases salinity at the top of the transition zone. These changes in salinity are explained by the flow system responses to the changes in dispersivity as shown in Figure 6 and described in the prior paragraph.

Dimensionless-scaled sensitivities of flow observations to dispersivity are mostly negative (Figure 5). An exception is flow observation F5, which has a positive sensitivity. Table 3 was designed to help explain the sign implications of these dimensionless-scaled sensitivities. For clarity, only the implications and results of increasing dispersivity are discussed in this paragraph. When the dimensionless-scaled sensitivity is negative and ground water is discharging to the sea (flow observations F1 and F2), increasing dispersivity increases the amount of ground water discharge. When the dimensionless-scaled sensitivity is negative and sea water is flowing into the aquifer (flow observations F3 and F4), increasing dispersivity decreases the amount of sea water inflow. When the sensitivity is positive and sea water is flowing into the aquifer (flow observation F5), increasing dispersivity increases in the amount of sea water inflow.

Effective Observation Locations for Estimating Dispersivity

Dimensionless-scaled sensitivity of hydraulic head observations to dispersivity range from 0.01 in the top third of the transition zone to 0.52 toward the toe of the transition zone (Figure 5). This result indicates that hydraulic head observations located toward the toe of the transition zone provide more information for estimating dispersivity than head observations located in the middle or top third of the transition zone. The control exerted by the sea, as simulated by the constant-head boundary condition in Biscayne Bay (Figure 1), probably explains this trend in sensitivity. Dimensionless-scaled sensitivities near this boundary are low because the constant heads prevent

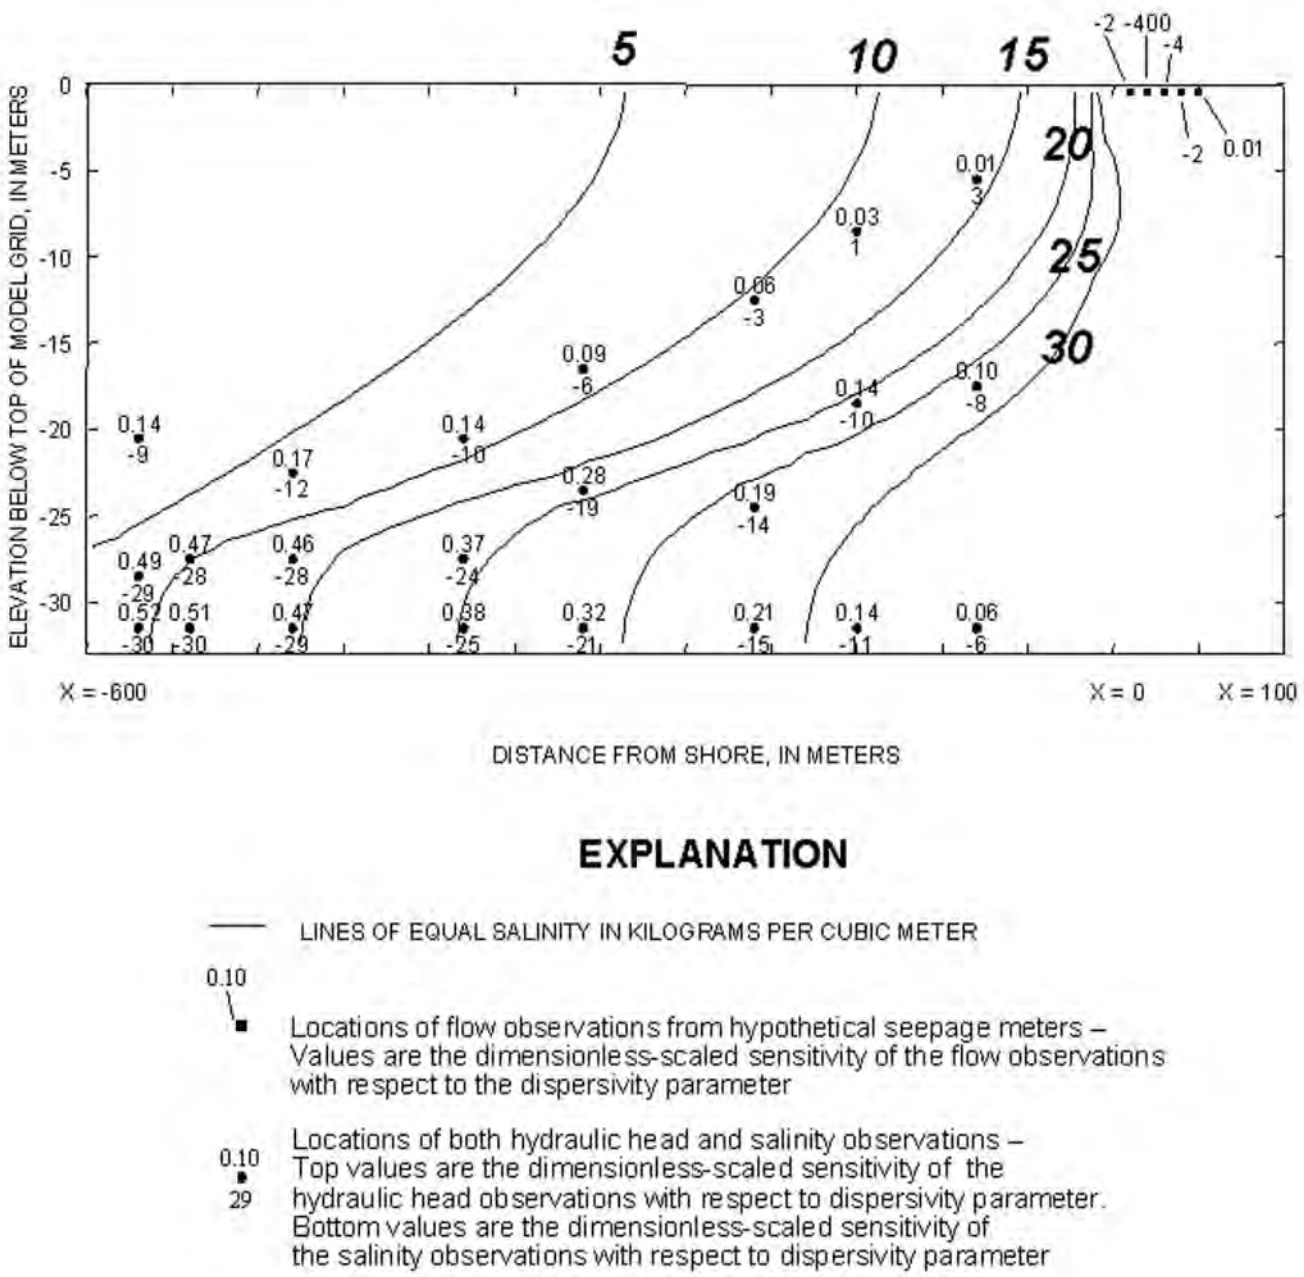

Figure 5. Cross section of dimensionless-scaled sensitivities for dispersivity.

simulated heads from changing when dispersivity is perturbed from an initial value.

Dimensionless-scaled sensitivity of salinity observations to dispersivity range from +3 to –30 (Figure 5). The large absolute values in the toe of the transition zone between fresh water and salt water suggest salinity observations in this location are most effective for estimating dispersivity. This evidence is consistent in that the toe of the transition zone seems most volatile in response to changing dispersivity values (Figure 6). For example, small values of dispersivity result in a toe of the transition zone that moves farther inland. Conversely, large values of dispersivity result in a toe of the transition zone that moves farther seaward. The top third of the transition zone changes only slightly with different values of dispersivity because of the control exerted by the sea, represented as a constant-concentration boundary condition (Figure 1).

Dimensionless-scaled sensitivities of flow observations to dispersivity range from–400.0 to +0.01 (Figure 5). In this model, flow observations within ~50 m of the coastline are most effective for estimating dispersivity (Figure 7). In other coastal aquifer systems, the distance would depend on the distance over which flow to the ocean diminished. This often can be evaluated using temperature sensors or by preliminary flow measurements or modeling. The large differences in the dimensionless-scaled sensitivities for the flow observations can be partly explained by the weights for these observations (recall from Equation 1 that the square root of the weight, $w^{1/2}$, is a term in the calculation of dimensionless-scaled sensitivity). This is illustrated using flow observations F1, F2, and F3. Table 3 shows that when dispersivity is increased to 10.1 from the base case value of 10.0, the magnitude of flow change is about the same at F1, F2, and F3, meaning that the sensitivity dy/db

Table 3
Changes in Flow Caused by Changes in the Dispersion Parameter

dsp = 9.9					
Flow Observation	**F1**	**F2**	**F3**	**F4**	**F5**
Flow change	~1% less	~85% less	~2% more	~0.5% more	Very small decrease
Direction of flow	Discharge to sea	Discharge to sea	Flow into aquifer	Flow into aquifer	Flow into aquifer
dsp = 10.0 (base case)					
Flow (m^3/d)	–136,500	–1470	61,780	86,600	84,920
Dimensionless-scaled sensitivity value	–2	–400	–4	–2	0.01
dsp = 10.1					
Flow Observation	**F1**	**F2**	**F3**	**F4**	**F5**
Flow change (%)	~1% more	~85% more	~2% less	~0.5% less	Very small increase
Flow change (m^3/d)	1220	1250	1080	430	–6
Direction of flow	Discharge to sea	Discharge to sea	Flow into aquifer	Flow into aquifer	Flow into aquifer

is about the same for each of the three observations. However, the dimensionless-scaled sensitivity at F2 is much larger than that at F1 or F3 because of the differences in the weights for these observations. These differences in the weights are related to differences in the magnitudes of observed flows at the three locations. Weights for the flows were defined using coefficients of variation (equal to 0.3), which means that each weight is inversely proportional to the magnitude of the observed flow. For example, the discharge to the sea at F1 is 136,500 m^3/d (Table 3), and $w^{1/2}$ for F1 is thus equal to $1 / (0.3 \times 136{,}500\ m^3/d) = 0.000024\ d/m^3$. The discharge to the sea at F2 is 1470 m^3/d (Table 3), and $w^{1/2}$ is thus equal to $1 / (0.3 \times 1470\ m^3/d) = 0.0023\ d/m^3$. Thus, the difference in the $w^{1/2}$ term for these two observations is clearly the primary reason for the differences in the dimensionless-scaled sensitivity.

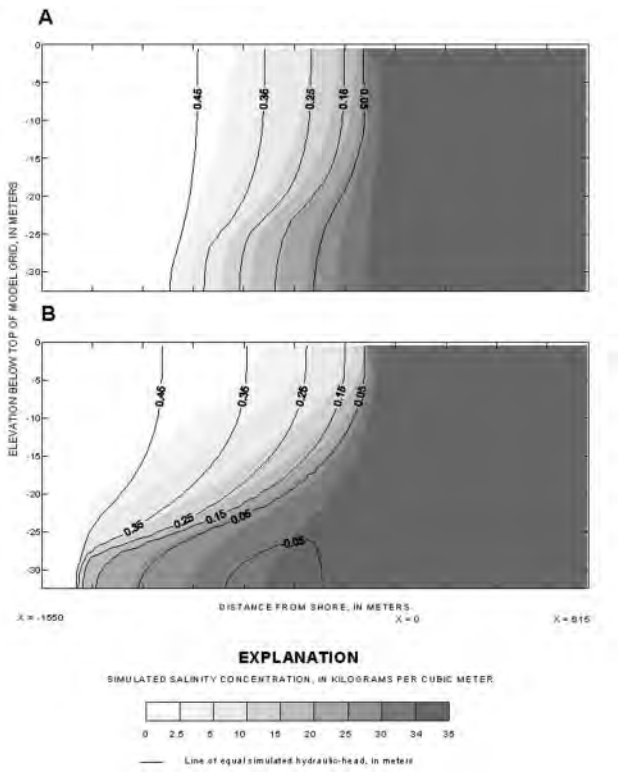

Figure 6. Cross sections showing the change in the geometry of the transition zone resulting from changes in the dispersivity parameter. The dispersivity parameter equals 15 m in cross section (a), and 5 m in cross section (b).

This analysis of the effect of the weights on the dimensionless-scaled sensitivity values also is applicable when considering the importance of the different flow observations in the context of calibrating this model using weighted least-squares regression. The weighting used would cause the F2 observation to have a greater influence in the regression and, thus, a greater influence on the estimated model parameter values compared to the observations at F1 and F3.

Although the weights clearly have a large influence on the relative importance of different flow observations, it is important to also consider the magnitudes of the changes in flux in response to a change in dispersivity when determining flow observation importance. For the five different flow observations considered in this study, these changes in flux suggest that observations at, and just landward of, the flow reversal location are likely to be most important to estimating dispersivity values.

Observation Types Likely to Be Important for Estimating Dispersivity

Examining the absolute magnitude of observation dimensionless-scaled sensitivities to dispersivity can give some insight into the observation types likely to be most effective for estimating dispersivity. Figure 5 shows that salinity observations are always more important than hydraulic head observations. Flow observations near the coastline can be effective, but observations too far from shore are ineffective for estimating dispersivity (Figure 7). As previously mentioned for this model, flow observations within ~50 m of the coastline and near the flow reversal zone appear to be most effective for estimating dispersivity. In other coastal aquifer systems, the locations of important

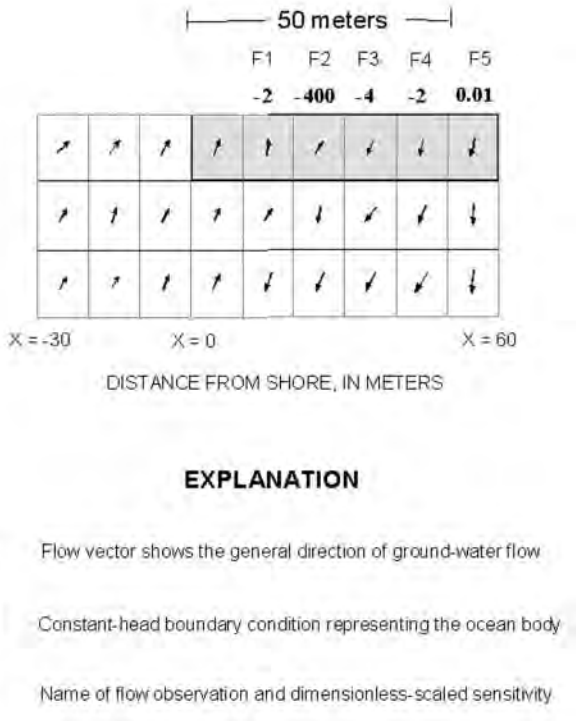

Figure 7. Cross section of the location and dimensionless-scaled sensitivity of flow observations in relation to ground water flow directions.

flow observations would likely depend on the magnitudes and variability of fluxes near the coastline.

Parameter Correlation Coefficients

Parameter correlation coefficients for six parameters in the five experimental simulations were calculated. The absolute values of the correlations for all parameter pairs were < 0.85 for all observation sets. The correlation coefficient for horizontal hydraulic conductivity and regional ground water flow was 0.84 when salinity observations (simulation 2) or hydraulic head and salinity observations (simulation 3) were used.

It is already well established that hydraulic-conductivity parameters and flow parameters representing, for example, recharge or ground water pumpage are correlated when calibrating a density-independent flow model solely using hydraulic head observations (Hill et al. 1998; Emsellem and de Marsily 1971). Therefore, the questions arise as to whether the hydraulic-conductivity and flow parameters are correlated in this density-dependent flow model when using solely hydraulic head observations, and how salinity observations affect the correlations. That is, are the calculated correlation coefficients reliably identifying all extreme parameter correlations in this problem? As previously mentioned, UCODE computes perturbation sensitivities that are less accurate than, for example, the derivative sensitivities computed by MODFLOW–2000. This loss of accuracy may produce unreliable correlation coefficients.

To test this concern, the model was run again with both hydraulic-conductivity and flow parameters in Table 1 multiplied by 100. The simulated heads and salinities in this additional scenario were the same as those in the baseline model (Figure 2). This means that if only head and/or salinity observations are available for calibration, these permeability and flow parameters are extremely correlated. In other words, 100 times more water flowing through a system that is 100 times more permeable produces the same simulated head and salinity results. This is consistent with the small sensitivity of all observations to porosity (Figure 4) as follows. Density would only affect the correlation between the hydraulic conductivity and flow parameters if the salinities were sensitive to the flow rate. This dependence would be indicated by a sensitivity of salinity to porosity. The result shown in Figure 4—that the sensitivity of salinity to porosity is very small relative to its sensitivity to the other parameters—indicates insensitivity to velocity.

In density-independent models, previous research suggests flow observations are useful for dramatically reducing extreme correlations between conductivity and flow parameters (Poeter and Hill 1998; Emsellem and de Marsily 1971; Barth and Hill in review). Apparently, flow observations serve the same role in density-dependent models. As previously mentioned, the correlation coefficient for hydraulic conductivity and ground water flow was ~0.84 when solely using salinity observations, or using hydraulic head and salinity observations. The value of these coefficients changed to–0.17 and 0.79, respectively, when flow observations were included in simulations 4 and 5. This suggests flow observations reduce correlation for this parameter pair. The prior statement is confirmed by results of running the model with both hydraulic-conductivity and flow parameters multiplied by 100. In this additional scenario, simulated flows at observation locations were ~100 times larger in absolute value than simulated flows in the baseline scenario. The hydraulic heads and salinities were basically the same.

A Short Note on Nonlinearity

This density-dependent flow model was nonlinear with respect to the dispersivity parameter in the transition zone between fresh water and salt water. In other words, parameter sensitivities and correlation coefficients changed with different values for dispersivity. For example, when using hydraulic head, salinity, and flow observations, while setting the dispersivity parameter equal to 15 m, the composite scaled sensitivities of effective porosity, ground water flow, and dispersivity are ~0.887, 27.6, and 9.77, respectively. When the dispersivity parameter is set equal to 5 m, the composite scaled sensitivities of effective porosity, ground water flow, and dispersivity are ~2.28, 16.5, and 58.4, respectively. The largest change in composite-scaled sensitivity occurred for the dispersivity parameter.

Apparently, the conclusions about preferable observation locations and types are robust in the presence of the nonlinearity in dispersivity. Simulations that were run with the dispersivity parameter set equal to 15 m/d and 5 m/d support this statement. Despite the dispersivity changes, dimensionless-scaled sensitivities still suggested that when estimating dispersivity: (1) hydraulic-head and salinity observations located in the toe of the transition zone are most favorable; (2) salinity values provide more information than hydraulic-head observations; and (3) flow observations located just landward of the area where the flow direction reverses at the bottom of the ocean are most effective.

Conclusions

A sensitivity analysis with a density-dependent ground water flow simulator was conducted to produce insight and understanding of salt water intrusion calibration problems. The approach used here clearly and defensibly shows (1) the relative importance of various flow and transport parameters for reproducing hydraulic head, salinity, and flow observations, (2) observation locations and observation types likely to be most effective for estimating a dispersivity parameter, (3) parameters that may not be uniquely estimated with a given set of observations because of extreme parameter correlation, and (4) the types of observations that may reduce correlation between parameter values and encourage unique estimates. These results were obtained for the transition zone between fresh water and salt water, a natural feature of coastal ground water flow systems that has previously proven to be very difficult to model and understand. The results apply regardless of how model calibration is pursued; that is, observations provide the same amount of information whether using gradient, global search, or manual trial-and-error methods. The methods investigated here clearly show the information provided by observations.

The following more specific conclusions can be drawn from this study.

1. Dispersivity was a very important parameter for reproducing the distribution of hydraulic head, salinity, and flow in the transition zone between fresh water and salt water, as indicated by composite-scaled sensitivities. It is expected that dispersivity is equally important in many field investigations.
2. The toe of the transition zone between fresh water and salt water, and areas near the coastline where submarine ground water discharge occur, are effective locations for (a) hydraulic head and salinity observations, and (b) flow observations collected on the ocean bottom with, for example, seepage meters. For layered systems in which toes occur at the base of multiple permeable layers, each of the toe locations is likely to be important.
3. Salinity observations are more effective than hydraulic head observations for estimating important dispersivity parameter values in the transition zone between fresh water and salt water. For the same purpose, flow observations located within or near areas of submarine ground water discharge are most effective. Flow observations located just landward of the area where the flow direction reverses at the bottom of the ocean (to the sea vs. from the sea) appear to be most effective for estimating important dispersivity parameter values. Flow observations located farther offshore generally are not useful.
4. As in density-independent models, flow parameters and permeability parameters were extremely correlated when calibrating this density-dependent model solely to hydraulic head and salinity observations. Adding flow observations perpendicular to the shoreline in areas where ground water is exchanged with the ocean reduced the correlation, potentially resulting in unique estimates of these parameter values.
5. The density-dependent flow model was nonlinear with respect to the dispersivity parameter. Thus, different values for dispersivity resulted in different parameter sensitivities and correlations. However, the conclusions about preferable observation locations and types were robust in the presence of the nonlinearity in dispersivity studied here.

Influence of Pore Pressure on Apparent Dispersivity of a Fissured Dolomitic Aquifer

by Darrell I. Leap[a] and Pamela Mai Belmonte[b]

Abstract

The U.S. Geological Survey's Amargosa Tracer Calibration Site in southern Nevada has been used for three different recirculating tracer tests using as tracers: (1) tritium, (2) sulfur-35, and (3) tritium and bromide together. Although the physical setup, well spacings, and thus apparent scale were the same in all tests, the recirculating rates and pore pressures were different. Apparent dispersivities found in the three tests differed considerably, revealing an inverse relationship between computed dispersivity and recirculation rate. These differences are believed to be caused primarily by changes in fissure-aperture widths and thus, hydraulic conductivities, with resulting changes in flow rates and directions caused by changes in pore pressure between different tests in the presence of high ambient pore pressure. The results of this study indicate that forced-gradient tracer tests for determination of dispersivity should not be performed when ambient pore pressure and/or testing pore pressure is a significant percentage of overburden pressure. In addition, apparent dispersivity calculated by forced-gradient tracer tests can differ considerably from that of unstressed natural situations, and consequent solute-transport estimates are likely to be in error.

Background

Hydraulic testing of fractured or fissured rocks in the presence of high ambient or high induced pore pressures is known to often yield erroneous values of hydraulic conductivity, or values not characteristic of the natural unstressed aquifer. Several field and laboratory investigations have verified such phenomena.

Tsang, Noorishad, and Witherspoon (1985), after studying a mathematical simulation of pressure-permeability relationships in a single fracture, concluded: "Pressure dependence of rock permeability due to fracture deformation may have a major effect on fluid flow behavior of fractured porous systems." They also concluded that traditional testing procedures are most likely to be valid when testing pressure does not exceed 10 percent of the overburden pressure.

Wood et al. (1985) noted greatly increased spring flow from fractured rocks in Idaho after an earthquake and concluded that pore pressures of 2.3 MPa are greater than horizontal compressional stresses in most sedimentary basins up to a depth of 488 m, and would be sufficient to cause widening of vertical fractures and thus increase flow rates.

Cruz et al. (1982) found that in field studies of pressure tests in wells, fractures 1 mm in width could allow a 120-percent increase in flow rate with a pressure increase of 1 kg/cm^2, but the flow rate for the same pressure increase lessened quite significantly with decreasing aperture size. This phenomenon can be explained by the "Cubic Law" as proven by Witherspoon et al. (1980) from laboratory experiment, i.e.,

$$Q/\Delta h = C(2b)^3 \quad (1)$$

where Q = flow rate; Δh = incremental change in head; $2b$ = fracture aperture width; and C = empirical constant.

Discussion open until July 1, 1992.

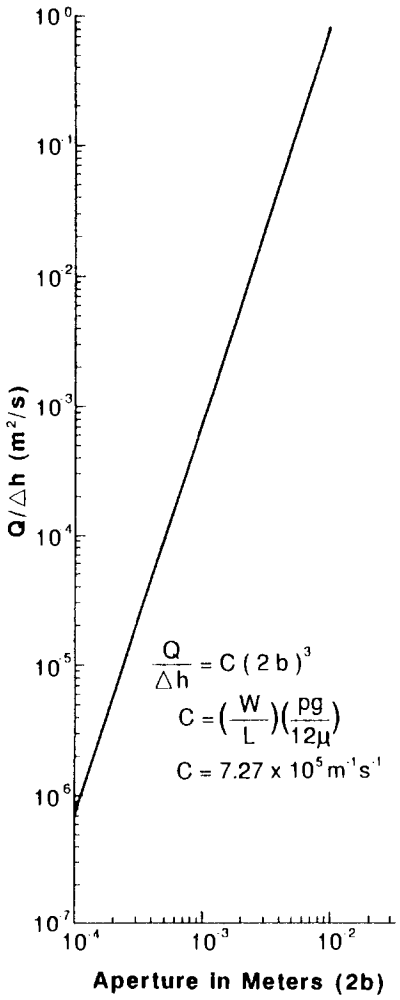

Fig. 1. Relationship of flow rate per-unit-head-drop to fracture-aperture width according to the "Cubic Law," for straight, linear flow.

This relationship shows that flow rate per unit increase in head (and consequently, increasing pore pressure) increases greatly with increasing aperture width. This is illustrated graphically in Figure 1, where for straight linear flow, the fracture width (W) and length (L) are both one meter; the product of density (ρ) and gravitational acceleration (g) is 9.8×10^3 N/m^3; and dynamic viscosity (μ) is 1.1×10^{-3} Nsm^{-2}.

Although the theoretical and experimental studies discussed below have been performed on solute transport in fractures, there is still no universal agreement about the true nature and quantification of dispersivity in fractured and fissured rocks. Dispersivity has been accepted traditionally as a function only of the aquifer, and dispersion is assumed to increase linearly with increasing velocity for constant values of dispersivity and diffusion constants

$$D_L = \alpha_L U + D^* \quad (2)$$

where D_L = longitudinal dispersion coefficient; α_L = longitudinal dispersivity (characteristic length); U = mean interstitial ground-water velocity; D* = coefficient of molecular diffusion for porous media; where

$$D^* = wD \quad (3)$$

and D = diffusion constant in water; $w < 1.0$ and is dependent upon tortuosity, packing, and other shape factors.

It could be assumed that in a single fracture with significant wall asperities, dispersivity would increase with decreasing aperture width, which would bring the asperities closer together to cause greater tortuosity and heterogeneity.

In complex natural systems containing many fractures and fissures of different size, orientation, and connectivity, dispersivity is far more complex. In complex, fractured systems dispersivity could be a function of not only aperture width, but also of scale (distance from source to measurement point) and velocity variations; all of these, in turn, are functions of fracture width, orientation, and connectivity as well as asperity distributions (Marsily, 1986).

Guinn, Kessler, and Greenkorn (1972), using a mathematical model based on the random walk approach, found that the dispersivity tensor may be a function of the average flow direction. They also concluded that the effects of velocity and medium properties are inseparable.

Freeze and Cherry (1979) and Marsily (1986) discussed the variations of flow types and dispersion within fractured and fissured rocks. They reported that the velocity of ground water within a fracture may deviate from the average velocity (computed by Darcy's Law) by orders of magnitude. Marsily summarized five types of flow velocities, described by Louis (1974), which depend upon the values of the Reynolds number and roughness of fracture walls—namely smooth laminar, smooth turbulent, rough turbulent, rough laminar, and very rough laminar.

Although average velocities through fractured and fissured rock masses can be computed by Darcy's Law, it provides no indication of velocities in individual fissures and fractures. The actual velocity in individual fissures and fractures depends not only on the gradients, but also on fracture aperture and wall roughness. Therefore, there are often wide ranges in flow velocities within single fractures and within a group of fractures; very high velocities can even be nonlinear, and therefore can affect computed apparent dispersion values by mechanisms not explainable by classical dispersion theories such as equation (2).

An additional complicating factor addressed by these authors is the frequent deviation of the principal directions of the dispersivity tensor from the principal directions of fracture orientation and, consequently, from the hydraulic-conductivity principal directions in fractured rocks, such that the longitudinal dispersivity constant will not necessarily have a single value regardless of the direction of the velocity vectors, as is often assumed in granular porous media.

Similarly, Molz, Güven, and Melville (1983), through a series of field experiments, concluded that macrodispersivity, and therefore dispersion, is caused primarily by velocity variations that result from natural hydraulic-conductivity variations between strata at different elevations within the flow regime.

Huyakorn and Anderson (1986) came to similar conclusions as the above investigators by modeling flow in a two-well recirculating test with curvilinear coordinates and

testing the numerical model against a physical model. They also concluded that large apparent dispersion is caused by lateral fluid spreading, caused in turn by natural hydraulic-conductivity variations over the aquifer thickness; they concluded that dispersivity is really not a function of velocity itself, but rather, of velocity distribution.

Finally, Hull, Miller and Clemo (1987) concluded, from a series of laboratory experiments, that development of a velocity profile within fractures and transverse diffusion across streamlines is sufficient to explain dispersion and thus, dispersivity is not only a function of fracture geometry and interconnection, but also of velocity.

In the last six references quoted above, the investigators assumed that structural properties of the aquifer, such as fracture-aperture width and orientation, as well as conductivity stratification, were static and intrinsic properties of the aquifer. We believe our study to be the first that has ever attributed changes in computed solute-transport parameters to changes in aquifer structure caused by pressure variations due to testing, with resultant changes in hydraulic properties and hydrodynamics.

This work is significant not only to understanding pressure-dispersivity relationships, but also to the understanding of pitfalls inherent in field-scale tracer studies of fractured and fissured rocks. It vividly illustrates the care that must be taken in performing such tests, especially with high ambient and/or induced pressures which can cause significant changes in solute-transport parameters.

Objectives

Two-well, recirculating tests reported herein were run in order (1) to determine the apparent longitudinal dispersivity of a fissured and fractured aquifer within the Cambrian Bonanza King dolomite draining the Nevada Test Site in southern Nevada; and (2) to study the usefulness of tritium, sulfur-35, and bromide as tracers in this aquifer.

Description of the Amargosa Tracer Calibration Site

The tests were performed at the U.S. Geological Survey's Amargosa Tracer Calibration Site (hereafter called the Tracer Site), located in the Amargosa Desert in southern Nevada, approximately 121 km northwest of Las Vegas and approximately 24 km southwest of Mercury, Nevada (Figure 2).

The facility was constructed as an experimental site for using various kinds of tracers and tracer tests to (1) determine effective porosity of a fissured carbonate aquifer draining the Nevada Test Site; (2) determine ambient, regional velocity of ground water; (3) evaluate sorption phenomena for different radioactive nuclides; and (4) determine apparent longitudinal dispersivity values.

The aquifer itself is believed to be a solution-modified, low-angle reverse fault zone within the Cambrian Bonanza King dolomite. Five wells completely penetrate this aquifer, whose thickness varies from 3.1 m at Tracer Wells 1 and 4 to 13.7 m at Tracer Well 2 (Figure 3). Transmissivity determined by a pumping test ranges from 4,800 m^2day to 10,900 m^2day (unpublished data in files of USGS, Water Resources

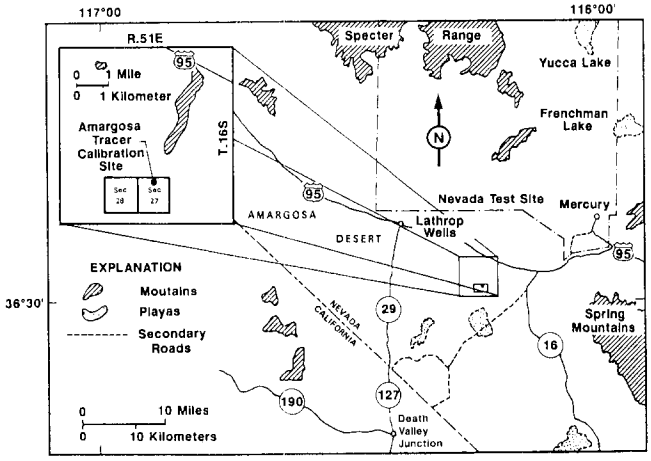

Fig. 2. Map showing location of Amargosa Tracer Calibration Site, southern Nevada.

Division, Denver, Colorado). The storage coefficient is approximately 5×10^{-4}, and the hydraulic gradient is between 10^{-4} and 10^{-5} (Claassen and Cordes, 1975).

Examination of drilling logs and cores taken during drilling of wells [in U.S. Geological Survey Core Library, Mercury, Nevada, and in Johnston (1968)], revealed permeable fractures ranging in width from less than one mm to 45 cm. The fracture-surface roughness, fracture connectivity, and nature of fracture asperities were impossible to assess between the wells, across the area of interest. Borehole flow-meter tests precisely defined the top and thickness of the permeable fissured and fractured zone which constitutes the aquifer thickness as shown in Figure 3.

Tracer Well 2, the pumping well, contained a high-capacity turbine pump driven by an external electric motor which was connected by a polyvinyl chloride (PVC) pipe, 15.0 cm in diameter, to Tracer Well 1 (the injection well) during two-well recirculating tests (Figure 4). These two wells were aligned parallel to the direction of regional

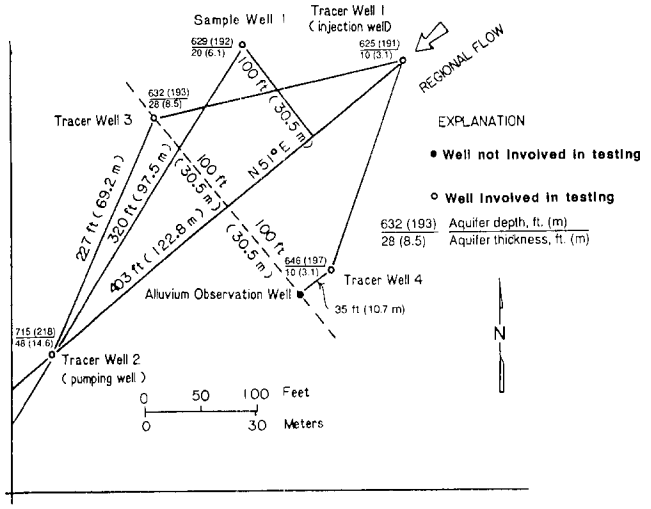

Fig. 3. Map showing locations of wells, aquifer depths, and thicknesses at Tracer Site.

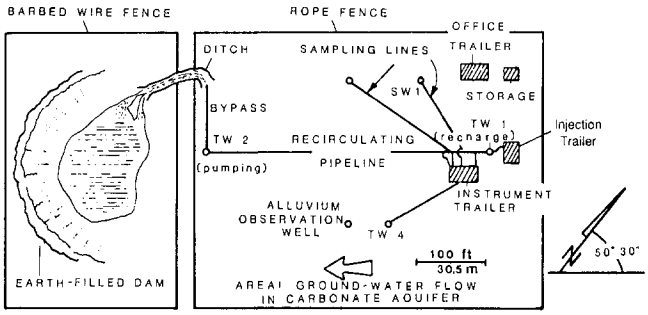

Fig. 4. Physical layout of Tracer Site (after Claassen and Cordes, 1975).

hydraulic gradient in order to minimize asymmetry of tracer flow paths caused by ambient ground-water flow. During tests reported here, samples were taken for analysis from the recirculating line downstream from Tracer Well 2; submersible pumps positioned within the aquifer were used for taking samples from Sample Well 1 and Tracer Well 3. All wells completely penetrated the aquifer and received water from only the aquifer.

Approach

Rectangular pulses (constant concentration over injection-time intervals) of tracer solution were injected into Tracer Well 1 during recirculation. Tracer-laden water was pumped from the sampling wells to automatic samplers in the Instrument Trailer (Figure 4). All pumps and samplers were activated automatically at preset times for sampling.

Breakthrough curves were constructed from analyses of effluent samples pumped from Tracer Well 2, taken from the recirculating pipeline downstream from the well. These curves were matched and compared to synthetic curves constructed for various combinations of porosity and dispersivity by the method of Grove (1971). Apparent dispersivities (characteristic lengths) of the aquifer were taken to be those of the best-fit synthetic curves, within an accuracy of ±3.0 m.

Three two-well recirculating tests were performed at the Tracer Site. The first, (Test 1, using tritium) was reported by Claassen and Cordes (1975). The second (Test 2, employing sulfur-35) and the third (Test 3, tritium and bromide together), were performed by the senior author of this paper. Test 3 was designed to: (1) mimic Test 1 as closely as possible to determine if multiple peaks on the Tracer Well 2 breakthrough curve could be obtained again, and (2) determine if the bromide ion could be used as a suitable surrogate for tritium in this aquifer.

Tritium and sulfur-35 were analyzed by liquid scintillation at the National Water Quality Laboratory of the U.S. Geological Survey, in Denver, Colorado, and decay corrected. Bromide was analyzed by neutron activation at the TRIGA reactor facility at the Pennsylvania State University. Data from all tests were analyzed, studied, and compared by Mai (1986) in order to determine any relation between recirculation rate and apparent dispersivity.

Theory of Two-Well, Recirculating Tracer Tests

Figure 5 shows a typical two-dimensional ground-water flow field of a two-well recirculating system in a homogeneous, isotropic aquifer, assuming negligible ambient regional velocity (Da Costa and Bennett, 1960; Webster et al., 1970). Each of the crescentic arcs can be visualized as a longitudinal dispersion column, and a tracer pulse added to the injection well will disperse longitudinally along the crescents. Assuming a constant hydraulic conductivity, the actual magnitude of longitudinal dispersion will depend upon the relative velocity of flow through each crescent. Transverse or lateral dispersion is not accounted for here and is not obtainable by this method.

The mathematical development of Grove's method for a homogeneous, isotropic aquifer, based on work in above references follows:

The Fickian model for one-dimensional longitudinal dispersion is given as

$$\partial C/\partial t = D_L\, \partial^2 C/\partial L^2 - U\partial C/\partial L \qquad (4a)$$

where L = distance along flow path; C = solute concentration; and t = time.

Boundary conditions are given as

$$C(O,t) = C_o \qquad t \geq O, \qquad (4b)$$

$$C(\infty,t) = O \qquad t \geq O; \qquad (4c)$$

and the initial condition as

$$C(L,O) = \qquad t \geq O. \qquad (4d)$$

Two solutions to equations (4) were given by Grove (1971), following Brenner (1962), as

$$C/Co = 1 - \exp[P(2-\bar{t})] \cdot \sum_{K=1}^{\infty} \frac{\lambda_k \sin(2\lambda_k)}{(\lambda_k^2 + P^2 + P)} \exp(-\lambda_k^2 \bar{t}/P), \qquad (5a)$$

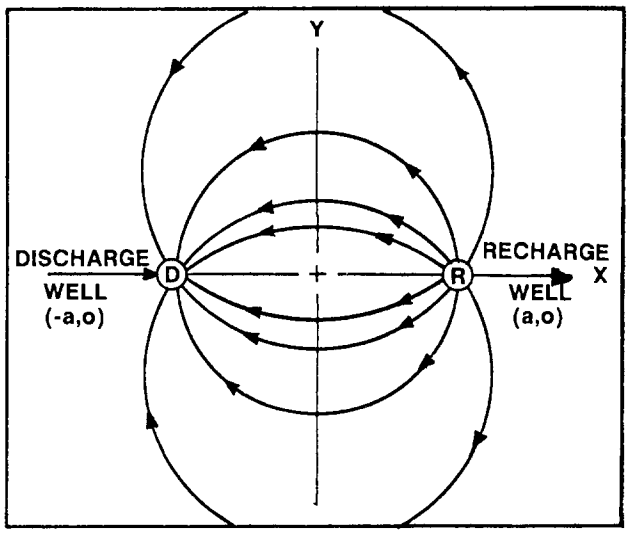

Fig. 5. Ground-water flow paths of an ideal, two-well, recirculating tracer test (after Grove and Beetem, 1971).

and

$$C/Co = \tfrac{1}{2}\mathrm{erfc}[(P/\bar{t})^{1/2}(1-\bar{t})] + (4P\bar{t}/\pi)^{1/2}[3 + 2P(1+\bar{t})]\exp[-P(1-\bar{t})^2/\bar{t}] - [\tfrac{1}{2} + 2P(3+4\bar{t}) + 4P^2(1+\bar{t})^2] \cdot \exp(4P)\,\mathrm{erfc}[(P/\bar{t})^{1/2}(1+\bar{t})] \quad (5b)$$

where Co = original concentration;

$$P = UL/4D_L, \text{ the Peclet Number;} \quad (6a)$$

which also can be written as

$$P = L/4\alpha_L \quad (6b)$$

because the dispersion coefficient is directly proportional to the velocity by a linear relationship when D* is small.

$\lambda_k = K^{th}$ positive root of the equation,

$$\tan 2\lambda = 2\lambda P(\lambda^2 - P^2); \quad (7)$$

$$\lambda_{2n-1} = \beta_n; \quad (8)$$

$$\lambda_{2n} = \gamma_n; \quad (9)$$

where β_n and γ_n are positive roots of the transcendental equations

$$\beta_n \tan \beta_n - P = 0 \text{ for } n \geq 1; \quad (10)$$

$$\gamma_n \cot \gamma_n + P = 0 \text{ for } n \geq 1; \quad (11)$$

$$\bar{t} = T/t, \text{ a dimensionless time variable;} \quad (12)$$

where T = time of interest. For computational purposes, Grove (1971) recommended use of equation (5a) when the value of P/t is less than 1.0 (when U is smaller or t is large), and equation (5b) otherwise. Both equations were used to generate a series of synthetic breakthrough curves for trial fitting to real breakthrough curves.

In Grove's actual computational procedure performed by computer, the two-well flow field was divided into 179 arcs, each of which was treated as a longitudinal dispersion column. For selected values of longitudinal dispersivity and porosity, a Peclet number and time of plug flow through each arc were computed for a particular pumping rate per unit aquifer thickness, porosity, and well spacing. Afterward, the relative concentration from each arc at a particular time was calculated and these relative concentrations were summed. This procedure was repeated for increasing values of time and a complete synthetic breakthrough curve was developed of concentration versus time.

Methodology and Results of the Three Tests

The potentiometric head of the aquifer is approximately 13.7 m below the ground surface and about 168 to 183 m above the top of the aquifer. Taking into account the overburden pressure of approximately 4.4 MPa exerted by both saturated and unsaturated materials above the aquifer, the ambient aquifer pore pressure was calculated to be 1.8 MPa, or 41 percent of the overburden pressure. During the tests, the pressure of actual injection (0.45 MPa) plus the pressure resulting from filling the casing of Tracer Well 1 with water to the land surface was added to the pore pressure in the aquifer at Tracer Well 1. As a result, the actual

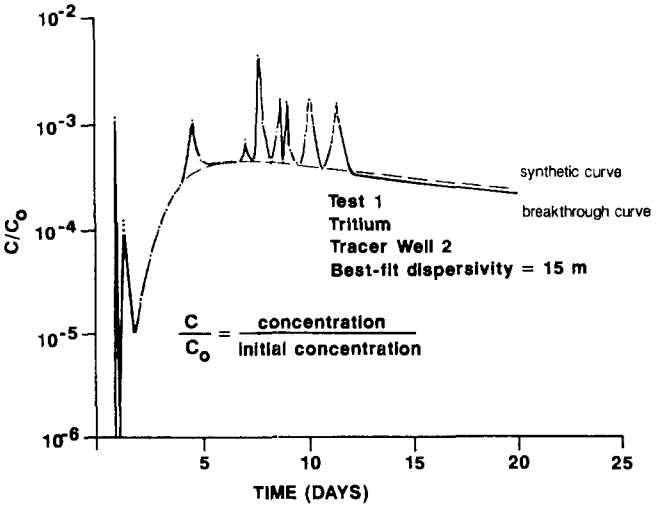

Fig. 6. Best-fit match of tritium breakthrough curve to synthetic curve: Tracer Well 2, Test 1 (after Claassen and Cordes, 1975).

pore pressures in the aquifer at Tracer Well 1 during the two-well recirculating tests were 2.2 MPa in Test 1, 2.4 MPa in Test 2, and 2.3 MPa in Test 3. These are 50, 55, and 52 percent, respectively, of overburden pressure; and 122, 133, and 128 percent, respectively, of ambient pore pressure.

During Test 1 the average recirculation rate was 22.5 L/s. The tracer pulse consisted of 14.1 Ci of tritiated water injected into Tracer Well 1 over a period of 14.4 minutes (0.01 day). The test lasted 30 days; a match of the breakthrough curve to synthetic curves (Figure 6) yielded an apparent dispersivity of 15 m and a porosity-thickness product of 0.88 m (Claassen and Cordes, 1975). Claassen and Cordes did not report thickness and porosity separately. Numerous sharp peaks are superimposed upon the base curve in this breakthrough curve and are discussed in the next section.

Test 2 ran for 38 days at an average recirculation rate of 13.7 L/s, the maximum that could be obtained for this test. Sulfur-35 in the form of sodium sulfate (Na_2SO_4) was injected into Tracer Well 1 over a 48-minute (0.03 day) time span at a constant rate. Apparent dispersivity of 22.9 m, porosity of 10 percent, and a porosity-thickness product of 0.84 m were the values obtained by fitting the breakthrough curve to a synthetic curve (Figure 7), but no sharp peaks

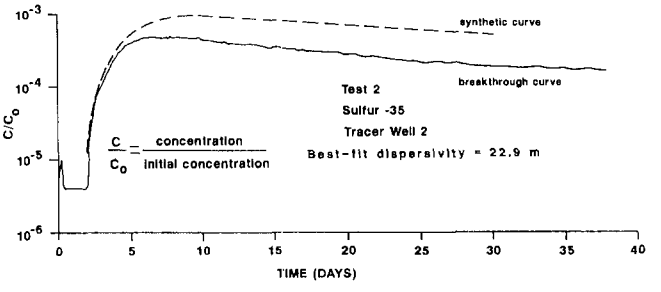

Fig. 7. Best-fit match of sulfur-35 breakthrough curve to synthetic curve: Tracer Well 2, Test 2.
